Another line of evidence also points to BHs: the jets of relativistic particles that are expelled from the centers of galaxies. Some jets are narrow (opening angles of less than 1°) and run straight for millions of light years, which argues that their emission has been constant over millions of years. Jets are often found in opposing directions. The phenomenon is ubiquitous and at the same time highly variable. Some galaxies seem quite ordinary except for the immense radio emission that takes place at the ends of the jets, far outside the galaxies themselves. Other galaxies contain *quasars*, which are very small sources of immense luminosity, from which emerge jets (Blandford *et al.*, 1982). Quasars in particular seem to be associated with young galaxies: a far larger fraction of galaxies exhibited the quasar phenomenon when the Universe was $\frac{1}{3}$ of its present age than today.

These facts fit the BH model too, chiefly because only BHs seem to be able to form stable centers of activity, to supply sufficient energy, and (through their rotation) to provide a consistent direction for jets. Gas probably forms an accretion disk around a massive BH, just as it does in binary systems. Something then forms jets of relativistic particles and expels them perpendicular to the disk in both directions. That something probably involves twisted magnetic fields, but it may also involve the BHs directly. Since BHs have an electrical conductivity (Sec. 2.2.5) and will in general rotate, they can interact with magnetic fields to produce large voltage differences from pole to equator, which can accelerate and indeed even create pairs of charged particles. The energy would come from spinning down the rotating BH (Blandford and Znajek, 1977). Modeling the quasar and jet activity of galaxies is one of the most active areas of theoretical astrophysics today.

2.4.3 Gravitational Lensing.

In Sec. 1.2.2.5 we saw that gravitational fields bend light, and that this can lead to a form of lensing. The amount of deflection depends on the theory of gravity, but the qualitative features are the same in all theories. Lensing was predicted more than 50 years ago, but the phenomenon does not seem to have been taken very seriously by astronomers until the now-famous "double quasar" 0957+561 was discovered in 1979 (Walsh *et al.*, 1979). Since then, dozens of examples of gravitational lenses have been found.

Gravitational lensing is one of the most dramatic confirmations of relativistic gravity. Lensed images come in many forms. Some are simply multiple images of a single point-like source, each with a different magnification. (The number of such images must always be odd, although they may not all be bright enough to be observed.) Sometimes images are smeared out into arcs. Some images do not change position but are "microlensed" by the gravitational field of a single star of an intervening galaxy that happens to move across the image, magnifying it briefly.

Lensing takes place at all scales, and to some extent in every astronomical image, but to be observable it must stand out from the confusion of other properties of images. The ideal situation is a compact image that is lensed into two or more similar images separated by a few arc seconds, far enough apart to be distinguished but close enough to be noticed as unusual. Spectra provide the "fingerprints" that convince one that the images are of the same object and not neighboring distinct objects. The lensing mass is typically a cluster of galaxies somewhere between the source and us.

Unless the galaxies in the cluster can all be seen, it is hard to model the lens. However, modeling has potential rewards. The biggest is to predict the Shapiro time delay (the excess travel time, as described in Sec. 3.2.1.2) along each of the image paths. Since the only data we have about the distance to and thus the linear size of the lens and the source are the redshifts produced in their spectra by the cosmological expansion, we need the *Hubble constant* (Sec. 2.4.5) to predict the actual time delays. Conversely, the measurement of the time delays between various images of a variable source in a well-modeled lens can provide a determination of the Hubble constant, and from it an estimate of the age of the Universe. This is a very active area of research today.

2.4.4 Solar System and Stellar Orbits.

General relativity makes small corrections to the orbits of bodies in the solar system. The effect may be described by a small $1/r^3$ correction to the gravitational acceleration produced by the Sun. It is smaller than the Newtonian term by the ratio of the Sun's gravitational radius to r, which is of order 10^{-7} or less for the planets. Its effect is to make the planet's ellipsoidal orbits *precess*: the direction from the Sun to the point of a planet's closest approach to the Sun (its *perihelion*) rotates with time.

The precession of Mercury's perihelion provided an early confirmation of GR, as we describe in Sec. 3.2.2. But at 43 seconds of arc per century, it is hard to measure, since the gravitational fields of other planets produce similar but much larger effects on Mercury's orbit. In fact, the measurement of the relativistic precession of any other planet is hopeless, partly because of the dominance of planetary perturbations.

When stars orbit each other, there are similar effects. They are easiest to observe in binaries containing pulsars, where we have excellent dynamical information about the orbit. Indeed, the periastron shift (as it is called for binaries) is necessary if we are to determine the masses of the individual stars. Fortunately, the orbits of such stars bring them much closer to each other than Mercury gets to the Sun, so the effect is larger. For the pulsar binary system PSR1913+16 (Sec. 3.3), the rate of periastron advance is 4.2° per year, easily measurable.

Another dramatic effect of GR on the orbits of stars is caused by the emission of GWs by the orbital motion. The energy lost to waves brings the stars gradually closer together, and also tends to make orbits more circular. As the stars approach, their orbital period decreases, and the system actually speeds up. This effect has been observed in PSR1913+16. It is also thought to control the evolution of certain classes of binaries, where mass is transferred from one star to another when they get too close. The transfer pushes the stars apart, but they come closer together because of gravitational radiation reaction. The net effect is a steady transfer of mass from one star to another.

2.4.5 Cosmology, Inflation, and the Origins of the Universe. General relativity opened the door to the study of cosmology, the Universe in the large. In Newtonian gravity it is not even possible to formulate the gravitational force consistently for a Universe of infinite size, and if one takes the Universe to be finite but large, then the exact shape of its boundary affects the gravitational field everywhere in a measurable way. General relativity gives a consistent picture of the Universe. The reader should consult the article GALAXIES AND COSMOLOGY for a complete survey of cosmology; we concentrate here on the general relativistic aspects of the study.

2.4.5.1 Cosmological Models. Observations suggest that we can make a good first approximation to describing the Universe by assuming that it is homogeneous on the largest scales and isotropic around us. Since the Universe is also expanding, these assumptions imply the existence of a special choice of time everywhere: "now" has to be chosen so that the density, say, is the same everywhere at that time. This choice of time is unique: the Universe has a preferred reference frame. When cosmologists speak of the distance between galaxies, they are referring to proper distance at a particular time in this preferred frame. Similarly, the age of the Universe is the proper time since the Big Bang, as measured in this frame.

There are only three possible geometries for the spaces of constant time in a homogeneous and isotropic cosmology: flat, open, and closed. In the flat model, space at a constant time is Euclidean. In the closed model it is a three-sphere, which is the locus of all points equidistant from a fixed point in four Euclidean dimensions (equidistant as measured by the four-dimensional Euclidean distance). In the open model it is a three-hyperbola, which cannot be described as a subsurface of Euclidean space; rather, it has the same geometry as the hyperbola in Minkowski spacetime that consists of all points at a given timelike interval from the origin.

Without a cosmological constant, the field equations of GR imply that all models have a singularity at some time: they expand from a singular point of infinite density, contract to one, or both (the closed model). Since we observe the Universe to be expanding (see Sec. 2.5.4.2), we infer that there was a singular point a finite time in the past. This is the *Big Bang.*

If the initial expansion velocity was sufficiently great compared to the overall gravitational attraction, the expansion will continue forever. The critical measure here is the local density of mass–energy. It turns out that models that expand forever have hyperbolic space sections; those that recontract are three-spheres; and the marginal case is flat. Therefore, measuring the actual mass–energy density has implications for the large-scale structure of the Universe.

Although much is sometimes made of the philosophical implications of this, it must be emphasized that we can only observe a small section of our Universe, and any assertion about the large-scale topology of space depends on our assuming that the parts of the Universe that are too far away to observe are in fact identical to the section we can observe. This can, of course, never be proved.

2.4.5.2 Hubble's Law: The Big Bang. The expansion velocity of the Universe is given by the Hubble constant. Edwin Hubble was the first to show, by painstaking systematic observation of many galaxies, that all distant galaxies recede from us, and more distant galaxies recede faster (see GALAXIES AND COSMOLOGY). He expressed this as a linear relation between the distance d of a galaxy and the recession velocity v:

$$v = Hd\,. \tag{26}$$

We call the proportionality constant H the Hubble constant. This law is what one expects in a Universe that expands homogeneously: in any given interval of time, galaxies twice as far away should have moved by twice as much, leading to twice the recession velocity.

A frequently suggested analogy is an expanding balloon. If one draws dots on the balloon and measures their separations, then when the balloon is twice as large the points will have receded from one another in exactly this way. The balloon is also an excellent two-dimensional analog of the geometry of the three-spherical (closed) universe.

2.4.5.3 Cosmic Microwave Background Radiation. The Big Bang picture provides a simple model for our history. At a finite time in the past, the Universe was infinitely dense. It began expanding and maintained thermal equilibrium among all the exotic species of particles for a short time. Gradually, as the temperature dropped, different species froze out. When nuclei froze out, about 20% of the mass was in helium, the rest in hydrogen. Later, hydrogen atoms froze out and the expanding cloud of gas became neutral. The mean free path of photons increased dramatically, and most photons in existence at the time have not scattered since. This epoch of "decoupling" of photons and matter left behind a thermal distribution of photons that has remained thermal as the Universe has expanded. The temperature of this distribution is inversely proportional to the expansion. Today this temperature is about 2.7 K, and the resulting *microwave background radiation*, discovered by Penzias and Wilson (1965), is one of the strongest pieces of evidence favoring the Big Bang model.

2.4.5.4 The Age of the Universe. The measurement of the Hubble constant is fraught with difficulties. The velocity v is easy to obtain from spectra, but measuring the distance is hard. Astronomers look for "standard candles": objects of known intrinsic brightness, whose apparent brightness can be used to infer their distance. No really reliable standard candles exist, and even today astronomers differ by up to a factor of 2 in their determinations of H. In the astronomers' customary units, where distances between galaxies are measured in megaparsecs ($1\ \mathrm{Mpc}=3\times10^{22}\ \mathrm{m}=3\times10^{6}$ light-years) and velocity is measured in km/s, H is likely to lie in the following range:

$$45\ \mathrm{km\,s^{-1}\,Mpc^{-1}} < H < 100\ \mathrm{km\,s^{-1}\,Mpc^{-1}}\ .$$

It is usual to parametrize H by $h=H/(100\ \mathrm{km\,s^{-1}\,Mpc^{-1}})$.

If the expansion were at a constant rate, then the age of the Universe (time since the Big Bang) would be $1/H$. If $h=1$, then $1/H=10^{10}$ yr. Smaller values of H lead, of course, to older Universes. In fact, gravity has been slowing down the expansion rate, so $1/H$ overestimates the age of the Universe. Therefore one can also constrain H by measuring the age of, say, the Earth, or better, of an old (hopefully first-generation) star or cluster of stars. The Earth seems to be about 4.5×10^{9} years old, but some clusters may be older than 10^{10} years.

2.4.5.5 Mass and Missing Mass. Once we know H we know the so-called critical density, the density of mass–energy just needed to stop the expansion, to make the Universe flat. In terms of h, the critical density is

$$\rho_c=2\times10^{-26}h^2\ \mathrm{kg\,m^{-3}}\ .$$

Measuring the actual mass-energy density is even harder than measuring H; the uncertainty seems to be a factor of 10 at present. The problem is that the mass that is radiating light, mainly in the form of stars, accounts for less than 1% of the critical density, and there is much evidence for at least 10 times this amount of dark or hidden mass. The evidence is dynamical: the rotation rates of spiral galaxies and the internal motions of large clusters of galaxies are simply much too large for these objects to stay together if their masses were only what we could infer from the light they emit. This dark mass may consist of BHs or other low-brightness remnants of the early evolution of stars, or (and this is the more popular idea at present) it may consist of a cosmological distribution of elementary particles of an unknown kind (Knapp and Kormendy, 1986). Searches are now under way for such particles randomly passing through the laboratory. Their detection would have important implications for high-energy physics as well as for astronomy.

Indirect evidence of this dark matter may be sought in the dynamics of galaxy formation. It turns out that density perturbations in ordinary baryons do not grow rapidly in the early Universe, mainly because these particles are charged and couple too strongly to the equilibrium radiation field. Once the Universe has expanded and cooled off enough for hydrogen to become neutral, the perturbations may grow, but that does not leave enough time for galaxies as we observe them—well separated objects even at early times—to have evolved.

A pervasive background of neutral particles could provide seeds for galaxy formation that grew unhindered in the early Universe. If the particles had reasonably large rest mass, they would cool off rapidly and form strong condensations. Computer simulations performed within this *cold dark matter* hypothesis provide reasonable consistency with the present distribution of galaxies and their clustering. It must be stressed, however, that there are many other possibilities for providing seeds for galaxy formation. Cosmic strings, mentioned below, are also attractive. The real story of galaxy formation may involve several such factors.

2.4.5.6 Microwave Anisotropies. The microwave background ought, if the Big Bang is correct, to be a very good black-body distribution. Indeed, measurements by the recent COBE spacecraft show it to be (Smoot *et al.*, 1992). However, its temperature need not be the same in all directions. For one thing, the Earth may be moving with respect to the cosmological rest frame, the mean rest frame of the matter at decoupling. This would produce a dipole anisotropy in the temperature, and this has been measured. The inferred velocity of the Sun is 370 km s^{-1}, again from the COBE measurements.

In 1992 COBE also measured another effect on the microwave temperature: fluctuations that arise from the early density irregularities of the Universe. While not surprising, these provide striking "baby pictures" of the condensations that eventually evolved into large aggregates of clusters of galaxies.

2.4.5.7 Inflation and the Homogeneity Problem. The measurements performed by COBE highlight a conceptual problem for cosmology: the structures seen by it were on a scale so large that light could not have traveled across the structure in the time between the Big Bang and the time of decoupling, when the radiation was produced. Yet the structures seen by COBE were relatively consistent right around the sky. How could they be causally related? And if they were not causally related, why are they so similar?

The same problem exists for other measurements. We can see quasars in opposite directions on the sky that are today so far apart that they could not have communicated since the Big Bang, and yet the distributions of quasars and other galaxies near them look similar at both places. How indeed can the Universe be homogeneous over distances that could not communicate?

A simple answer is that it is all in the initial conditions of the Big Bang. But such an explanation is unsatisfying to many scientists, and an attractive alternative has been proposed: inflation. If, in the early universe, just after the Big Bang, the laws of high-energy physics at energy scales inaccessible to present-day experimentation were of a certain form, then the Universe could at some point have undergone a phase transition that pushed it into very rapid expansion, much more rapid than one would infer by working backwards from today's expansion. The expansion would in fact have been exponential, hence the term *inflation*. If it halted after many *e*-foldings, then parts of the Universe that now seem too far apart to have communicated would in fact have been much closer before inflation, and could have been causally connected. Inflation can solve, at least in this sense, the homogeneity problem (Guth and Steinhardt, 1984; Blau and Guth, 1987).

Inflation has side benefits, one of which is that it might produce exactly the spectrum of seed perturbations that COBE saw. Observational evidence is slim at present, but by the year 2000 one can expect much stronger constraints on inflationary models.

3. TESTS OF GRAVITATIONAL THEORIES AND THEIR TECHNOLOGICAL DEMANDS

For the first half-century of GR's existence, experimental tests were infrequent, largely because the smallness of the predicted effects made them extremely difficult to measure with any accuracy. The validity of the theory rested on two tests, the deflection of light, measured in 1919, and the resolution of an anomaly in Mercury's perihelion advance. But beginning in the 1960s, advances in technology made high-precision tests of the theory possible, and there followed a systematic effort to put the theory to the test (for a review of these tests see Will, 1993).

3.1 Tests of the Einstein Equivalence Principle

3.1.1 Tests of Special Relativity. The Einstein equivalence principle described in Sec. 1.2.2.2 demands that in any local, freely falling reference frame (in which gravity is absent locally), the nongravitational laws of physics (such as mechanics, electromagnetism, quantum mechanics) must be compatible with special relativity. As we have seen, a consequence of this principle is that gravity must be described by spacetime curvature.

Special relativity has become such a successful and integral part of such areas of modern physics as quantum field theory, nuclear physics, and particle physics that physicists often take its validity for granted. But in many of these subdisciplines of physics, the experiments are designed to test particular models of fields and interactions rather than the underlying special relativistic framework. The Michelson–Morley experiment and its modern-day descendants provide clean tests of SR in that they can constrain directly and quantitatively possible violations of SR (see RELATIVITY, SPECIAL).

3.1.1.1 Michelson–Morley Experiments. One way to understand the significance of these tests is to imagine an explicit violation of SR in electrodynamics, by permitting the limiting speed of material particles, c_m, to differ from the speed of electromagnetic waves, c_e. Since moving frames are no longer equivalent, this assumption establishes a preferred universal rest frame. From the field-theoretic point of view, such a violation is likely to be induced by some long-range field created by the matter in the universe; hence the preferred frame is likely to be that of the smoothed out distribution of matter, or equivalently of the cosmic microwave background. The resulting observable violations of SR in such a model depend on the fact that the Earth is moving through the universe at about 370 km/s, and are parametrized by $\delta=(c_m/c_e)^2-1$. By placing a limit on a difference in the speed of light in two perpendicular directions using an interferometer, the 1887 Michelson–Morley experiment set a limit $|\delta|<10^{-4}$. A 1979 laser-interferometric version of the experiment improved the limit to 10^{-9} (Brillet and Hall, 1979).

3.1.1.2 Hughes–Drever Experiment. But in 1960, a substantial improvement in the limit on δ resulted from experiments that tested the "isotropy of inertia", done independently by Hughes *et al.* (1960) and Drever (1961). If SR is violated in the way described above, then the energy levels of an atom or nucleus can depend both on the velocity of the nucleus through the preferred frame and on the orientation of the quantization axis relative to the direction of motion. Anomalous shifts of energy levels can then occur. The Hughes–Drever experiments used nuclear magnetic resonance techniques to look for such anomalous shifts as the Earth rotated in space. More recently, new techniques of atomic physics, such as laser-cooled ion and atom traps, have yielded improved limits on such variations with direction in the energy levels of beryllium ions, neon atoms, and mercury isotopes, ranging from 2×10^{-19} to 2×10^{-21} eV. These results give the bound $|\delta|<10^{-21}$, a truly high-precision confirmation of SR (Prestage *et al.*, 1985; Lamoreaux *et al.*, 1986; Chupp *et al.*, 1989).

3.1.2 The Eötvös Experiment, the Weak Equivalence Principle, and the Fifth Force

3.1.2.1 Eötvös and the Weak Equivalence Principle. Another experiment that helped lay the foundation for GR was the Eötvös experiment (1889,1908), which verified what we have called the weak equivalence principle (WEP), the equality of gravitational acceleration of objects of different composition. The precision achieved was a few parts in 10^9. Two new experiments, by Dicke at Princeton University in the early 1960s (Roll *et al.*, 1964), and by Braginski at Moscow State University in 1970 (Braginski and Panov, 1971), improved the accuracy by two orders of magnitude.

3.1.2.2 Fifth-Force Experiments. In 1986, there was renewed interest in the Eötvös experiment. As a result of a detailed reanalysis of Eötvös's original data, Fischbach *et al.* (1986) suggested the existence of a "fifth force" of nature, with a strength of about a percent of that of gravity, but with a range (as defined by the range λ of a Yukawa potential $e^{-r/\lambda}/r$ augmenting the usual Newtonian potential) of a few hundred meters. This proposal dovetailed with earlier hints of a deviation from the inverse-square law of Newtonian gravitation derived from measurements of the gravity profile down deep mines in Australia.

During the next four years, over a dozen new experiments looked for evidence of the fifth force by searching for composition-dependent differences in acceleration, with variants of the Eötvös experiment or with free-fall Galileo-type experiments. Many of the Eötvös-type torsion-balance experiments took advantage of new high-Q torsion suspension systems, advanced seismic isolation, and sophisticated arrangement of component masses to reduce gravity-gradient couplings.

One of the free-fall experiments used laser interferometry to measure the differential acceleration of two chambers, fitted with corner retroreflectors, containing different materials. Although two early experiments reported positive evidence, all others yielded null results. Over the range between 1 and 10^4 m, the null experiments produced upper limits on the strength of a postulated fifth force of between 10^{-3} and 10^{-6} the strength of gravity. Interpreted as tests of the WEP (corresponding to the limit of infinite-range forces), the results of a University of Washington experiment (dubbed Eöt-Wash) were comparable to that of Dicke (Adelberger *et al.*, 1991).

At the same time, tests of the inverse-square law of gravity were carried out by comparing variations in gravity measurements up tall towers or down mines or boreholes with gravity variations predicted using the inverse-square law together with Earth models and surface gravity data mathematically "continued" up the tower or down the hole. Despite early reports of anomalies, three independent tower measurements now show no evidence of a deviation (see, for example, Jekeli *et al.*, 1990). The consensus at present is that there is no credible experimental evidence for a fifth force of nature (for recent reviews see Adelberger *et al.*, 1991; Fischbach and Talmadge 1992; and Will 1990).

3.1.3 Gravitational Redshift. Although the gravitational redshift of light is a simple consequence of the EEP (Sec. 1.2.2.2), as Einstein found some eight years before he completed the full theory, it was not confirmed experimentally until the Pound–Rebka experiment of 1960, in which the frequency shifts of γ rays rising and falling in a tower were observed, making use of the Mössbauer effect to reduce recoil broadening of the emission and absorption γ-ray lines (Pound and Rebka, 1960).

Other tests included transporting atomic clocks on jet aircraft, and measuring the shift of solar spectral lines. The most accurate confirmation to date has been a 1976 rocket experiment, in which a hydrogen maser clock was launched on a Scout rocket to an altitude of 10 000 km, and its rate compared with an identical clock on the ground, resulting in a 0.02% test (Vessot *et al.*, 1980). Recently, a measurement of the shift of the rate of oscillator clocks on the Voyager spacecraft caused by Saturn's gravitational field yielded a 1% test (Krisher *et al.*, 1990).

The gravitational redshift now has practical consequences. In satellite-based navigation systems, such as the U.S. Air Force's Global Positioning System, the atomic clocks on the satellites tick faster, as a consequence of the gravitational frequency shift and the special relativistic time dilation, than do clocks on the ground by over 30 000 ns per day. Yet the navigational accuracy requirement of 10 m demands timekeeping accuracy to 30 ns at all times, and therefore general relativistic corrections *must* be taken into account in order for the system to function. Since GPS is now used extensively both for military and civilian navigation, this represents a new "applied" side of GR.

3.2 Solar-System Tests of General Relativity

3.2.1 The Deflection and Retardation of Light

3.2.1.1 Light Deflection. One of the first calculations that Einstein performed in November of 1915, when he had the final (vacuum) field equation of GR, was the deflection of light. Earlier, in 1911, he had determined the deflection in a preliminary theory based essentially purely on the EEP (Sec. 1.2.2.2) and got the answer, $2GM/Rc^2$, as in a Newtonian gravity theory in which light was treated as a corpuscle (see Sec. 1.2.2.5).

The result of Einstein's 1915 calculation was to double the prediction. For a light ray that grazes the Sun, for example, the deflection would be 1.75″ instead of 0.875″. The difference can be understood as follows: half the deflection indeed comes directly from the Einstein principle, or equivalently from a Newtonian ballistic calculation; the remaining part derives from the curvature of space near the Sun relative to space far away. The first contribution is the same in any theory of gravity that is a metric theory. The second, space-curvature contribution varies from one metric theory to another, and is conventionally represented by the PPN parameter γ, whose general-relativistic value is 1 (see Sec. 1.2.5). In this parametrized language, the deflection of a light ray by the Sun is given by

$$\Delta\theta=\tfrac{1}{2}(1+\gamma)1.75''/d\,, \tag{27}$$

where d is the distance of closest approach of the ray to the Sun, in units of a solar radius.

The measurement of this effect by British astronomers during a total solar eclipse in 1919 (Dyson *et al.*, 1920) catapulted Einstein and GR to worldwide fame. However, the accuracy was 20% at best. A few measurements during the next 45 years failed to yield substantial improvements. The development of radio interferometry during the 1960s coupled with the discovery of quasars led to dramatically better accuracy (see RADIO TELESCOPES). The technique involved monitoring the relative angle between a pair or group of quasars as they passed near the Sun as seen from Earth. During the passage, the light from a quasar whose image is closer to the Sun would be deflected more than that from a more distant one, leading to a displacement of one image relative to the other. Between 1969 and 1975 a dozen measurements of this sort were carried out systematically, culminating in confirmations of GR at about the 1.5% level (Fomalont and Sramek, 1976). After 1975, further direct measurements of the deflection of light to test relativity essentially ceased.

However, in the early 1980s systematic efforts were initiated by geophysicists to monitor the Earth's rotation state accurately by means of very-long-baseline interferometric (VBLI) measurements of the positions of radio galaxies and quasars. Using transcontinental and intercontinental baselines, and improved timing accuracy made possible by hydrogen maser and other atomic clocks, these measurements reached the several hundred *microarcsecond* level in accuracy, making it necessary to take the relativistic deflection of light into account over the entire celestial sphere, not just near the Sun. For a ray that approaches the Earth from a direction 90° away from the Sun, for example, the deflection is 4 milliarcseconds and is readily detectable. A by-product of this effort was a 0.1% confirmation of GR (Robertson *et al.*, 1991).

The European Space Agency (ESA) satellite HIPPARCOS, which is completing its mission as this is being written (1993), has similarly made precise determinations of the positions of some 10^5 stars, for which it has to take into account (and therefore measure) the light deflection over the whole celestial sphere. This will measure γ to similar accuracy.

3.2.1.2 *Shapiro Time Delay.* There is another important test of the propagation of light through curved spacetime, which was not around in 1915, yet which is closely related to the deflection of light. It was first predicted as a consequence of GR by Shapiro (1964), and is now commonly called the Shapiro time delay. It is an excess propagation delay of light passing through a region of curved space near a body compared to the analogous propagation time if the ray passes far from the body. A light ray that passes the Sun on a round-trip, say, from Earth to Mars at superior conjunction (when Mars is on the far side of the Sun) suffers a delay given by

$$\Delta t \approx \tfrac{1}{2}(1+\gamma)250(1-0.16\ \ln d)\ \mu\text{s}\ . \qquad (28)$$

The close relationship between this effect and the deflection of light is reflected in the factor $\frac{1}{2}(1+\gamma)$ and is to be expected, since any phenomenon that bends light (refraction, curved space) may be expected to alter its propagation time as well. Observations of the Shapiro time delay began in the mid-1960s with the use of radar echoes from Mercury and Venus. Later, use was made of interplanetary spacecraft equipped with radar transponders, such as Mariners 6, 7, and 9 and the Viking landers and orbiters. Data from Viking yielded a 0.1% test (Reasenberg *et al.*, 1979).

The result of these measurements on light is $\gamma=1.000\pm0.002$, in agreement with GR. This precise determination of the parameter γ is one of the crowning achievements of experimental gravitation.

3.2.2 Mercury's Perihelion Advance. The first effect that Einstein calculated in November 1915 using his new field equations was the advance of the perihelion of Mercury. The discrepancy between the observed advance and the amount that could be accounted for from the Newtonian gravitational perturbations of Mercury by the other planets was a problem that had bedeviled celestial mechanicians for the latter half of the nineteenth century. As mentioned in Sec. 2.4.4, GR predicted an amount that neatly accounted for the discrepancy. Einstein wrote later that he had palpitations of the heart upon finding this result. For another half a century, this stood as one of the triumphs of general relativity.

The predicted rate of advance of the perihelion of Mercury (excluding the part from planetary perturbations) can be written in the following form, in seconds of arc per century:

$$d\omega/dt = 42.98''\lambda_p, \tag{29}$$

$$\lambda_p := \tfrac{1}{3}(2+2\gamma-\beta) + 0.0003(J_2/10^{-7})\ . \tag{30}$$

The first term in the coefficient λ_p is the relativistic contribution to the advance, in a form that encompasses a wide class of alternative metric theories of gravity. The parameter γ is the same parameter that appeared in the deflection of light and the Shapiro time delay, while the parameter β is a rough measure of how "nonlinear" gravity is in a given theory. Both parameters are unity in GR. The second term comes from the Newtonian effect of a possible oblateness of the Sun, which will alter its external gravitational field from the pure inverse-square form of a spherical body. The oblateness is measured by the quantity $J_2 = (I_3 - I_1)/(M_\odot/R_\odot^2)$, where I_3 is the Sun's moment of inertia about its rotation axis and I_1 is the same about an equatorial axis; for a Sun that rotates uniformly with its observed surface angular velocity, so that the oblateness is caused by centrifugal flattening, J_2 is estimated to be of order 10^{-7}.

Now, the measured perihelion shift of Mercury is known very accurately because of the combination of two factors: improved radar ranging to Mercury since 1966, leading to a more accurate determination of its orbit, and improved data on the masses and orbits of the other planets from radar ranging and spacecraft encounters, leading to improved values for the planetary perturbations. After those perturbing effects have been accounted for, the excess shift is known to about 0.1%, with the result that $\lambda_p = 1.000 \pm 0.001$ (Shapiro, 1990).

If J_2 were indeed as small as 10^{-7} this would be in complete agreement with GR. However, in 1966, a value for J_2 of 2.5 ± 10^{-5} was inferred from visual solar-oblateness measurements made by Dicke and Goldenberg (1974), a result that, if confirmed, would have disagreed strongly with GR. Between 1966 and 1980 J_2 values ranging over two orders of magnitude were reported. Beginning around 1980, however, the observation and classification of modes of oscillation of the Sun ("helioseismology") made it possible to obtain information about its internal rotation rate, thereby constraining the possible centrifugal flattening; current results favor a value $J_2 \approx 1.7 \pm 10^{-7}$ (Brown *et al.*, 1989), making the perihelion shift of Mercury another success for general relativity.

3.2.3 Test of the Strong Equivalence Principle. Another important Solar-System experiment tests a generalization of the EEP, known as the strong equivalence principle (SEP). The strong equivalence principle states, for example, that *all* bodies should fall with the same acceleration in an external gravitational field, including bodies with significant internal gravitational binding energy, such as planets, stars, and so forth. In the WEP, one considers only laboratory-sized bodies, whose internal structures are dominated by nongravitational energies. Different theories of gravity can treat the effect of gravity on gravitational energy differently, and so could predict violations of the SEP by massive, self-gravitating bodies. General relativity is one of the few theories that actually obeys the SEP. The Brans–Dicke theory, for example, does not.

Since 1969, this principle has been tested using lunar laser ranging (LURE), in which laser pulses sent from Earth bounce off corner retroreflectors deposited on the Moon during U.S. and Soviet lunar landings. The goal is to look for the orbital effects of a possible difference in acceleration between the Earth and Moon toward the Sun (the *Nordtvedt effect*: Nordtvedt, 1968a,b). No orbital perturbation of this type has been found to date down to the 6-cm level, placing a limit of 7 parts in 10^{13} on a difference in acceleration between the two bodies (Dickey *et al.*, 1989; Shapiro, 1990; Müller *et al.*, 1991). The accuracy of lunar laser ranging is approaching the level of several millimeters, at which point the accuracy of this experiment as a test of the effect of gravity on gravitational energy (test of the SEP) will be limited by the accuracy of laboratory tests of the weak principle, because the composition of the Earth (iron rich) and Moon (iron poor) differ.

3.3 The Binary Pulsar: An Astronomical Relativity Laboratory

Until 1974, the solar system provided the principal testing ground for GR, because it is a "clean" system (few uncertain or messy physical processes to complicate the gravitational effects) and it is accessible to high-precision tools. However, the discovery of the binary pulsar PSR1913+16 in 1974 by astronomers at the Arecibo Radio Telescope in Puerto Rico (Hulse and Taylor, 1975) showed that certain kinds of distant astronomical systems may also provide precision laboratories for testing GR. The system consists of a 59-ms-period pulsar in an 8-h orbit with a companion that has not been seen directly, but that is generally believed to be another NS. The unexpected stability of the pulsar "clock" and the cleanliness of the orbit allowed radio astronomers to determine the orbital and other parameters of the system to extraordinary accuracy, by analyzing the variations in pulse arrival times caused by the orbital displacements (for the most recent data, see Taylor *et al.*, 1992).

Furthermore, the system is highly relativistic ($v_{\text{orbit}}/c \approx 10^{-3}$). Observation of the relativistic periastron advance (4.226 628 ±0.000 018 deg per year) and of the effects on pulse arrival times of the gravitational redshift caused by the companion's gravitational field and of the special relativistic time dilation caused by the pulsar's orbital motion (0.15% accuracy) have been used, assuming that GR is correct, to constrain the nature of the system. In GR, these two effects depend in a known way on measured orbital parameters and on the unknown masses m_p and m_c of the pulsar and companion (assuming that the companion is sufficiently compact that tidal and rotational distortion effects can be ignored), and consequently the two masses may be calculated with these two pieces of data, with the result $m_p = (1.4411 \pm 0.0007) M_\odot$ and $m_c = (1.3873 \pm 0.0007) M_\odot$. These are the most accurately known masses of any astronomical bodies outside the Solar System. It is interesting how GR plays a crucial role in this high-precision determination of astrophysical parameters.

This binary system should radiate GWs, which, unfortunately, are of too low a frequency to be detected directly by a ground-based GW detector. On the other hand, the loss of energy in GWs should cause the orbiting stars to spiral together, and the orbital period to *decrease*. The "quadrupole formula" (Sec. 2.3.3) determines the rate of loss of energy and the consequent orbital damping rate. It was first detected successfully in 1979, with about 10% precision. Using the measured orbital elements and the two masses, one can predict the rate of decrease of the period to be $dP/dt_{\text{predicted}} = -(2.402\,43 \pm 0.000\,05) \times 10^{-12}$ s/s. Because of the extraordinary stability of the pulsar, and with the added ability to transfer stable atomic time from the world's system of atomic clocks to the Arecibo Radio Telescope via the Global Positioning System, the observations of this period decrease have now reached 0.5% in accuracy, giving $dP/dt_{\text{observed}} = -(2.408 \pm 0.015) \times 10^{-12}$ (Taylor *et al.*, 1992). This agrees completely with the prediction and is very strong indirect evidence for the correctness of GR's predictions about GWs.

3.4 Future Work in Experimental Gravitation

3.4.1 Search for Gravitomagnetic Effects. According to GR, moving or rotating matter should produce a contribution to the gravitational field that is the analog of the magnetic field of a moving charge or a magnetic dipole (Sec. 2.1.1). Although gravitomagnetism plays a role in a variety of measured relativistic effects, it has not been seen to date, isolated from other post-Newtonian effects.

The Relativity Gyroscope Experiment at Stanford University (also known by the NASA terminology Gravity Probe B, or GP-B) is in the advanced stage of developing a space mission to detect this phenomenon directly (Everitt, 1988). A set of four superconducting-niobium-coated, spherical quartz gyroscopes will be flown in a low polar Earth orbit, and the precession of the gyroscopes relative to the distant stars will be measured. The predicted effect of gravitomagnetism is about 42 milliarcseconds per year, and the accuracy goal of the experiment is about 0.5 milliarcseconds per year.

To achieve this accuracy, which corresponds to a precession rate of 10^{-16} rad/s, numerous technical challenges have had to be met, including fabricating gyroscopes that are homogeneous and spherical to better than a part per million; developing and testing a "London moment" readout system that exploits the magnetic dipole moment developed by a spinning superconductor and uses SQUIDs to read out the varying currents in superconducting loops surrounding the gyroscope; and developing a magnetic shield of novel design to reduce the ambient magnetic field of the Earth below 10^{-7} G. Recently, a full-size flight prototype of the instrument package was tested as an integrated unit. Current plans call for a test of the final flight hardware on the Space Shuttle followed by a shuttle-launched science experiment.

Another proposal to look for an effect of gravitomagnetism is to measure the relative precession of the line of nodes of a pair of laser-ranged geodynamics satellites (LAGEOS), with supplementary inclination angles; the inclinations must be supplementary in order to cancel the dominant nodal precession caused by the Earth's Newtonian gravitational multipole moments (Ciufolini, 1989). A third proposal envisages orbiting an array of three mutually orthogonal, superconducting gravity gradiometers around the Earth to measure directly the contribution of the gravitomagnetic field to the tidal gravitational force (see, for example, Mashhoon *et al.*, 1989).

3.4.2 Tests of the Einstein Equivalence Principle. The concept of an Eötvös experiment in space has been developed as a possible joint NASA-ESA mission, with the potential to test the WEP to 10^{-17}, a millionfold improvement over current ground-based results (Worden, 1988). Such an experiment could also look for additional long-range, fifth-force-type interactions, with ranges in excess of about 40 km, and could lead to improvements in the value of the Newtonian constant G. It would also map the multipole moments of the Earth's Newtonian field to high accuracy.

The accuracy of measurements of gravitational redshift could be improved to the 10^{-9} level, and higher-order effects could be seen for the first time by placing a hydrogen maser clock on board Solar Probe, a proposed spacecraft that would travel to within four solar radii of the Sun (Vessot, 1989).

3.4.3 Further Fifth-Force Searches. Because they are relatively inexpensive and because they have the potential to constrain certain classes of particle-physics models, laboratory fifth-force experiments are likely to continue at some level for many years.

4. GRAVITATIONAL-WAVE DETECTION: A TECHNOLOGICAL FRONTIER

4.1 Likely Sources of Detectable Waves

In Sec. 2.3 we learned about GWs. Here we discuss their detection. Although detectors have been under development since Weber (1960) built the first one at the University of Maryland in the early 1960s, it is only recently that technology has permitted the design of a detector that meets theoretician's predictions about the likely strengths of expected waves. It is not unreasonable to expect that, by the year 2000, the first direct detection of a GW will have occurred.

Simple detection is not the main goal of the present detector development. GWs carry information about their sources that is obtainable in no other way. In order to extract maximum information from the waves, one needs to be able to infer their amplitude and direction. Since GW detectors are not directional, this can only be done with a worldwide network of detectors, which infer directions from the relative times of arrival of waves at different locations. Three detectors is the minimum for extraction of full information from the waves.

The first aspect of designing a detector is to estimate what amplitudes and frequencies one might expect from astronomical sources. These set targets for the experimental development.

We can dispose of one source right away: laboratory generators. It is not possible to build a laboratory generator of detectable GWs. One can make an apparatus that disturbs a detector by generating a time-depending gravitational field; this has been done in several laboratories (for example, Astone *et al.*, 1991a). But it is always the near-zone Newtonian field, and the disturbance would be the same in Newtonian gravity. To detect waves one must be at least one wavelength λ away from the source, and at this distance all reasonable sources are too weak.

We look therefore to relativistic sources in astronomy. All of these are powered by their internal gravitational forces, and so the key equation for estimating the strength of their emissions is Eq. (24), which sets a relatively simple upper bound on the amplitude we can expect. Here is a brief review of the principal candidates and the astronomical information we might expect to get from them. It is by no means an exhaustive list, but it represents the most conservative predictions that have been made about possible sources.

4.1.1 Supernovae. Supernovae are rare events, occurring once in perhaps 50 years in any galaxy. We would like to be able to detect them, therefore, in a volume of space containing perhaps 2000 galaxies, so that we have a reasonable chance of seeing one. This means that realistic detectors must reach as far as the Virgo cluster, a cluster of galaxies about 15 Mpc away, containing more than 1000 galaxies.

Supernovae will give off GWs if the collapse event is very nonspherical. The mass involved will be about a solar mass, and the size of the emission region is about 10 km. These give, from Eq. (24), an upper limit of a few times 10^{-21} for waves from the Virgo cluster. Given that this is an upper bound, the usual target is 10^{-21}. A detector with that sensitivity has some chance of seeing an occasional supernova explosion, unless they are all very symmetrical.

The expected frequency can be inferred from the collapse time scale. The whole collapse takes about 10 ms, but not much radiation comes off during most of this time. The bounce time scale is about 1 ms, and subsequent oscillations may also have this time scale. The relevant frequency is the inverse, about 1 kHz. One expects a broadband burst of this central frequency from a supernova explosion.

If such bursts are seen, they may allow us to identify the object (NS or BH) formed by the collapse; they may provide crucial information about high-density nuclear physics; they may allow rapid notification of other astronomers that a supernova has occurred at a particular position; and they will enlighten our understanding of the late stages of stellar evolution.

Bursts of radiation will also be emitted if galactic-size BHs are formed in a single event or if compact stars fall into such BHs. The frequency of the emitted radiation is inversely proportional to the mass of the hole, and for holes in the centers of galaxies this can be in the millihertz region or lower. Such events are not observable from the ground since ground vibrations and the near-zone Newtonian gravitational disturbances produced by atmospheric mass motions in this frequency range are too strong to screen out. But studies have shown (Bender *et al.*, 1989) that space-based detectors could be very sensitive at these frequencies. A suitable detector could see a giant BH formation event anywhere in the Universe; it could verify or rule out that mode of formation of galactic BHs.

4.1.2 Coalescing Binaries. The remarkable binary pulsar described in Sec. 3.3 will be even more remarkable in about 10^8 years, when the orbit has shrunk to the point that the two NSs in the system are orbiting 10 or more times per second. The system will be a strong source of GWs at relatively high frequency during the remaining few seconds before the stars coalesce. The frequency of the waves is twice the orbital frequency.

Such events are, of course, rare, occurring perhaps once every 10^5 to 10^7 years in any galaxy (Narayan *et al.*, 1991; Phinney, 1991; Tutukov and Yungelson, 1993). We therefore would need to be able to detect them in a volume of space up to 200 000 times larger than that for supernovae, or as much as 60 times further away. Fortunately, this is made possible by the regularity and predictability of the signal from such a system.

In contrast to supernovae, which are likely to be messy, binaries of compact objects emit a steady, almost monochromatic "chirp" signal, whose frequency increases with time in a predictable way. If one has N cycles of such a signal in one's data stream, then one can use pattern-matching techniques (such as matched filtering) to find it at an amplitude that is smaller by a factor of $\sqrt{N}$ than one could find if one had only a single cycle. Supernovae are basically single-cycle signals, so we can see binaries 60 times further away if we can detect 3600 cycles. The binary wave train will be followed by a much less predictable burst associated with the coalescence of the two stars.

The detector has to have a broad bandwidth at a few tens or hundreds of hertz to permit such filtering and following of the signal. In fact, the broadband interferometers described below are less noisy at the lower frequencies of binary signals, but on the other hand the intrinsic signal from a binary is a bit weaker than the strongest possible supernova (because ϕ_{internal} is smaller when the stars are still several radii apart), so that the calculation must be done carefully. The result is that detectors will have about 40 times the range for binaries as they have for moderate supernova explosions. Detectors that can just barely see supernovae in Virgo (such as the first-stage interferometers described below) are unlikely to see coalescing binaries. But the second stage of development, with 10 times better amplitude sensitivity, ought to see hundreds per year.

The binary signal contains much information, including the individual masses of the component stars. By observing them, we will directly identify NSs and BHs and get much better statistics on their mass distributions. Since they occur at great distances, these events sample the cosmological mass distribution on very large scales. The signal contains enough information to allow the absolute distance to the binary to be estimated: they are true standard candles. They therefore contain cosmological information, including the possibility of measuring the Hubble constant (Schutz, 1986). The actual coalescence of the two objects (NSs and/or BHs) may be associated with the mysterious γ-ray bursts seen by satellite detectors (Meegan *et al.*, 1992). If so, they will be easier to model and understand. Finally, the detection of the radiation from the merger of two BHs will provide a strong test of GR itself; modeling this event on computers is an area of current research.

4.1.3 Pulsars. A NS that is axially symmetric will not emit GWs when it rotates, but we know that pulsars are not symmetrical; they have off-axis magnetic fields. If they have other asymmetries, perhaps mass deformations that help to pin the magnetic poles in one place, then they may give off detectable radiation. There is an upper limit on the strength of this radiation for any pulsar whose spin-down rate has been measured: GWs probably do not carry away more than the rotational energy loss of the pulsar.

The signal will be steady, so one's ability to find it increases with the square root of time, for exactly the same reason as for coalescing binaries. Again, a broadband detector is desirable, so that signals of any frequency can be detected. Given a few months' observation, second-stage interferometers are expected to be able to beat the upper limits on several pulsars by factors of 10 or more.

It is possible to conduct searches for unknown pulsars through their GW emission. Here, as for known pulsars, one must remove the Doppler effects caused by the Earth's motion before the signal becomes periodic. This correction depends on the position of the pulsar. To perform a sensitive all-sky search is a demanding computational task, and the sensitivity will be limited by the capacity of available computers (Schutz, 1991).

4.1.4 Ordinary Binaries. Binary star systems emit radiation at twice the frequency of their orbit. For all except the coalescing binaries considered before, this is a very low frequency, not observable from the ground (Sec. 4.1.1). But space-based detectors would be able to reach as low as 10^{-4} Hz and could detect steady radiation from many binaries. One of the most prominent would be PSR1913 +16. Other compact binaries might be discovered this way.

Binaries containing white dwarfs are so numerous that at the lower frequencies they provide a chaotic background of waves that might mask other sources, at least if only one detector is used in space.

4.1.5 Cosmological Background. Just as there is a cosmological background of electromagnetic radiation, one expects a background of GWs. The thermal background may be too weak to see, but many other potential sources have been discussed. Most rely on aspects of high-energy physics that give rise to inflation or to topological anomalies.

Theories that produce cosmic strings have been studied extensively. Strings are massive linear regions of trapped field, which can seed galaxy formation and can emit GWs. If strings do provide the seeds for galaxy formation, then they ought to produce a background of GWs that is detectable by interferometers (Allen and Shellard, 1992).

Searches for such a background rely on cross-correlation of the output of two detectors, since in a single detector the background appears simply as another source of noise. If the detectors are close enough, the background will produce a correlated response in both that can stand out against other local sources of noise.

4.1.6 Unexpected Sources. One of the most exciting prospects is that there might be significant radiation from unpredicted sources. Whenever new windows on astronomy have been opened, such as radio or x-ray astronomy, completely unexpected objects have been found. This will undoubtedly be true for GWs as well, but of course one does not know what sensitivity will be required to reveal them. By going 10 times deeper in amplitude (100 times in energy) than the strongest predictions for bursts, second-stage interferometers must stand a good chance of making such discoveries.

4.2 Detectors

The reason for the current interest in GWs is technological: it now seems possible to build a detector that meets theoretical predictions about sources. But detectors of various types have been under development since 1960, and six or seven detectors around the world are able to make observations today. In this section we review the techniques, with an emphasis on the areas of technology that are relevant.

4.2.1 Bar-Type Detectors. Weber designed and built the first GW detector in the 1960s. It was based on a cylinder of aluminum, suspended and isolated from ground vibrations (Weber, 1967). When a GW hits the bar broadside, the tidal forces represented in Fig. 1 stretch it along its axis. By monitoring the excitation of the fundamental longitudinal mode of vibration of the bar, one can look for GWs.

Weber chose a bar that had a resonant frequency in the kilohertz region to look for supernova events. He showed that, even for a burst event, it is desirable for the vibrational mode to have a large Q; such a mode is weakly coupled to the thermal bath of the other modes, making it easier to recognize the rapid change in its excitation caused by a GW.

The dominant background is thermal vibrations. Subsequent generations of bars have been cooled to 4.2 K to reduce this background. A further generation of bars now under construction (1993) may reach 10 mK (for example, see Astone *et al.*, 1991b). Weighing several tons, such bars will be the coldest large objects the Universe has ever seen! Where Weber's original bar had a sensitivity limit of $h \sim 10^{-16}$ for a broadband burst around 1 kHz, cryogenic bars today reach about 10^{-18}, and the new bars may go to 10^{-20}.

For bars to go below this to the interesting level of 10^{-21} means defeating the *quantum limit*. This refers to the fact that, in classical terms, the excitation energy deposited in a bar by a GW of that amplitude will be smaller than the energy of one phonon of longitudinal excitation. Although one might think this would be an absolute limit, GW theorists showed that one can use the uncertainty principle to "squeeze" the uncertainty in a particular observable (not the phonon number) and deduce from that the amplitude of the incident GW (Caves *et al.*, 1980).

Incidentally, when the same theory was applied to the laser interferometric detectors, the notion of "squeezed light" was developed (Caves, 1981). Although it had been discussed before, GW detectors stimulated the current strong interest in the quantum optics and communications community in this technique for reducing photon noise.

Despite more than a decade of research into squeezing for bars, no practical scheme has emerged, and one cannot be hopeful that bars will break the 10^{-21} barrier. For the next five years, while interferometers are being constructed, the ultracryogenic bars will have the best chance of detecting GWs. If a supernova occurs in our Galaxy or in a nearby one, they may well succeed.

4.2.2 Laser-Interferometric Detectors. An interferometer is designed to measure the relative difference in two optical paths. If one places an interferometer in the center of the ring in Fig. 1, with the ends of two perpendicular arms on the ring, then the subsequent motion of the ends relative to the center can be detected by interferometry.

The relative motions are small, however, and so the technical challenge is large. For the end mirrors to respond as free masses, they must be hung from supports and isolated from ground vibration. Because the tidal gravitational forces scale with distance, it is desirable to make the arms as long as possible. Present prototypes (see the various articles in Blair, 1991) are in the 10–40-m range, but detectors now under construction (see below) will be as long as 4 km. It is this ability to take advantage of the tidal scaling that gives interferometers the edge over bars.

Even over 4 km, a disturbance of 10^{-21} translates into a mirror motion of 4×10^{-16} cm, less than 0.01 fm. To sense average displacements of the surface of a macroscopic object to this accuracy with optical or infrared photons whose wavelengths are 12 orders of magnitude larger requires many photons. In turn, this requires excellent mirrors and high-power continuous-wave lasers. The physical principles of such detectors have been reviewed by Giazotto (1989).

The detectors will be built in stages. The first stage will aim at a sensitivity to broadband bursts of 10^{-21}. The second stage will aim for 10^{-22}. Current designs anticipate mirrors with losses well below 10^{-4} per reflection, and neodymium-doped yttrium aluminum garnet (YAG) lasers as sources for the second stage. (See LASERS, SOLID STATE.) For the second stage, light will have to be conserved, and designers like R. W. P. Drever and the late B. J. Meers have devised clever methods of optimizing the use of light. It is now clear that, although the detectors are intrinsically broadband, they can also be tuned to narrow frequency ranges if desired.

The light must travel along the arms in a good vacuum, better than 10^{-8} Torr for the second stage. This is not hard in principle, but the volume to be evacuated is large: tubes 4 km in length and 1.5 m in diameter. The cost of this vacuum system is the dominant cost of the detectors.

Data will flow from these detectors at an enormous rate. Recent short observing runs using prototypes at Glasgow University and the Max Planck Institute for Quantum Optics in Garching, Germany, produced data rates approaching 1 Gbyte/h. The storage and analysis of data from a network of interferometers are formidable problems.

There are proposals for a number of interferometric detectors around the world. A project called LIGO to build two in the United States (Abramovici *et al.*, 1992) is funded, and should begin construction in 1993. If present (1993) schedules hold, LIGO could begin observing by 1998. A French–Italian detector called VIRGO, to be built near Pisa, Italy, is likely to get final approval in 1993 (Bradaschia *et al.*, 1990). There are further proposals for a British–German detector near Hannover, Germany, and an Australian detector near Perth that are awaiting funding. Japan is planning an intermediate-sized detector (300 m). Because detectors have broad quadrupolar antenna patterns, an accurate direction to a detected source can only be obtained by triangulation, using the time delays among various detectors. For this reason, a minimum of three detectors worldwide is required for the extraction of full information from detected signals.

4.2.3 Space-Based Detectors. As we noted in Sec. 4.1.1, the interesting frequency range around 1 mHz is only accessible to space-based detectors. Space-based searches for GWs have already been made using transponding data from interplanetary space probes. A passing GW would affect the time delays of round-trip signaling to the probes; the signature of this effect is unique, and sensitive searches can be made at very low frequencies. No positive detections have been reported (e.g., Armstrong *et al.*, 1987). As the principal limit on sensitivity is propagation disturbances of the radio communication signals, sensitivity can be increased by using multiple-frequency communication, by going to higher frequencies, and by using multiple spacecraft. A three-spacecraft experiment was performed in 1993 using NASA's Mars Observer and Galileo probes and the European Space Administration's Ulysses solar observatory. When the data are analyzed, they may improve previous limits by a factor of 10 or more.

Proposals have been made for purpose-built interferometers in space. Laser interferometers using the Earth–Moon or even the Sun–Earth Lagrangian points to stabilize their orbits look very promising.

GLOSSARY

Cosmology: The study of the large-scale properties of the observable universe as a whole.

Geodesics: Locally straight lines of a curved space or spacetime. They are also paths of extremal proper distance.

Homogeneous Cosmology: A cosmology in which there is a choice of time (a reference frame) such that all its properties are the same everywhere at a constant time.

Isotropic Cosmology: A cosmology that is homogeneous and in which, in addition, there is no preferred direction in space, such as a systematic velocity of the matter.

Reference Frame: A coordinate system for space and time that includes facilities for measuring and recording the exact location and time of any event. In special relativity, a *Lorentz* reference frame has rigid spacings between spatial coordinate locations, and its clocks are synchronized everywhere. In gen eral relativity, a *local* reference frame makes measurements only in a restricted region.

INTRODUCTION

In mathematics the term Green's function is usually given to a solution of an initial- or boundary-value problem of a differential equation with a δ-function inhomogeneous term. Let us be more specific. Consider an ordinary or partial differential equation

$$L_x G(x,x') = \delta(x-x'), \tag{1}$$

with L_x a linear differential operator with respect to the variable x. Here, x may stand for either the position $\mathbf{r}$, the time t, or the pair $(\mathbf{r},t)$. Then the solution $G(x,x')$ is called the Green's function if it satisfies a given homogeneous boundary condition—a condition relating the value of G to its derivative G_x on the boundary of the domain, a simple example of which is $G(x,x')=0$ or $G_x(x,x')=0$. In physics and applied physics, however, the term Green's function is often used without explicitly referring to the boundary condition. For example, a fundamental solution in mathematics is often called simply a Green's function. Thus it is desired to seek an alternative and more generalized definition that enables us to deal with a wider class of functions encountered in various areas of physical science. This can be achieved by formulating the concept of Green's functions in terms of response theory: The Green's function is then a response function that connects the output signal $O(x)$ of the system with the input signal $I(x)$ in the form of a linear integral transform:

$$O(x) = \int G(x,x')I(x')dx', \tag{2}$$

the integral range over x' depending upon the problem under consideration. In the present article the term Green's function is employed in this generalized sense.

When the linear response of a system is described by a linear operator L_x, which may be differential, integral, integro-differential, or of any other kind, the two signals $O(x)$ and $I(x)$ are related through

$$L_x O(x) = I(x). \tag{3}$$

Comparing this equation with Eq. (2), we see that the Green's function is formally defined by L_x^{-1}. When, in particular, L_x is a differential operator in Eq. (3) and a homogeneous boundary condition, $u(x)=0$, for example, is imposed on the boundary Γ, the definition used in mathematics is recovered. This is because the superposition over x' in Eq. (2) solves the problem when G satisfies Eq. (1) with the boundary condition $G(x,x')=0$ for x on Γ. There are, however, many cases where it is difficult to specify the operator L_x for describing the response. The relationship between the responses of a black box to a δ-function type and distributed input signals is shown in Fig. 1.

Although the principle of superposition and hence the validity of the form given by Eq. (2) hold only when the solution satisfies a homogenous boundary condition, Green's functions are also central when one tries to construct a solution of a boundary-value problem with an inhomogeneous boundary condition—for example, a solution having a prescribed nonzero value on the boundary. This is one reason why Green's functions are so widely used.

The quantities called "resolvent," "resolvent kernel," "signal function," "point response function," or "transfer function," encountered in various fields of mathematics, physics, applied physics, and engineering, are nothing but the Green's functions in the generalized definition. We note that in Eq. (1) the Green's function $G(x,x')$ describes the response to a "point" input source and in Eq. (2) it "transfers" the input signal into the output response of the system in question. When one recalls that many problems in physics and applied physics ultimately reduce to finding the output $O(x)$ for a given input $I(x)$, one can

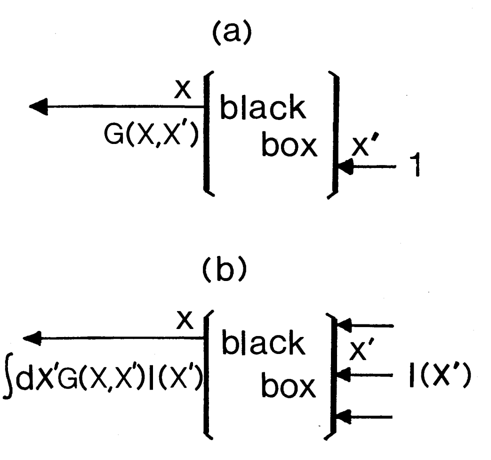

FIG. 1. Response at x of a black box to an input signal: (a) an input signal localized at x' with unit strength, (b) an input signal distributed with magnitude $I(x')$.

understand why Green's functions are very popular today in many fields—hydrodynamics, electrodynamics, acoustics, elasticity, quantum mechanics, solid-state physics, elementary-particle physics, and so on. To imagine how widely they are used, it is enough to remember the diverse names given to them, listed above. Their usefulness is still growing progressively today, as various numerical techniques continue to develop for calculations involving Green's functions.

The subjects of the present article are the definitions, significances, constructions, utilizations, and usefulness of Green's functions. We try to make the description as illustrative as possible. The Green's functions we deal with in this article range from those treated in mathematical textbooks to the ones used in many fields of pure and applied physics.

Although, unless stated otherwise, the concrete forms of the Green's functions will be given for the case of three-dimensional space, the reader should keep in mind that they depend intrinsically on the dimensionality of the space considered. The reader can consult the monographs quoted in the text for the case of other dimensionalities. Also, it should be noted that in defining a Green's function in this article the coefficient of a δ function of the point input signal is not always unity, reflecting some arbitrariness existing in the literature.

The present article is organized as follows. We sketch in Sec. 1 a brief history of Green's functions including their modern development. In Sec. 2 some typical methods of constructing Green's functions are explained for several differential equations. The usefulness of Green's functions in initial- and boundary-value problems is demonstrated in Sec. 3. The boundary-element method, devised to handle boundary-value problems for a nontrivial geometry, is explained in Sec. 4, together with the presentation of some of its applications. Up to this point, the description is given for the role of Green's functions as a convenient tool for solving a mathematical or physical problem. In Sec. 5, a number of Green's functions are given which have a direct relevance with a physical reality. The treatments as combined with perturbation method are described in Sec. 6. The Green's functions popular in many-body problems are described in Sec. 7, where, among other things, we review their extremely important application in linear response theory of condensed-matter physics. A brief sketch of their use in quantum field theory is also given.

1. HISTORY OF GREEN'S FUNCTIONS

In the history of Green's functions, it will be appropriate to go back to 1828, when N. Green put forth Green's formula (Kellog, 1939)

$$\int_{\Omega}[u(\mathbf{r})\Delta v(\mathbf{r})-v(\mathbf{r})\Delta u(\mathbf{r})]d^3\mathbf{r} = \int_{\Gamma}\left(u(\mathbf{r})\frac{\partial}{\partial n}v(\mathbf{r})-v(\mathbf{r})\frac{\partial}{\partial n}u(\mathbf{r})\right)ds. \tag{4}$$

It converts the volume integral within a region Ω of the left-hand side into the surface integral on its boundary Γ, with Δ the Laplacian and $(\partial/\partial n)v(\mathbf{r})=\hat{\mathbf{n}}\cdot\nabla v(\mathbf{r})$, $\hat{\mathbf{n}}$ being the outward normal with unit length to the boundary Γ. This formula holds for arbitrary $u(\mathbf{r})$ and $v(\mathbf{r})$. When, in particular, $u(\mathbf{r})$ is a harmonic function, $\Delta u(\mathbf{r})=0$, and $v(\mathbf{r})$ is the Green's function of the Laplace equation

$$\Delta v(\mathbf{r})=-\delta(\mathbf{r}-\mathbf{r}') \tag{5}$$

or

$$v(\mathbf{r})=1/(4\pi|\mathbf{r}-\mathbf{r}'|), \tag{6}$$

Green's formula yields for $\mathbf{r}$ within Ω

$$u(\mathbf{r})=\frac{1}{4\pi}\int_{\Gamma}\left(\frac{1}{|\mathbf{r}-\mathbf{r}'|}\frac{\partial}{\partial n'}u(\mathbf{r}') - u(\mathbf{r}')\frac{\partial}{\partial n'}\frac{1}{|\mathbf{r}-\mathbf{r}'|}\right)ds'. \tag{7}$$

It shows that, as in Cauchy's formula for regular functions of complex argument $z=x+iy$, we can express a harmonic function inside a region as an integral over its boundary: we may evaluate the value of $u(\mathbf{r})$ inside Ω only if we know values of both $u(\mathbf{r})$ and $\partial u(\mathbf{r})/\partial n$ on Γ. If we let the argument $\mathbf{r}$ approach the boundary Γ, Eq. (7) becomes a Fredholm integral equation, which allows us to express $u(\mathbf{r})$ in terms of $\partial u(\mathbf{r})/\partial n$. Likewise, differentiating Eq. (7) over $\mathbf{r}$ and letting $\mathbf{r}$ tend to Γ lead to the equation for $\partial u(\mathbf{r})/\partial n$. Thus $u(\mathbf{r})$ and $\partial u(\mathbf{r})/\partial n$ cannot both be specified freely on Γ. From this fact stem the

Dirichlet and Neumann problems of the Laplace equation, i.e., the problems of finding a harmonic function $u(\mathbf{r})$ that has a prescribed boundary value $u(\mathbf{r})$ and outward derivative $\partial u(\mathbf{r})/\partial n$, respectively, on the boundary Γ.

In the latter half of the 19th century, Green's functions played a fundamental role in the discussion of the existence and uniqueness of the solution of internal or external boundary-value problems (Courant and Hilbert, 1937). In addition to their significance in these basic problems, they were also the key quantities in the practical side of constructing the solutions of boundary-value problems, as analyzed fully by Lyapunov for the potential problem (Smirnov, 1965).

Towards the end of the 19th century and at the beginning of the 20th century, Green's functions were used in examining the completeness property (closure property) of the set of eigenfunctions of self-adjoint operators and in proving the expansion theorem for an arbitrary function in terms of the complete set obtained from, say, a Sturm-Liouville operator (Courant and Hilbert, 1937). In mathematics, these concepts opened the way to functional analysis, which has since refined and generalized greatly the theory of partial differential equations (Yosida, 1965). In the fields of pure and applied physics, not only were they adopted in solving various practical problems, but they were also used in clarifying many fundamental concepts underlying quantum mechanics, which was founded in 1925 and has been developing ever since. Indeed, one of the easiest ways to recognize a marked peculiarity of quantum mechanics contrasting with classical mechanics is to change the action integral for a classical motion into the form involving the Green's function of the Schrödinger equation (Sakurai, 1985). Also, in many quantum-mechanical applications, the Green's functions enable us to take into account a perturbation series to an infinite order to give a deep insight not attainable by a finite-order treatment.

As elementary-particle physics and solid-state physics began to develop rapidly after World War II, the extended applications of Green's functions were actively pursued. One example is seen in many-particle physics in which the Green's functions are defined in terms of field operators and used in conjunction with the graphical representation of many-body processes (see, e.g., Feynman, 1972). In these graphs, which have came to be called Feynman diagrams, each line standing for a Green's function describes temporal and spatial evolution of an elementary particle or excitation. The crossing or branching of the lines represents the interaction among particles, implying that the Green's function carries all the information on the "personal history" of an electron, proton, photon, etc. Because of this characteristic, these Green's functions are more often called "propagators." Their contributions in the development of quantum electrodynamics (Bogoliubov and Shirkov, 1959) and solid-state physics (Abrikosov *et al.*, 1963) have been quite remarkable. Despite the apparent difference in definition, Green's functions defined in terms of Feynman's path integral in quantum field theory constitute the second example belonging to this category (Feynman and Hibbs, 1965; Itzykson and Zuber, 1980). Since the functional integral seems to be the most powerful tool to date to quantize nonlinear Lagrangians, the Green's functions will continue to be a useful tool in the future development of this field. As a last example, we refer the reader to linear response theory applied widely in condensed-matter physics. In this example. too, Green's functions have been very useful in that the theory of Kubo is most powerful when it is applied in conjunction with the temperature Green's functions introduced by Matsubara (Kubo *et al.*, 1991).

Parallel to such generalizations in pure physics, the Green's functions of traditional usage have been refined in various ways, yielding many important concepts. Especially, many practical problems related to the Laplace, heat, wave, or Schrödinger equation, previously left untouched simply because the boundaries of the domains in question were too complex for analytical treatment, have come to be solved with the help of numerical techniques. The boundary-element method, one of the methods designed for just such problems, takes full advantage of the Green's-function approach (Brebbia, 1978; Brebbia and Walker, 1980). Green's functions are now so widely used everywhere that familiarity with them is becoming more and more important.

2. CONSTRUCTION OF GREEN'S FUNCTIONS

A number of typical methods of constructing Green's functions are illustrated.

2.1 One-Dimensional Equation of Sturm-Liouville Type with Dirichlet-Type Boundary Conditions

The Green's function for the Sturm-Liouville operator satisfies $[p(x)>0]$

$$L[G(x,x')]\equiv\frac{d}{dx}\left(p(x)\frac{d}{dx}G(x,x')\right)-q(x)G(x,x')=-\delta(x-x'),\tag{8}$$

where the one-dimensional region $0<x<1$ is assumed. Suppose that a Dirichlet-type boundary condition is imposed on G:

$$G(x,x')=0 \quad \text{at } x=0 \text{ and } 1.\tag{9}$$

The solution of this problem is constructed as follows:

$$G(x,x')=\begin{cases}\gamma u_<(x)u_>(x'), & 0\leqslant x\leqslant x'\leqslant 1,\\ \gamma u_>(x)u_<(x'), & 0\leqslant x'\leqslant x\leqslant 1.\end{cases}\tag{10}$$

Here $u_<(x)$ is a solution of $L[u_<(x)]=0$ with the boundary value $u_<(0)=0$ at the left boundary, while $u_>(x)$ satisfies $L[u_>(x)]=0$ with $u_>(1)=0$ at the right boundary. The constant γ in Eq. (10), independent of x and x', is given by

$$\gamma=\frac{1/p(x')}{u'_<(x')u_>(x')-u'_>(x')u_<(x')},\tag{11}$$

with $u'_<(x')=(d/dx')u_<(x')$. It is determined such that

$$p(x')[G'(x'^+,x')-G'(x'^-,x')]=-1,\tag{12}$$

with $G'(x'^\pm,x')=(d/dx)G(x,x')|_{x=x'^\pm}$, which is the condition obtained by integrating both sides of Eq. (8) in the infinitesimal interval $x'^-<x<x'^+$, where $x'^\pm=x'\pm\epsilon$ $(\epsilon\to 0+)$. When the left-hand solution $u_<(x)$ happens to satisfy simultaneously the condition $u_<(1)=0$, i.e., when $u_<(x)$ happens to be the true eigenfunction of the operator L with zero eigenvalue, the constant γ diverges, meaning that the system resonates with the point external force expressed by the δ function in Eq. (8). Still, in this case, one can redefine a generalized Green's function so that Eq. (2) remains valid in taking into account the inhomogeneous term (Smirnov, 1965). In the case of a Neumann- or mixed-type homogeneous boundary condition in place of Eq. (9), Eq. (10) still provides us with the Green's function if $u_<(x)$ and $u_>(x)$ therein satisfy the given boundary conditions. For various types of Sturm-Liouville operators and their generalizations, Green's functions are tabulated in many books. See, e.g., Butkovskiy (1982).

2.2 Retarded, Advanced, and Causal Green's Functions of the Helmholtz Equation

The Green's function of the Helmholtz equation is defined by

$$(\Delta+\kappa^2)G(\mathbf{r},\mathbf{r}';\kappa)=-\delta(\mathbf{r}-\mathbf{r}').\tag{13}$$

By Fourier transform we find

$$G(\mathbf{r},\mathbf{r}';\kappa)=\int\frac{d^3k}{(2\pi)^3}\frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')]}{k^2-\kappa^2}.\tag{14}$$

As such the Green's function is undetermined because the integral is divergent. If we add a small imaginary part $i\epsilon$ to κ $(\epsilon\to 0+)$, one may construct the following three types of Green's functions:

1. By putting κ equal to $\kappa+i\epsilon$, one obtains

   $$G_R(\mathbf{r},\mathbf{r}';\kappa)=\exp(i\kappa|\mathbf{r}-\mathbf{r}'|)/4\pi|\mathbf{r}-\mathbf{r}'|,\tag{15}$$

   which is called the retarded Green's function. It is regular in the upper half of the complex κ plane.
2. By putting κ equal to $\kappa-i\epsilon$, one obtains a complex conjugate of the retarded function,

   $$G_A(\mathbf{r},\mathbf{r}';\kappa)=\exp(-i\kappa|\mathbf{r}-\mathbf{r}'|)/4\pi|\mathbf{r}-\mathbf{r}'|.\tag{16}$$

   This Green's function is called the advanced Green's function and is regular in the lower half of the complex κ plane.
3. By putting κ equal to $\kappa+i\epsilon\,\mathrm{sgn}\,\kappa$, $\mathrm{sgn}\,\kappa$ being $\kappa/|\kappa|$, (i.e., κ^2 to $\kappa^2+i\epsilon$), one obtains the causal Green's function

   $$G_C(\mathbf{r},\mathbf{r}';\kappa)=G_R(\mathbf{r},\mathbf{r}';\kappa)\theta(\kappa)+G_A(\mathbf{r},\mathbf{r}';\kappa)\times\theta(-\kappa),\tag{17}$$

the Heaviside step function $\theta(\kappa)$ being defined by

$$\theta(\kappa)=\begin{cases}1, & \kappa>0,\\ 0, & \kappa<0.\end{cases} \tag{18}$$

We see that G_R (G_A) is obtained by analytically continuing G_C of the range $\kappa>0$ ($\kappa<0$) to the upper (lower) half of the complex κ plane. Except in many-body theories, G_C is seldom used [see Eq. (88)]. The names "retarded" and "advanced" come from the time dependence of the Green's functions of the (time-dependent) wave equation

$$\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\Delta\right)G(\mathbf{r},t;\mathbf{r}',t')=\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'), \tag{19}$$

c being a positive constant. Upon converting from t to the Fourier space ω, we obtain the Helmholtz equation given by Eq. (13) with $\kappa^2=\omega^2/c^2$. The inverse Fourier transform back to the variables t and t' of Eq. (14) [or Eq. (15) or (16)] shows that $G_R(\mathbf{r},t;\mathbf{r}',t')$ has nonzero values only in the case $t>t'$, while G_A is finite in the opposite case, $t<t'$. Namely, when G_R or G_A is substituted for G in the input-output relation (2), it turns out that

$$O(\mathbf{r},t)=\int_{-\infty}^{t} dt' \times\int d^3\mathbf{r}' G_R(\mathbf{r},t;\mathbf{r}',t')I(\mathbf{r}',t'),$$

$$O(\mathbf{r},t)=\int_{t}^{\infty} dt' \times\int d^3r' G_A(\mathbf{r},t;\mathbf{r}',t')I(\mathbf{r}',t'). \tag{20}$$

That is, the retarded Green's function duly satisfies the causality condition in the sense that a perturbation due to $I(\mathbf{r}',t')$ precedes its consequence observed at time t. The advanced Green's function describes the time-reversed process of the physical one. These features are also obvious in the time-independent version $G(\mathbf{r},\mathbf{r}';\kappa)$, which describes the scattering of, e.g., a monochromatic sound wave with a fixed frequency ω ($\kappa=\omega/c$, c being the velocity of sound). Here G_R given by Eq. (15) leads properly to the outgoing scattered wave, while G_A gives rise to an incoming scattered wave (Sommerfeld, 1949). To summarize, the three Green's functions of wave equation are defined by

$$\begin{aligned}
G_R(\mathbf{r},t;\mathbf{r}',t')&=\lim_{\epsilon\to 0}\int \frac{d^3k\,d\omega}{(2\pi)^4}\,\frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')-i\omega(t-t')]}{k^2-(\omega+i\epsilon)^2/c^2},\\
G_A(\mathbf{r},t;\mathbf{r}',t')&=\lim_{\epsilon\to 0}\int \frac{d^3k\,d\omega}{(2\pi)^4}\,\frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')-i\omega(t-t')]}{k^2-(\omega-i\epsilon)^2/c^2},\\
G_C(\mathbf{r},t;\mathbf{r}',t')&=\lim_{\epsilon\to 0}\int \frac{d^3k\,d\omega}{(2\pi)^4}\,\frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')-i\omega(t-t')]}{k^2-\omega^2/c^2-i\epsilon}.
\end{aligned} \tag{21}$$

After evaluating the integrals, we find

$$\begin{aligned}
G_R(\mathbf{r},t;\mathbf{r}',t')&=(c/2\pi)\theta(t-t')\\
&\quad\times\delta(c^2(t-t')^2-|\mathbf{r}-\mathbf{r}'|^2),\\
G_A(\mathbf{r},t;\mathbf{r}',t')&=(c/2\pi)\theta(t'-t)\\
&\quad\times\delta(c^2(t-t')^2-|\mathbf{r}-\mathbf{r}'|^2),\\
G_C(\mathbf{r},t;\mathbf{r}',t')&=[ic/(2\pi)^2]/[|\mathbf{r}-\mathbf{r}|^2\\
&\quad-c^2(t-t')^2+i\epsilon].
\end{aligned} \tag{22}$$

The first of the three leads to Huygens's principle (See Sec. 5.1).

2.3 Green's Functions Obtained by Fourier Transform

As shown in Sec. 2.2, the Fourier transform is a convenient way to obtain Green's functions. It is powerful only for obtaining the Green's function for an infinite domain, however, i.e., a fundamental solution. Nevertheless, it should be noted that such a Green's function enables us to derive a Green's function subject to a homogeneous boundary condition on the boundary of a finite domain (see Sec. 2.4). Note also that the infinite-domain Green's functions are used very often to solve the problems for a finite domain [the boundary-element method is one of the examples (see

Secs. 4.2 and 4.3)]. With this remark in mind, we will in this section give some Green's functions obtained by Fourier transform.

2.3.1 Heat Equation. The Green's function of the heat equation is defined by

$$\left(\frac{\partial}{\partial t}-\sigma^2\Delta\right) G(\mathbf{r},t;\mathbf{r}',t')=\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'). \tag{23}$$

In Fourier space, it holds that

$$\begin{aligned} G(\mathbf{r},t;\mathbf{r}',t') &= \int \frac{d^3k\, d\omega}{(2\pi)^4} \frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')-i\omega(t-t')]}{\sigma^2k^2-i\omega} \\ &= \begin{cases} [4\pi\sigma^2(t-t')]^{-3/2}\exp\{-|\mathbf{r}-\mathbf{r}'|^2/[4\sigma^2(t-t')]\}, & t>t', \\ 0, \quad t<t', \end{cases} \end{aligned} \tag{24}$$

the second relation being obtained by calculating the residue in the ω integral. We should note that the integral over ω is well defined in contrast to the wave equation treated in Sec. 2.2. The finiteness of the Green's function only in the case $t>t'$ is in accord with the law of increase of entropy or the second law of thermodynamics.

2.3.2 Time-Dependent Schrödinger Equation. The Green's function for a free particle with mass m obeying Schrödinger's equation is defined by

$$\left(i\hbar\frac{\partial}{\partial t}+\frac{\hbar^2}{2m}\Delta\right) G(\mathbf{r},t;\mathbf{r}',t')=i\hbar\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'). \tag{25}$$

Fourier transform then yields

$$\begin{aligned} G_R(\mathbf{r},t;\mathbf{r}',t') &= i\int \frac{d^3k\, d\omega}{(2\pi)^4} \frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')-i\omega(t-t')]}{\omega-\hbar k^2/2m+i\epsilon} \\ &= \begin{cases} [m/2\pi i\hbar(t-t')]^{3/2}\exp[im|\mathbf{r}-\mathbf{r}'|^2/2\hbar(t-t')], & t>t', \\ 0, \quad t<t'. \end{cases} \end{aligned} \tag{26}$$

In the ω integral, we have replaced ω by $\omega+i\epsilon$ to obtain the retarded Green's function. The advanced Green's function, finite for $t<t'$, is obtained by putting ω equal to $\omega-i\epsilon$. Thus the Schrödinger equation allows a time-reversed solution, like what we have seen for the wave equation [Eq. (19)].

2.3.3 Klein-Gordon Equation. The Green's functions of the Klein-Gordon equation are defined by

$$\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\Delta+\mu^2\right) G(\mathbf{r},t;\mathbf{r}',t')=\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'), \tag{27}$$

c and μ being two positive constants. Replacing μ^2 by $-\mu^2$ defines the Green's function of the telegraphic equation. By Fourier transform we find

$$G(\mathbf{r},t;\mathbf{r}',t')=\int \frac{d^3k\, d\omega}{(2\pi)^4} \frac{\exp[i\mathbf{k}\cdot(\mathbf{r}-\mathbf{r}')-i\omega(t-t')]}{k^2+\mu^2-(\omega/c)^2}. \tag{28}$$

Since the integral is not well defined, we can construct three Green's functions, G_R, G_A, and G_C, by replacing ω as in Eq. (21). They are obtained, respectively, as (Bogoliubov and Shirkov, 1959)

$$\begin{aligned} G_R(x) &= -\theta(t-t')\Delta(x;\mu^2), \\ G_A(x) &= \theta(t'-t)\Delta(x;\mu^2), \\ G_C(x) &= \bar{\Delta}(x;\mu^2) + (i/2)\Delta^{(1)}(x;\mu^2). \end{aligned} \tag{29}$$

Here $G(\mathbf{r},t;\mathbf{r}',t')$ is expressed simply as $G(x)$, x standing for $(c(t-t'),\mathbf{r}-\mathbf{r}')$, and $\theta(t-t')$ is the step function defined by Eq. (18). The other quantities are defined by

$$\begin{aligned} \Delta(x;\mu^2) &= (-c/2\pi)\operatorname{sgn}(t-t')[\delta(x^2) \\ &\quad -\theta(x^2)(\mu^2/2)J_1(\mu x)/(\mu x)], \\ \bar{\Delta}(x;\mu^2) &= -\tfrac{1}{2}\operatorname{sgn}(t-t')\Delta(x;\mu^2), \\ \Delta^{(1)}(x;\mu^2) &= (c/4\pi|\mathbf{r}-\mathbf{r}'|)(\partial/\partial r) \\ &\quad \times[\theta(x^2)N_0(\mu x) - i\theta(-x^2) \\ &\quad \times H_0(i\mu(-x^2)^{1/2})], \end{aligned} \tag{30}$$

where $\operatorname{sgn}(t)=t/|t|$, $x^2=c^2(t-t')^2-|\mathbf{r}-\mathbf{r}'|^2$, $x=(x^2)^{1/2}$, J_1 is the first-order Bessel function, and N_0 and H_0 are the Neumann and first-kind Hankel functions of the zeroth order, respectively (Abramowitz and Stegun, 1965). In quantum field theory, the Green's functions in Fourier space [$(\mathbf{k},\omega)$ representation] are more often used than the $(\mathbf{r},t)$ representation given above. The Green's functions treated in Sec. 2.2 are reproduced by taking the limit $\mu \to 0$ in the above.

2.4 Green's Functions Matching Homogeneous Boundary Conditions at the Boundary of a Finite Region

As an illustration, let us consider the Green's function of the Laplace equation for a region Ω:

$$\Delta G(\mathbf{r},\mathbf{r}') = -\delta(\mathbf{r}-\mathbf{r}'), \tag{31}$$

with a homogeneous Dirichlet condition imposed on the boundary Γ:

$$G(\mathbf{r},\mathbf{r}')|_{\mathbf{r}\text{ on }\Gamma}=0. \tag{32}$$

Were it not for the restriction (32), the Green's function would be nothing more than the fundamental solution of the Laplace equation, the Coulomb potential given by Eq. (6). It satisfies the boundary condition $G(\mathbf{r},\mathbf{r}') \to 0$, as $r \to \infty$. To match the boundary condition (32), the Green's function must have the form

$$G(\mathbf{r},\mathbf{r}') = g(\mathbf{r},\mathbf{r}') + 1/4\pi|\mathbf{r}-\mathbf{r}'|, \tag{33}$$

where $g(\mathbf{r},\mathbf{r}')$ is the solution of the homogeneous equation

$$\Delta g(\mathbf{r},\mathbf{r}') = 0 \tag{34}$$

subject to the boundary condition

$$g(\mathbf{r},\mathbf{r}')|_{\mathbf{r}\text{ on }\Gamma} = -1/(4\pi|\mathbf{r}-\mathbf{r}'|)|_{\mathbf{r}\text{ on }\Gamma}. \tag{35}$$

The second term of Eq. (33) takes account of the δ function of the Poisson equation, while the first term $g(\mathbf{r},\mathbf{r}')$ incorporates the boundary condition. The problem of finding the Green's function thus reduces to an orthodox Dirichlet problem of Eqs. (34) and (35) of finding a harmonic function $g(\mathbf{r},\mathbf{r}')$ satisfying the inhomogeneous boundary condition. Although the existence and uniqueness of the solution is well established, a concrete expression for $g(\mathbf{r},\mathbf{r}')$ is hard to obtain analytically, unless the boundary Γ has a good symmetry (Kellog, 1939; Smirnov, 1965). Nevertheless, this method of obtaining the Green's functions satisfying the boundary condition has a wide applicability in many differential equations, and is not restricted to the Laplace equation treated here.

2.5 Spectral Representation of Green's Functions

As an example of Green's functions of three-dimensional self-adjoint operators, we treat here that of the Schrödinger equation defined by

$$[E-H(\mathbf{r})]G(\mathbf{r},\mathbf{r}';E) = i\hbar\delta(\mathbf{r}-\mathbf{r}'). \tag{36}$$

For an electron in a hydrogen atom, for example, the Hamiltonian H is given by

$$H(\mathbf{r}) = -\frac{\hbar^2}{2m}\Delta - \frac{e^2}{4\pi\epsilon_0 r}, \tag{37}$$

the proton being taken as the origin of coordinates. From Eq. (36) one obtains

$$G(\mathbf{r},\mathbf{r}';E) = \sum_n i\hbar\psi_n(\mathbf{r})\psi_n(\mathbf{r}')^*/(E-E_n), \tag{38}$$

with the eigenfunction ψ_n satisfying

$$H(\mathbf{r})\psi_n(\mathbf{r}) = E_n\psi_n(\mathbf{r}). \tag{39}$$

Equation (38) can easily be verified by applying $E-H(\mathbf{r})$ to both sides and using the completeness of $\{\psi_n\}$ for the self-adjoint operator $H(\mathbf{r})$. The set of states n includes not only the states with discrete energy eigenvalues but also the states within continuous spectra, if there are any, as in the case of a hydrogen atom. To describe a physical process occurring in a hydrogen atom, we must use the retarded version of the Green's function obtained by changing E to $E+i\epsilon$ in Eq. (38), in accordance with the remark made in 2.2.

Even in a finite-domain problem subject to a homogeneous restriction imposed on the boundary, the expression (38) remains valid, with the understanding that the ψ_n's are now the solutions for the eigenvalue problem with that boundary condition.

3. GREEN'S FUNCTIONS USED IN SOLVING INITIAL- AND BOUNDARY-VALUE PROBLEMS

In solving an initial- or boundary-value problem, the Green's function is useful in taking account of not only an inhomogeneous term but also an inhomogeneous initial or boundary condition. Some examples are given in Kellog (1939) and Morse and Feshbach (1953).

3.1 Dirichlet and Neumann Problems of Poisson's Equation

The internal Dirichlet problem of the Poisson equation is defined by

$$\Delta u(\mathbf{r})=-f(\mathbf{r}), \tag{40}$$

with the inhomogeneous boundary condition imposed on Γ,

$$u(\mathbf{r})|_\Gamma=g(\mathbf{r}). \tag{41}$$

The solution $u(\mathbf{r})$ of this problem may be written down if we know the Green's function $G_1(\mathbf{r},\mathbf{r}')$ of the Laplace equation satisfying the boundary condition $G_1(\mathbf{r},\mathbf{r}')|_\Gamma=0$ [i.e., the Green's function given by Eq. (33)]. It reads

$$u(\mathbf{r})=\int_\Omega G_1(\mathbf{r},\mathbf{r}')f(\mathbf{r}')d^3r' - \int_\Gamma \left(\frac{\partial}{\partial n'} G_1(\mathbf{r},\mathbf{r}')\right)g(\mathbf{r}')ds', \tag{42}$$

where n defines the outward normal to Γ as in Eq. (4). The right-hand side is being written solely in terms of the given boundary value $g(\mathbf{r})$. The reader can easily convince himself that this formula is correct by noting that the first term satisfies the Poisson equation with the boundary value $u(\mathbf{r})|_\Gamma=0$, while the second is the solution of the Laplace equation with $u(\mathbf{r})|_\Gamma=g(\mathbf{r})$, as can be checked by the use of the Green's formula (4) with $u=u(\mathbf{r})$ and $v=G_1(\mathbf{r},\mathbf{r}')$.

Let $G_2(\mathbf{r},\mathbf{r}')$ be the Green's function satisfying the homogeneous Neumann-type condition, $(\partial/\partial n)G_2(\mathbf{r},\mathbf{r}')=0$ for $\mathbf{r}$ on Γ. If we employ G_2 in place of G_1 and replace $-\partial G_1/\partial n'$ by G_2, the expression given by Eq. (42) gives the solution of the Poisson equation subject to the inhomogeneous Neumann-type boundary condition, $(\partial/\partial n)u(\mathbf{r})|_\Gamma=g(\mathbf{r})$, in place of Eq. (41). The external problems are treated analogously.

3.2 Initial- and Boundary-Value Problem for the Heat Equation

The Green's formula (4) is generalized to an arbitrary second-order differential operator L—to that of the heat equation, $L=\partial/\partial t-\sigma^2\Delta$, for example. By using it, we can express the solution for, say, the following problem of the heat equation for $\mathbf{r}\in\Omega$ and $t>0$:

$$\left(\frac{\partial}{\partial t}-\sigma^2\Delta\right) u(\mathbf{r},t)=f(\mathbf{r},t), \tag{43}$$

with the initial temperature distribution specified by

$$u(\mathbf{r},0)=g(\mathbf{r}) \tag{44}$$

and the boundary condition of Dirichlet type given by

$$u(\mathbf{r},t)|_\Gamma=h(\mathbf{r},t). \tag{45}$$

Suppose we already happen to know the Green's function $H_1(\mathbf{r},t;\mathbf{r}',t')$ for the operator M $(=-\partial/\partial t-\sigma^2\Delta)$, the adjoint of the operator L:

$$\left(-\frac{\partial}{\partial t}-\sigma^2\Delta\right)H_1(\mathbf{r},t;\mathbf{r}',t')=\delta(\mathbf{r}-\mathbf{r}')\delta(t-t'), \tag{46}$$

which satisfies the homogeneous boundary condition

$$H_1(\mathbf{r},t;\mathbf{r}',t')|_{\mathbf{r}\text{ on }\Gamma}=0. \tag{47}$$

Then it is shown that the solution of the problem (43)–(45) is given by

$$u(\mathbf{r},t)=\int_0^t dt'\int_\Omega d^3r' H_1(\mathbf{r}',t';\mathbf{r},t)f(\mathbf{r}',t')$$
$$+\int_\Omega d^3r' H_1(\mathbf{r}',0;\mathbf{r},t)g(\mathbf{r}')$$
$$-\sigma^2\int_0^t dt'\int_\Gamma ds'\frac{\partial H_1(\mathbf{r}',t',\mathbf{r},t)}{\partial n'}$$
$$\times h(\mathbf{r}',t'). \qquad (48)$$

If we employ, in place of H_1, another Green's function H_2 satisfying the boundary condition $[\partial H_2(\mathbf{r},\mathbf{r}')/\partial n]|_\Gamma=0$ instead of Eq. (47), we obtain the solution of Eqs. (43) and (44) with, in place of Eq. (45), the Neumann-type inhomogeneous boundary condition, $(\partial/\partial n)\times u(\mathbf{r})|_\Gamma=h(\mathbf{r},t)$. We should note that, as in Sec. 3.1, $-\partial H_1/\partial n'$ in Eq. (48) must be replaced by H_2.

The present examples given for operators that are not self-adjoint will suffice to illustrate the practical value of Green's functions in a rather wide class of boundary-value problems. An important point is that the Green's function used in the input-output relation (2) is not defined by a δ-function inhomogeneous term for the operator L but by the one for its adjoint operator M. Also, note that the reciprocity relation of Green's functions is in general established between the Green's functions G and H for the operator L and its adjoint M. Namely, for the Green's function G and H for the operators L and M, respectively, it holds that

$$G_i(\mathbf{r},t;\mathbf{r}',t')=H_i(\mathbf{r}',t';\mathbf{r},t), \qquad (49)$$

$i=1$ and 2 corresponding to the Dirichlet and Neumann boundary conditions, respectively. If the operator L is self-adjoint, with the relation $L=M$, the Green's function H is automatically identical to G, leading to the well-known reciprocity relation:

$$G_i(\mathbf{r},t;\mathbf{r}',t')=G_i(\mathbf{r}',t';\mathbf{r},t). \qquad (50)$$

The operator L for the Laplace, wave, Klein-Gordon, or Schrödinger equation is self-adjoint but that for the heat equation is not (Courant and Hilbert, 1937).

4. BOUNDARY-ELEMENT METHOD

4.1 Practical Boundary-Value Problems

In actual situations, we often encounter a complex boundary Γ. If we insist on applying the formulas given in Sec. 3, we will be forced to solve additional boundary-value problems in order to find Green's functions G_1, H_1, etc., as the example in Sec. 2.4 shows. Therefore these formulas are not very helpful in such problems, and more direct methods, taking full advantage of numerical techniques, are more often employed in practice. The difference method and finite-element method are two such popular examples. The boundary-element method, developed and applied widely in recent years, also belongs to this class. In contrast to the former two, which have nothing to do with Green's functions, this method is related deeply to Green's formula and hence Green's functions. Conceptually, it is a revival of the old method of expressing the solution of the Laplace equation in the form of the potential caused by a monopole or dipole layer on the boundary Γ, the unknown density of which is determined by solving the Fredholm integral equation (Courant and Hilbert, 1937). The Green's functions involved are the fundamental solution (6) (in the case of the Laplace equation), instead of the complicated Green's functions G_1, etc. Let us briefly see the characteristic points of the boundary-element method (BEM) through the following examples (Brebbia and Walker, 1980).

4.2 Poisson's Equation as Treated by the Boundary-Element Method

We return to the Poisson equation treated in Sec. 3.1. If the fundamental solution of the Laplace equation [Eq. (6)] is substituted for $v(\mathbf{r})$ in Green's formula (4), we can express the solution for the Poisson equation by using the boundary values of both $u(\mathbf{r})$ and $\partial u(\mathbf{r})/\partial n$

on Γ. The result is the extension of Eq. (7) to the Poisson equation. For $\mathbf{r}\in\Omega$, we find

$$u(\mathbf{r}) = \int_\Omega G(\mathbf{r},\mathbf{r}')f(\mathbf{r}')d^3\mathbf{r}' + \int_\Gamma \left(G(\mathbf{r},\mathbf{r}')\frac{\partial u(\mathbf{r}')}{\partial n'} - \frac{\partial G(\mathbf{r},\mathbf{r}')}{\partial n'}u(\mathbf{r}') \right) ds' \qquad (51)$$

with $G(\mathbf{r},\mathbf{r}') = 1/4\pi|\mathbf{r}-\mathbf{r}'|$. Since we know the value of $u(\mathbf{r})$ on Γ through the Dirichlet condition (41), $u(\mathbf{r})=g(\mathbf{r})$, this formula provides us with the solution of the original problem, if we somehow find the value of $\partial u(\mathbf{r})/\partial n$ on Γ on the right-hand side. The procedure characterizing the BEM is that the unknown quantity $\partial u/\partial n$ is determined from Eq. (51) by letting **r** tend to a point on Γ and setting $u(\mathbf{r})=g(\mathbf{r})$. The result is a Fredholm integral equation of the first kind for the unknown function $\partial u(\mathbf{r})/\partial n$ on Γ:

$$\tfrac{1}{2}g(\mathbf{r}) - \int_\Omega G(\mathbf{r},\mathbf{r}')f(\mathbf{r}')d^3\mathbf{r}' + \int_\Gamma \frac{\partial G(\mathbf{r},\mathbf{r}')}{\partial n'}g(\mathbf{r}')ds' = \int_\Gamma G(\mathbf{r},\mathbf{r}')\frac{\partial u(\mathbf{r}')}{\partial n'}ds'. \qquad (52)$$

Here the factor $\frac{1}{2}$ takes account of the discontinuous nature of $\partial G/\partial n$ in letting **r** tend to the boundary. What Eq. (52) shows is that we need to make a numerical calculation of the unknown quantity $[\partial u(\mathbf{r})/\partial n]|_\Gamma$. This can be carried out readily by discretizing the integral on Γ using the well-established algorithm of the finite-element method. Following similar steps, the internal Neumann problem and the external problems are eventually reduced to an integral equation on the boundary Γ as in this example.

4.3 Applications of the Boundary-Element Method

4.3.1 Fluid Mechanics. In fluid mechanics, this method has been known as the surface-singularity method. For an incompressible and irrotational fluid, it is well known that the velocity potential satisfies the Laplace equation. Hence Eq. (52), with the inhomogeneous term $f(\mathbf{r})$ dropped, is the key equation in analyzing various boundary problems for perfect fluids. In practical problems, such as the analyses for the air flow around an aircraft or a space shuttle flying with relatively low velocity, a distribution of vortices must often be taken into account. In such cases the final integral equation like Eq. (52) needs to be modified, but the BEM is still quite powerful. See for details the report by Morino *et al.* (1975).

4.3.2 Sound and Electromagnetic Waves. If the retarded Green's function G_R for the Helmholtz equation [Eq. (15)] is used in place of *G*, Eq. (52) turns out to be the key equation for the wave equation [here $f(\mathbf{r})$ therein is an inhomogeneous term of the wave equation]. Then if we let $u(\mathbf{r})$ stand for the velocity potential associated with a sound wave, the boundary values for $u(\mathbf{r})$ and $\partial u(\mathbf{r})/\partial n$ will be related, respectively, to the pressure and the velocity on Γ. For a region bounded by a rigid wall, it holds that $[\partial u(\mathbf{r})/\partial n]|_\Gamma=0$. When $f(\mathbf{r})=0$, Eq. (52) becomes a homogeneous integral equation for $g(\mathbf{r})$, yielding the eigenfrequencies for the sound modes established in that region, which can be, in an actual problem, an auditorium or a complicated resonator such as that of a violin. By converting the integral equation to the linear coupled equations, we can find the eigenvalues ω [involved in the Green's function through $\kappa=\omega/c$ in Eq. (15)].

An external problem may be formulated similarly to deal with sound propagation from a source with a complicated shape. Needless to say, the BEM for the wave equation is not limited to acoustics.

4.3.3 Elasticity. The final example we give on the application of the BEM is the problem of determining the strain tensor of an elastic body caused by a body force $\mathbf{f}(\mathbf{r})$ and a surface force $\mathbf{p}(\mathbf{r})$, both applied externally. Since the basic equation of elasticity is rather complicated, an analytical treatment is possible only for the exceptional case of very simple $\mathbf{f}(\mathbf{r})$ and $\mathbf{p}(\mathbf{r})$, applied to an elastic body whose shape, too, is very simple. In the BEM, these restrictions may be largely relaxed. First we need the Green's function for an infinite elastic body. For an isotropic and homogeneous system the tensor of the Green's functions satisfies (Landau and Lifshitz, 1986)

$$\Delta G_{ij}(\mathbf{r},\mathbf{r}')+\frac{1}{1-2\sigma}\sum_k\frac{\partial}{\partial x_i}\frac{\partial}{\partial x_k}G_{kj}(\mathbf{r},\mathbf{r}')$$
$$=-\frac{2(1+\sigma)}{E}\delta_{ij}\delta(\mathbf{r}-\mathbf{r}') \qquad (53)$$

with Young's modulus E, Poisson's ratio σ, and Kronecker's delta δ_{ij}. Here G_{ij} is the ith component of the deformation field at $\mathbf{r}$ induced by the j-directed point force at $\mathbf{r}'$ with unit strength. The solution to Eq. (53) is known as Kelvin's solution, which reads

$$G_{ij}(\mathbf{r},\mathbf{r}')=\frac{1+\sigma}{8\pi E(1-\sigma)}[(3-4\sigma)\delta_{ij}+n_in_j]$$
$$\times\frac{1}{|\mathbf{r}-\mathbf{r}'|}, \qquad (54)$$

where $\mathbf{n}=(\mathbf{r}-\mathbf{r}')/|\mathbf{r}-\mathbf{r}'|$. In terms of G_{ij} one may obtain the basic integral equation on the external surface Γ, involving the body force $\mathbf{f}(\mathbf{r})$, an analog of Eq. (52) for the strain tensor $u_{ij}(\mathbf{r})$ (Brebbia and Walker, 1980). The boundary value for $\Sigma_j\partial u_{ij}/\partial x_j$ on Γ may be related to the given surface force $\mathbf{p}(\mathbf{r})$.

5. GREEN'S FUNCTIONS HAVING A DIRECT RELEVANCE TO PHYSICAL REALITY

The Green's functions treated in Secs. 3 and 4 were used mainly as a tool for solving a partial differential equation. The reader will recall that by definition they describe an output signal in response to a point input signal. This suggests that they are also usually related to a physical reality. That this is indeed so will be seen through the examples presented below.

5.1 Wave Front of Radiation Emitted from a Point Source and Huygens's Principle

The retarded Green's function given by Eq. (22) for the wave equation shows where the wave front of the radiation is found at time t, when it is emitted at a former time t' from the point source located at $\mathbf{r}'$. If we consider conversely a point of observation fixed at $\mathbf{r}$ and point sources distributed around that point, we can regard the radiation observed there at time t as a composition of the propagating wavelets that leave at $t=0$ the various point sources, whose distance from point $\mathbf{r}$ is ct (Fig. 2). In fact, this situation is well expressed by the solution of the following initial-value problem for the wave equation in three-dimensional space;

$$\left(\frac{1}{c^2}\frac{\partial^2}{\partial t^2}-\Delta\right)u(\mathbf{r},t)=h(\mathbf{r},t) \qquad (55)$$

with the initial conditions

$$u(\mathbf{r},0)=f(\mathbf{r}),\quad u_t(\mathbf{r},0)=g(\mathbf{r}). \qquad (56)$$

The solution is given by Kirchhoff's formula (Baker and Copson, 1950; Morse and Feshbach, 1953)

$$u(\mathbf{r},t)=\int_{|\mathbf{r}-\mathbf{r}'|<ct}d^3r'\,\frac{h(\mathbf{r}',t-|\mathbf{r}-\mathbf{r}'|/c)}{4\pi|\mathbf{r}-\mathbf{r}'|}$$
$$+\frac{\partial}{\partial t}[tf(\mathbf{r})^{ct}]+tg(\mathbf{r})^{ct}. \qquad (57)$$

Here the first term takes into account the inhomogeneous term of Eq. (55) in the form of a retarded potential. The quantities f^{ct} and g^{ct} are the averages of their values on the surface of the sphere centered at $\mathbf{r}$ with radius ct: for example,

$$f(\mathbf{r})^{ct}=\int d\Omega\, f(\mathbf{r}+ct\hat{\mathbf{r}}_0)/4\pi, \qquad (58)$$

the integral being over the solid angle in the direction $\hat{\mathbf{r}}_0$ from the point $\mathbf{r}$. Equation (57) demonstrates in mathematical form the well-

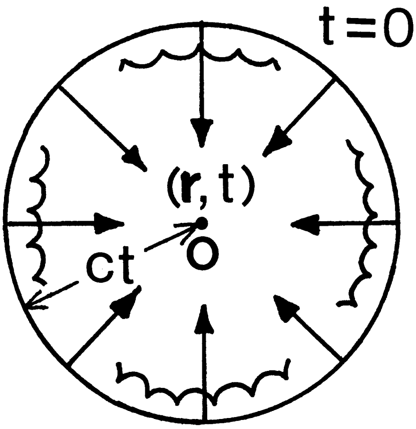

FIG. 2. Huygens's principle for wave propagation. The wave observed at the observation point $O(\mathbf{r},t)$ is the sum of the wavelets leaving, at $t=0$, the sources distributed on the sphere with radius ct, c being the velocity of the wave.

known Huygens's principle. Although the detailed derivation is omitted, the important role of the Green's function in this principle will be understood if the constraint imposed by Green's functions in Eq. (22) is compared with those involved in the integrals in Eqs. (57) and (58). The name "propagators" given very often to the Green's functions of the wave equation or its generalizations stems from the concepts involved in Huygens's principle.

5.2 Retarded Green's Function of Schrödinger's Equation

The inverse Fourier transform of the retarded version of the Green's function given by Eq. (38) is

$$G_R(\mathbf{r},t;\mathbf{r}',t')=\begin{cases}\Sigma_n\psi_n(\mathbf{r})\psi_n^*(\mathbf{r}')\exp[-(i/\hbar)E_n(t-t')], & t>t',\\ 0, & t<t'.\end{cases} \tag{59}$$

This quantity provides the probability amplitude for a particle observed at $(\mathbf{r}',t')$ to be found at $(\mathbf{r},t)$. To see this, we note that Eq. (59) is the solution of the Schrödinger equation

$$i\hbar\frac{\partial}{\partial t}\Psi(\mathbf{r},t)=H(\mathbf{r})\Psi(\mathbf{r},t), \tag{60}$$

subject to the condition that at time t'

$$\Psi(\mathbf{r},t')=\delta(\mathbf{r}-\mathbf{r}'). \tag{61}$$

This interpretation applies to an arbitrary Hamiltonian and is not restricted to that of an electron in a hydrogen atom, which we had in mind in Sec. 2.5. The above argument, when taken together with the brief explanation to be given in Sec. 7.5 on the path-integral approach to quantum mechanics, shows that the Green's function of the Schrödinger equation bridges the gap between quantum mechanics and classical dynamics (Sakurai, 1985). Also, in the perturbational treatment, we can follow an actual process of electron scattering in $(\mathbf{r},t)$ space, by making use of the Green's function (see Secs. 6.2 and 6.3).

5.3 Dislocations

A dislocation is a line of singularities in the deformation field of an elastic body. Equation (53) thus describes a dislocation if the strength and distribution of the δ functions of the right-hand side are specified appropriately. For example, around a straight edge dislocation on the z axis with a y-directed Burgers vector $\mathbf{b}$ ($|\mathbf{b}|=b$), the elastic deformation $\mathbf{u}(\boldsymbol{\rho})$ as a function of the two-dimensional coordinate $\boldsymbol{\rho}=(x,y)$ is given by (Landau and Lifshitz, 1986)

$$\mathbf{u}(\boldsymbol{\rho})=\mathbf{u}_0(\boldsymbol{\rho})+\mathbf{w}(\boldsymbol{\rho}). \tag{62}$$

Here the vector $\mathbf{u}_0(\boldsymbol{\rho})=(u_{0x}(\boldsymbol{\rho}),u_{0y}(\boldsymbol{\rho}),u_{0z}(\boldsymbol{\rho}))$ takes account of the multivaluedness of the deformation field and is defined by $u_{0z}(\boldsymbol{\rho})=0$ and

$$u_{0x}(\boldsymbol{\rho})+iu_{0y}(\boldsymbol{\rho})=i(b/2\pi)\ln(x-iy). \tag{63}$$

It is essentially a fundamental solution of the two-dimensional Laplace equation. On the other hand, the vector $\mathbf{w}(\boldsymbol{\rho})$ in Eq. (62) is obtained as

$$w_i(\boldsymbol{\rho})=\frac{Eb}{(1+\sigma)}\int_{-\infty}^{\infty}G_{iy}(\mathbf{r},\mathbf{r}')dz', \tag{64}$$

with $\mathbf{r}=(\boldsymbol{\rho},0)$, $\mathbf{r}'=(0,0,z')$, and G_{ij}, Kelvin's solution, given by Eq. (54). The integral over z' takes account of the line of δ-function singularities on the z axis. From Eqs. (63) and (64), one can determine the strain and stress fields around a straight edge dislocation.

5.4 Magnetic Field around a Vortex Line in a Type-II Superconductor

It is well known, as the Meissner effect, that a magnetic field applied externally cannot penetrate into a superconductor. In a type-II superconductor, however, superconducting and nonsuperconducting regions coexist in a phase called the mixed phase, which is realized above a certain threshold strength for the magnetic field: As the field strength increases to pass the threshold, the magnetic flux begins to penetrate the sample in the form of a quantized flux line, called a vortex. Well below the upper critical field, above which the superconducting phase can no longer exist, the density of such vortices is so low that one may treat each of them as independent. It is shown that around an isolated rectilinear vortex, the microscopic magnetic field configuration is determined by (in cgs units following the convection of this field)

$$(\Delta-\lambda^{-2})\mathbf{h}(\mathbf{r}) = -\phi_0\lambda^{-2}\hat{\mathbf{z}}\delta(\boldsymbol{\rho}), \qquad (65)$$

$\phi_0=hc/2e$ being the flux quantum and λ the penetration depth (Fetter and Hohenberg, 1969). Here $\hat{\mathbf{z}}$ is the unit vector in the z direction and the vortex line is assumed to be situated on the z axis $\boldsymbol{\rho}=0$, $\boldsymbol{\rho}=(x,y)$ being the two-dimensional position vector. The field $\mathbf{h}(\mathbf{r})$ is thus expressed by the Green's function of the two-dimensional Helmholtz equation [note, however, that κ^2 in Eq. (13) is replaced by $-\lambda^{-2}$]:

$$\mathbf{h}(\mathbf{r}) = (\phi_0\lambda^{-2}/2\pi)\hat{\mathbf{z}}K_0(\rho/\lambda), \qquad (66)$$

with K_0 the modified Hankel function of order zero. If the right-hand side of Eq. (65) is replaced by a two-dimensional periodic distribution of δ functions, one may determine the magnetic field set up in a vortex lattice and calculate the gain in the free-energy density. The discussion of the equilibrium lattice structure that minimizes the free-energy density provides us with a basis for the more complete analysis due to Abrikosov *et al.*, based on the Ginzburg-Landau equations. See for details Fetter and Hohenberg (1969).

6. PERTURBATIONAL TREATMENT TO OBTAIN GREEN'S FUNCTIONS

When an operator can be divided into two parts and the Green's function for one of the two is obtained straightforwardly, one may treat the remaining part perturbatively to obtain the full Green's function. For illustration, let us consider the stationary solution of the Schrödinger equation for the Hamiltonian of the following form:

$$H=H_0+V. \qquad (67)$$

It is very convenient to define the Green's function using the operator $(E-H)^{-1}$, which is sometimes called the Greenian, and to examine it as a function of the energy variable E. One may show that the quantity $\langle\mathbf{r}|(E-H)^{-1}|\mathbf{r}'\rangle$, the $(\mathbf{r},\mathbf{r}')$ matrix element of the Greenian, behaves as a Green's function, and one may reasonably denote it simply as $G(\mathbf{r},\mathbf{r}';E)$ (see, e.g., Schiff, 1968). [The present definition leads to the Green's function $(i\hbar)^{-1}$ times that defined in Eq. (38)]. Rewriting the operator $(E-H)^{-1}$ as a power series with respect to the perturbation V, we obtain the following integral equation for G:

$$G(\mathbf{r},\mathbf{r}';E)=G_0(\mathbf{r},\mathbf{r}';E)+\int d^3r_1 G_0(\mathbf{r},\mathbf{r}_1;E) \times V(\mathbf{r}_1)G(\mathbf{r}_1,\mathbf{r}';E), \qquad (68)$$

$G_0(\mathbf{r},\mathbf{r}';E)$ being the unperturbed Green's function $\langle\mathbf{r}|(E-H_0)^{-1}|\mathbf{r}'\rangle$. The expression is given for a local operator V, i.e., $\langle\mathbf{r}|V|\mathbf{r}'\rangle=V(\mathbf{r})\delta(\mathbf{r}-\mathbf{r}')$. Iterating the right-hand side, we find

$$G=G_0+G_0VG_0+G_0VG_0VG_0+\cdots=G_0+G_0TG_0. \qquad (69)$$

Here the simplified notation of G_0VG_0, etc., should be interpreted as in the second term of Eq. (68) by supplementing the arguments and integrals. The series in the first equality, the Born series, defines the operator T, which is usually called the t matrix by identifying its $(\mathbf{r},\mathbf{r}')$ matrix element $T(\mathbf{r},\mathbf{r}';E)$ with the operator itself. It is an effective scattering potential, taking into account the multiple scattering effect to all orders of V through the relation

$$\begin{aligned} T&=V+VG_0V+VG_0VG_0V+\cdots \\ &=V+VGV. \end{aligned} \qquad (70)$$

Note that the Green's function in the second equality is G, not G_0, which already takes full account of the effect of V.

6.1 Slater-Koster Model

As shown by Eqs. (38) and (39), the eigenvalues for a Hamiltonian operator H are given by the poles of the Green's function $\langle\mathbf{r}|(E-H)^{-1}|\mathbf{r}'\rangle$. The Slater-Koster model is a typical model in which the series (69) is exactly calculable. Usually, it is defined by the model Hamiltonian which has a δ-function-type (contact-type) perturbation, $V(\mathbf{r})=v_0\delta(\mathbf{r})$, v_0 being a constant for the potential strength. In this case, Eq. (69) leads to

$$G(\mathbf{r},\mathbf{r}';E)=G_0(\mathbf{r},\mathbf{r}';E)+G_0(\mathbf{r},0;E)\{v_0/[1-v_0G_0(0,0;E)]\}G_0(0,\mathbf{r}';E). \qquad (71)$$

Thus, the zeros of the denominator of the second term as a function of E provide the eigenvalues for the full Hamiltonian:

$$1-v_0G_0(0,0;E)=0. \tag{72}$$

Considering that G_0 has poles at the unperturbed energy eigenvalues [the eigenvalues of the Hamiltonian H_0 in Eq. (67)], we see that this equation has a form quite adequate to see how these eigenvalues are modified by the perturbation. Using Eq. (72), one can discuss, for example, how a plane-wave state $\mathbf{k}$ is affected by the potential $V(\mathbf{r})$ and whether or not a bound state appears for an attractive potential $V(\mathbf{r})$ for a given unperturbed energy spectrum. In condensed-matter physics these problems are very frequently encountered in dealing with electrons, phonons, magnons, etc. For a detailed analysis, see, e.g., the book by Economou (1990).

The treatment for a photon along this line is just the perturbational treatment of the Maxwell equations. For example, the reflection and transmission of light for a rough solid surface was analyzed successfully by this approach (see, e.g., Maradudin *et al.*, 1990).

6.2 Scattering Cross Section of a Plane Wave from a Scatterer with Spherical Symmetry

In the scattering of an incident wave ψ_0 of, say, an electron with energy E by a perturbing potential $V(\mathbf{r})$, the total wave function for the Schrödinger equation $H\psi=E\psi$ with H given by Eq. (67) may be expressed as (Schiff, 1968)

$$\begin{aligned}\psi(\mathbf{r})&=\psi_0(\mathbf{r})+\int d^3r'G_0(\mathbf{r},\mathbf{r}';E)\,V(\mathbf{r}')\psi(\mathbf{r}')\\&=\psi_0(\mathbf{r})+\iint d^3r_1d^3r_2G_0(\mathbf{r},\mathbf{r}_1;E)\\&\qquad\times T(\mathbf{r}_1,\mathbf{r}_2;E)\psi_0(\mathbf{r}_2).\end{aligned} \tag{73}$$

The second equality is obtained by iterating the first equality and using the definition (70) for the t matrix T. For a spherically symmetric potential $V(\mathbf{r})=V(r)$, we may go further by resolving $\psi(\mathbf{r})$ and $\psi_0(\mathbf{r})$ into partial waves according to the magnitudes of angular momentum $\hbar l$. The partial-wave expansion of the incident plane wave with wave vector $\mathbf{k}_i$ is

$$\psi_0(\mathbf{r})=e^{i\mathbf{k}_i\cdot\mathbf{r}}=\sum_{l=0}^{\infty}(2l+1)i^lj_l(k_ir)P_l(\cos\theta), \tag{74}$$

where $j_l(k_ir)$ is the spherical Bessel function of order l, the scattering angle θ is the angle between $\mathbf{k}_i$ and $\mathbf{r}$, and $P_l(\cos\theta)$ is the Legendre function of order l. Asymptotically, the solution ψ in Eq. (73) behaves as

$$\psi(\mathbf{r})=\psi_0(\mathbf{r})+f(\theta)e^{ik_sr}/r, \tag{75}$$

with k_s the wave number of the scattered spherical wave. Comparing Eqs. (73) and (75) and using the form given by Eq. (15), we find that the amplitude of the outgoing spherical wave is given by

$$f(\theta)=-(m/2\pi\hbar^2)T(\mathbf{k}_s,\mathbf{k}_i;E), \tag{76}$$

where

$$\begin{aligned}T(\mathbf{k}_s,\mathbf{k}_i;E)=\iint& e^{-i\mathbf{k}_s\cdot\mathbf{r}}T(\mathbf{r},\mathbf{r}';E)\\&\times e^{i\mathbf{k}_i\cdot\mathbf{r}'}d^3r\,d^3r',\end{aligned} \tag{77}$$

with $\mathbf{k}_s$ the wave vector of the scattered wave, directed from the origin to the observation point $\mathbf{r}$ ($k_s=k_i$ by energy conservation). The t matrix $T(\mathbf{k}_s,\mathbf{k}_i;E)$ for the two wave vectors, both related to the incident energy E through the relation $k_i=k_s=(2mE/\hbar^2)^{1/2}$, is called the t matrix on the energy shell and is known to be expressed in terms of the phase shift $\delta_l(E)$ of the partial wave l. In this way, $f(\theta)$ is finally expressed as

$$f(\theta)=\frac{1}{2ik_i}\sum_{l=0}^{\infty}(2l+1)(e^{2i\delta_l}-1)P_l(\cos\theta). \tag{78}$$

The differential and total cross sections are then obtained from $|f(\theta)|^2$.

To carry out the partial-wave expansion for the Maxwell equations, we need the tensor of the Green's functions (Mahan, 1990) and the vector spherical wave for each l (Stratton, 1941). With the difference that we now require two kinds of phase shifts for each l because of the character of light as a transverse vector field, the Mie and Rayleigh scatterings of light (Born and Wolf, 1975) may be treated compactly as in the electron case.

6.3 Band Structure of Electrons and Photons and Diffraction Experiments

The band structure of electron states in solids may be viewed as arising from the electron scattering by atoms arrayed periodically in a lattice. With the difference that the perturbation V is now due to a periodic array of scatterers, Eqs. (67)–(70) still hold here without modification. Since the poles of the full Green's function are identical to those of the t matrix [Eq. (69)], the calculation of the t matrix for arrayed scatterers is equivalent to the band-structure calculation. If we denote the multiple-scattering effect of the kth scatterer by the t matrix t_k, the scattering from the array as a whole is described by the following t matrix:

$$T = \sum_{k} t_k + \sum_{\substack{k,k' \\ (k \neq k')}} t_k G_0 t_{k'} + \cdots , \qquad (79)$$

where G_0 is the Green's function for free motion. The first term describes the scattering from a single site. The second exhibits the process where an electron, once scattered by the kth scatterer, propagates to another site k' and undergoes a multiple scattering there. The constraint $k \neq k'$ eliminates double counting, because the term $t_k G_0 t_k$ to be removed is already involved in the single t matrix t_k [see the series expansion of the first equality of Eq. (70)]. The higher-order terms in Eq. (79) incorporate processes involving three or more scatterers. These scattering processes are exhibited in Fig. 3. If the potentials are spherical and nonoverlapping with each other, as is usually the case to a good approximation, only the on-the-energy-shell values are involved in each t_k (see Sec. 6.2). Since G_0 sandwiched between t_k and $t_{k'}$ in Eq. (79) describes the free propagation of an electron from one atom k to another k', it depends solely upon the structure of the lattice. Therefore Eq. (79) shows that the band structure of electron energies in solids is determined quite generally by two quantities: the phase shifts of the atoms and the structure factor of the periodic array they form. This is indeed explicit in the Korringa-Kohn-Rostoker (KKR) eigenvalue equation for the band structure of electrons. See the monograph by Lukes (1969) for the derivation of the KKR equation based on Eq. (79).

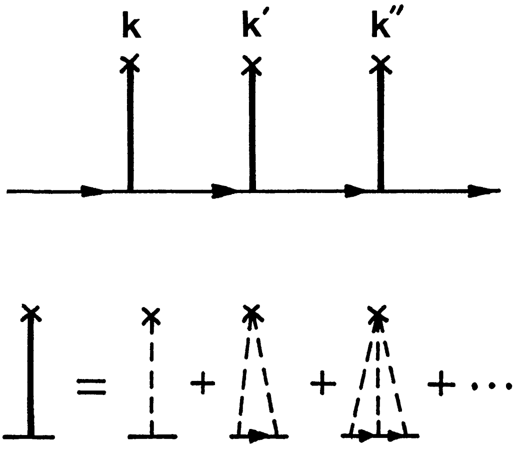

FIG. 3. Scattering of an electron in a solid. The vertical solid line at site k is the t matrix t_k used in Eq. (79) and the arrowed horizontal lines show G_0. The t matrix t_k is defined by the lower graph, which shows the series given by Eq. (70) with the dotted lines for the atomic potential V.

When we apply Eq. (73) to a periodic array of scatterers, the solution $\psi(\mathbf{r})$ describes how the atomic array responds to an incident electron. When, in particular, an incident electron from the outside has an energy that is not very different from the positions of the poles of the t matrix, the amplitude of the scattered wave reflects, through $T(\mathbf{r}_1,\mathbf{r}_2;E)$ of Eq. (73), the detailed band structure as a function of incident energy E and wave vector. This is essentially the origin of the fine structure observed in the usual low-energy-electron diffraction (Tong, 1975).

Similar fine structure is expected to arise in the diffraction of visible light, i.e., in the light scattered from a periodic array of scatterers with periodicity in the visible range. X-ray diffraction is simply its high-energy limit. For details of the diffraction of visible light reflecting the photon band structure, see Ohtaka (1980) and Inoue and Ohtaka (1982) and the analysis by Yablonovitch and Gmitter (1989).

7. GREEN'S FUNCTIONS IN MANY-BODY THEORIES

The developments of condensed-matter physics and elementary-particle physics owe considerably to the use of Green's functions in the treatment of many-body interactions. How they are defined and why they have been so widely used will be shown through several examples. For more details, see the books by, e.g., Abrikosov *et al.* (1963), Fetter and Walecka (1971), Economou (1990), and Mahan (1990). For illustration we have in mind a model Hamiltonian for interacting spinless particles, either bosons or fermions:

$$K=\int d^3r\,\Psi^\dagger(\mathbf{r})[(-\hbar^2/2m)\Delta-\mu]\Psi(\mathbf{r})$$
$$+\frac{1}{2}\int\int d^3r\,d^3r'\Psi^\dagger(\mathbf{r})\Psi^\dagger(\mathbf{r}')$$
$$\times v(|\mathbf{r}-\mathbf{r}'|)\Psi(\mathbf{r}')\Psi(\mathbf{r})$$
$$=K_0+K' \tag{80}$$

expressed in the second quantized form. Here $\Psi^\dagger(\mathbf{r})$ and $\Psi(\mathbf{r})$ are the field operators for creating and annihilating, respectively, a particle at position $\mathbf{r}$. The term proportional to the chemical potential μ in the first term on the right-hand side shows that we are considering the grand canonical ensemble. The two-body correlation described by the operator K' may be treated using Green's functions.

7.1 Single- and Two-Particle Green's Functions

The single-particle Green's function is defined in many-body theories by

$$G(x,x')=-\frac{i\langle\Phi_0|T(\Psi(x)\Psi^\dagger(x'))|\Phi_0\rangle}{\langle\Phi_0|\Phi_0\rangle}. \tag{81}$$

Here x and x' denote $(\mathbf{r},t)$ and $(\mathbf{r}',t')$, respectively, Φ_0 is the exact ground state for the Hamiltonian given by Eq. (80), and the time-dependent operators $\Psi(x)$ etc. are the operators in the Heisenberg picture defined by

$$\Psi(x)=e^{iKt/\hbar}\Psi(\mathbf{r})e^{-iKt/\hbar}. \tag{82}$$

The symbol T in Eq. (81) is the time-ordering operator that is defined by the rule

$$T(\Psi(x)\Psi^\dagger(x'))=\begin{cases}\Psi(x)\Psi^\dagger(x'), & t>t',\\ \pm\Psi^\dagger(x')\Psi(x), & t<t',\end{cases} \tag{83}$$

the upper (lower) sign referring to bosons (fermions). Aside from the presence of the time-ordering operator T, the Green's function defined by Eq. (81) can be given the physical interpretation of a probability amplitude, analogous to that given by Eq. (59). Indeed, when the particle interaction vanishes, i.e., $K=K_0$ in Eq. (80), G tends to the unperturbed Green's function

$$G_0(x,x')=-i\langle 0|T(\Psi(x)\Psi^\dagger(x'))|0\rangle, \tag{84}$$

$|0\rangle$ being the normalized ground state for K_0. It satisfies

$$\left(i\hbar\frac{\partial}{\partial t}+\frac{\hbar^2}{2m}\Delta+\mu\right)G_0(x,x')=\hbar\delta(x-x'). \tag{85}$$

The inhomogeneous term comes from the presence of the operator T, the origin of the step function via Eq.(83), and the commutation (anticommutation) relation of the field operators for bosons (fermions). Through Eq. (85), we see obviously that iG_0 is the many-body analog of the single-particle Green's function treated in Sec. 5.2.

The first reason why the single-particle Green's function is so useful is that many important observables such as the ground-state energy, number or current density, etc. of the many-body system, are expressed in terms of the Green's function (81). The second reason is that the effect of K' may be handled by applying Wick's theorem and interpreted visually with the help of Feynman diagrams (see Sec. 7.2). Third, part of the interaction process is taken into account to all orders with respect to K'.

For example, the modification of a single-particle energy due to the mutual interaction K' is taken into account by Dyson's equation

$$G(\mathbf{k},\omega)=G_0(\mathbf{k},\omega)+G_0(\mathbf{k},\omega)\Sigma(\mathbf{k},\omega)G(\mathbf{k},\omega) \tag{86}$$

in the Fourier space $(\mathbf{k},\omega)$. From this, we find

$$G(\mathbf{k},\omega)=[\omega-(\hbar k^2/2m)+(\mu/\hbar)-\Sigma(\mathbf{k},\omega)]^{-1}, \tag{87}$$

where we have used

$$G_0(k,\omega)=[\omega-(\hbar k^2/2m)+(\mu/\hbar)+i\epsilon\,\mathrm{sgn}(\omega)]^{-1} \tag{88}$$

given by Eq. (85). Note that G_0 has a causal form (see Sec. 2.2). The complex quantity $\Sigma(\mathbf{k},\omega)$ is called the self-energy part. The form (87) provides an exact expression for G, if the self-energy part is exactly given. In this sense, Dyson's equation (86) is one of the key equations in treating many-body interactions. The imaginary part of $\Sigma(\mathbf{k},\omega)$ determines the lifetime of a plane-wave state $\mathbf{k}$, caused by the many-body interaction. Although it is generally a hopeless task to attempt to make an exact calculation of $\Sigma(\mathbf{k},\omega)$ with all possible many-body processes included, an important subset may usually be taken into account. For a system of electrons interacting with Coulomb repulsion (the electron-gas model), for example, we may now say that some of the physical quantities have so far been obtained almost exactly.

The two-particle Green's function is defined by

$$G(x_1,x_2;x_1',x_2') = (-i)^2\langle\Phi_0|T(\Psi(x_1)\Psi(x_2) \times\Psi^\dagger(x_2')\Psi^\dagger(x_1'))|\Phi_0\rangle/\langle\Phi_0|\Phi_0\rangle. \quad (89)$$

It is so called because it deals with the two particles created at x_1' and x_2'. Since a correlation function between two physical quantities is usually expressed by the two-particle Green's function, the latter is an important quantity, yielding transport coefficients, conductivity, and dielectric constant, for example (see Sec. 7.4). As mentioned before, Wick's theorem is a key theorem for calculating the Green's function. The names "random-phase approximation," "ladder approximation," etc., are each assigned to a special choice of infinite series of Feynman diagrams considered in two-particle Green's functions. We give in Fig. 4 two typical examples, which exhibit how the two particles interact with each other, sometimes involving other particles.

7.2 Wick's Theorem and Feynman Diagrams

The Green's functions (81) and (89) are defined in terms of the operators in the Heisenberg picture for the full Hamiltonian K. In calculating them perturbationally, using the relationships between Φ_0 and $|0\rangle$ and between the operators in the Heisenberg and interaction representations, we encounter the following types of quantities:

$$\langle 0|T(\Psi_0(x_1)\Psi_0(x_2)\Psi_0(x_3)\cdots\Psi_0^\dagger(x_{2n-1}) \times\Psi_0^\dagger(x_{2n}))|0\rangle, \quad (90)$$

where $\Psi_0(x)$ etc., are the operators in the interaction picture defined by

$$\Psi_0(x) = e^{iK_0t/\hbar}\Psi(\mathbf{r})e^{-iK_0t/\hbar}. \quad (91)$$

Quantities such as (90) are the expectation values in the state $|0\rangle$ of the time-ordered product of an equal number of operators $\Psi_0(x)$ and $\Psi_0^\dagger(x)$. Wick's theorem handles just such quantities and guarantees that the quantity given above may be resolved into a sum of products of n unperturbed Green's functions G_0's, formed by pairing a Ψ_0 with a $\Psi_0^\dagger$ in all possible ways. For a rigorous proof, see, e.g., Fetter and Walecka (1971). In this way the perturbation series for a Green's function, either a single-particle one or a two- or many-particle one, is expressed as a sum of products of a number of G_0's, and each product is given a graphical representation called Feynman diagram (Feynman graph), where a line represents an unperturbed propagator G_0. Some examples were already given for the two-particle Green's functions in Fig. 4. For K given by Eq. (80), several second- and higher-order corrections for the single-particle Green's function are shown in Fig. 5.

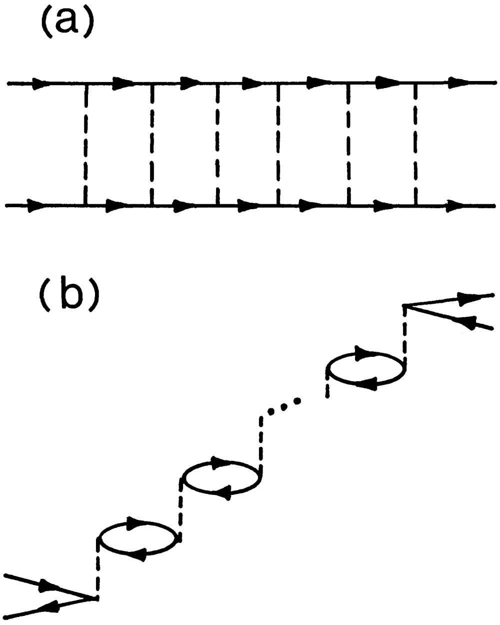

FIG. 4. Two-particle Green's function taking into account the particle interaction: (a) ladder diagram, (b) random-phase approximation. The dotted lines show the particle interaction, v of Eq. (80), and the arrowed solid lines show the unperturbed Green's function G_0, defined by Eq. (84). When v is an attractive short-range interaction for an narrow energy range, the ladder diagram for a singlet pair of electrons leads to superconductivity. When v is a repulsive Coulomb potential, the random-phase approximation leads, in the low-density limit, to the exact ground-state energy of interacting electrons.

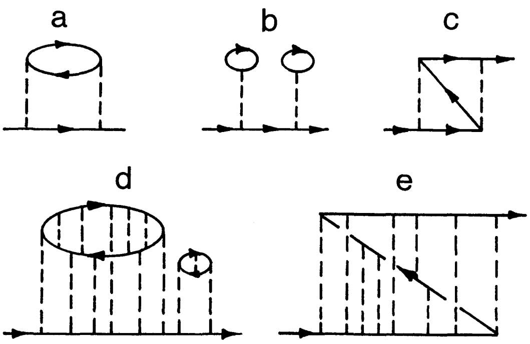

FIG. 5. Examples of Feynman diagrams. The graphs *a* through *c* show examples of second-order corrections to the single-particle Green's functions for the Hamiltonian given by Eq. (80). The vertical dotted lines show the particle interaction *v*. The graphs *d* and *e* are two higher-order corrections.

7.3 Temperature Green's Functions

The temperature Green's functions are essentially the Green's functions treated in Sec. 7.1 with the time argument t and t' replaced by the imaginary time $-i\tau$ and $-i\tau'$, respectively, and with the expectation value $\langle\Phi_0|\cdots|\Phi_0\rangle$ for the ground state replaced by the thermal average $\langle\cdots\rangle$. The temperature Green's function also goes under the name of Matsubara, who first introduced them (Kubo *et al.*, 1991). They are convenient tools for calculating various physical quantities in thermal equilibrium—for instance, the single-particle energy and thermodynamic potential. Wick's theorem holds here again. Because of the periodic properties with respect to the argument $\tau-\tau'$, the Fourier components of the Green's function $G(\tau-\tau')$ are defined at the discrete frequencies $\omega_n=(2n+1)\pi k_BT/\hbar$ for fermions and $\omega_n=2n\pi k_BT/\hbar$ for bosons, n being an integer, T the temperature, and k_B the Boltzmann constant. For those frequencies, the Dyson equation (86) holds and is solved algebraically. The single-particle energy is obtained by analytically continuing $G(\omega_n)$ from the discrete points $i\omega_n$ on the imaginary axis to the complex ω plane. For the BCS Hamiltonian of superconductivity, for example, all the predictions of the BCS theory (Bardeen *et al.*, 1957) have been reproduced straightforwardly in this way and the Ginzburg-Landau equations, originally introduced semiphenomenologically, have been given an unambiguous microscopic foundation. The developments of the theory and experiment of superconductivity owed much to the use of temperature Green's functions (see, e.g., Abrikosov *et al.*, 1963; Parks, 1969; Mahan, 1990). The advantage of the two-particle temperature Green's functions can be best appreciated in connection with the linear response theory of Kubo treated below.

7.4 Linear Response Theory of Kubo and Temperature Green's Functions

How the system responds to a small external signal is summarized by the Kubo formula of linear response theory. Its essence lies in that the response function is given by a spatial and temporal correlation function of fluctuations, calculated in thermal equilibrium without the external perturbation. For example, when a weak electric field, whose v component is $E_v(\mathbf{r}',t')$, of frequency ω is an input signal $I(\mathbf{r}',t')$ in the input-output relation given by Eq. (2), an Ohmic electric current at the position $(\mathbf{r},t)$ is the output signal $O(\mathbf{r},t)$. The response function, the Green's function $G(x,x')$ in Eq. (2), is in this case the ac conductivity tensor $\sigma_{\mu v}(x,x')$. Here the fluctuation in the Kubo formula is that of the current density. Letting $j_\alpha(x)$ be the operator for the current density in the α direction in the Heisenberg picture, the fluctuation is defined by $j_\alpha(x)-\langle j_\alpha(x)\rangle$ [$=j_\alpha(x)$, because $\langle j_\alpha(x)\rangle=0$ in equilibrium]. The response function is then expressed by

$$\sigma_{\mu v}(x,x')=i(ne^2/m\omega)\delta_{\mu v}\delta(\mathbf{r}-\mathbf{r}')+(-1/\hbar\omega)\times\langle[j_\mu(x),j_v(x')]\rangle\theta(t-t'), \qquad (92)$$

with n the electron density, m the mass, and the Heaviside step function in the second term guaranteeing causality (see Sec. 2.2). The square bracket in the second term is the commutator and $\langle\ \rangle$ denotes the thermal average. Because of the presence of the step function, quantities like that in the second term of Eq. (92) are called retarded Green's functions in linear response theory, in analogy with their counterpart for the wave equation in Sec. 2.2.

The way of calculating the Fourier transform of the correlation function involved in the second term of Eq. (92) is summarized by the theorem, sometimes called the Abrikosov-Gor'kov-Dzyaloshinski-Fradkin theorem, which relates a retarded Green's function to the corresponding temperature Green's function (Abrikosov *et al.*, 1963). According to this theorem, the first step is the calculation of the two-particle temperature Green's function

$$\tilde{G}_2(\mathbf{r},\tau;\mathbf{r}',\tau')=\langle T_\tau(j_\mu(\mathbf{r},\tau)j_\nu(\mathbf{r}',\tau'))\rangle \tag{93}$$

for the Fourier component $\tilde{G}_2(\mathbf{k},\omega_n)$, and the second is the analytic continuation of the result to the real frequency ω, carried out simply by changing $i\omega_n$ to $\omega+i\epsilon$. The first step is carried out with the help of Wick's theorem, and the second is a procedure analogous to that used in obtaining a retarded Green's function in Sec. 2.2 (Abrikosov *et al.*, 1963).

Since this method of calculation using the temperature Green's functions was introduced, the usefulness of the Kubo formula has increased remarkably. This was indeed one of the key steps in the development of condensed-matter physics.

7.5 Green's Functions in Quantum Field Theories

One typical way of quantizing a classical Lagrangian is based on the functional integral. One of the merits of this method is that we may treat the field theory and statistical physics on the same footing (Amit, 1984).

The Green's functions and the related quantities developed in this field are outlined here by taking an interacting scalar Bose field $\phi(x)$ in four-dimensional space as an example (Ramond, 1981). The Lagrangian density $L(\phi(x))$ for the model called the ϕ^4 model is defined [in natural units, where $c=\hbar=1$ and the dimension of the field $\phi(x)$ is $(\text{length})^{-1}$] by

$$L(\phi)=L_0(\phi)+L_{\text{int}}(\phi), \tag{94}$$

with

$$\begin{aligned}L_0(\phi)&=\phi_t(x)^2-\phi_x(x)^2-\mu^2\phi(x)^2,\\ L_{\text{int}}(\phi)&=(\lambda/4!)\phi^4(x),\end{aligned} \tag{95}$$

ϕ_t and ϕ_x being $\partial\phi/\partial t$ and $\partial\phi/\partial x$, respectively. The functional $Z(J)$ for generating the Green's functions is defined by

$$Z(J)=\mathcal{N}^{-1}\int \mathscr{D}\phi \exp\left(i\int [L(\phi)+J\phi]d^4x\right). \tag{96}$$

Here $J(x)$ is a fictitious external field linearly coupled to $\phi(x)$, the factor $\mathcal{N}^{-1}$ normalizes $Z(J)$ such that $Z(0)=1$, and the measure $\mathscr{D}\phi$ of the functional integral is defined by

$$\mathscr{D}\phi=\lim_{N\to\infty}\prod_{n=1}^{N} d\phi(x_n). \tag{97}$$

Here it is understood that the integral over x in Eq. (96) is treated as a sum over the integrand at N discrete points $\{x_n\}$ in four-dimensional space, and the limit for N is taken after the integrals over the N independent variables $\{\phi(x_n)\}$ have been carried out. Equation (96) is a generalization of the quantization scheme for the classical one-dimensional motion of a particle carried out through the quantity

$$F(t_2,t_1)=\int \mathscr{D}q \exp\left(\frac{i}{\hbar}\int_{t_1}^{t_2} L(q(t),q'(t))dt\right), \tag{98}$$

where the classical Lagrangian L is defined in terms of $q(t)$ and $q'(t)$, the particle position and velocity at time t, respectively. With the restriction $q(t_1)=q_1$ and $q(t_2)=q_2$ imposed on the path, it may be shown that, if the measure $\mathscr{D}q$ is defined appropriately (Sakurai, 1985), Eq. (98) is identical to the quantum-mechanical probability amplitude of a particle, just described by the Green's function treated in Secs. 2.3.2 and 5.2. Thus the quantization through the functional integral is well established.

From Eq. (96), the Green's function is obtained as follows:

$$\begin{aligned}G(x_1,x_2)&=\left.\frac{\delta^2 Z(J)}{\delta J(x_1)\delta J(x_2)}\right|_{J=0}\\ &=-\mathcal{N}^{-1}\int \mathscr{D}\phi\, T\left[\phi(x_1)\phi(x_2)\times\exp\left(i\int L(x)d^4x\right)\right],\end{aligned} \tag{99}$$

where the functional derivative $\delta Z(J)/\delta J(x_1)$ is defined by the ratio of the induced change of $Z(J)$ to the infinitesimal variation $\delta J(x_1)$ at x_1 of the external field. Many-point correlation functions, $G_2(x_1,x_2,x_3,x_4)$, etc., are defined similarly. The unperturbed Green's function is then calculated from $Z_0(J)$, the generating function for $L=L_0$. It is shown that

$$Z_0(J)=\exp\left(\frac{i}{2}\int\int J(x)g(x-y)\times J(y)d^4x\,d^4y\right), \qquad (100)$$

with $g(x-y)$ the Green's function for the Klein-Gordon equation, G_R, G_A, or G_C of Eq. (29), according to the way of avoiding the poles in the ω integral (see Secs. 2.2 and 2.3.3). From Eq. (99), the unperturbed Green's function G_0 is then obtained as

$$G_0(x_1,x_2)=ig(x_1-x_2). \qquad (101)$$

In order to take into account L_{int}, the following relation is useful:

$$Z(J)=\mathcal{N}^{-1}\exp\left[i\int d^4x\,L_{\text{int}}\left(-\frac{i\delta}{\delta J(x)}\right)\right]\times Z_0(J), \qquad (102)$$

$Z_0(J)$ being given by Eq. (100). With Eqs. (100) and (102), we can calculate Green's functions to any desired order. For example, to obtain the perturbation expansion of G with respect to the parameter λ involved in L_{int}, we have only to expand the exponential of Eq. (102) in terms of L_{int}.

It is remarkable that Wick's theorem, Dyson's equation, Feynman diagrams, etc., all apply here without any modification. The difficulty of ultraviolet divergence is thus handled and then a number of physical quantities are defined by a procedure that extracts the finite part of every term in the perturbation series. This is the regularization and renormalization program.

To connect field theory with statistical physics, we need only to change the time t to the imaginary time $-i\tau$ (called in this field the Wick rotation), just as in introducing the temperature Green's functions in Sec. 7.3. The point is that the generating function $Z(J)$ converts itself essentially to a partition function. In our example this will be seen by noting that the Lagrangian is then transformed to minus the Hamiltonian. Taking advantage of this remarkable connection, and combining it with renormalization-group procedures, the critical properties of a statistical system near a second-order phase transition can be discussed using field-theoretical methods. For example, the critical index of the specific heat of the Ising model can be successfully obtained in this way. See, for more detail, e.g., Amit (1984) and Itzykson and Drouffe (1989).

GLOSSARY

Adjoint Operator: For a second-order differential operator L with respect to x, y, and z, we may transform the integral in the region Ω,

$$\int_\Omega v(\mathbf{r})L[u(\mathbf{r})]d^3r,$$

by integrating by parts until all the derivatives on $u(\mathbf{r})$ in the volume integral are transferred to $v(\mathbf{r})$. Finally the volume integral reduces to the form

$$\int_\Omega u(\mathbf{r})M[v(\mathbf{r})]d^3r,$$

with a new differential operator M, called the adjoint operator of L. Thus we obtain the following relation, the generalized Green's formula:

$$\int_\Omega (vL[u]-uM[v])d^3r = \int_\Gamma (Px_n+Qy_n+Rz_n)ds.$$

The right-hand side shows the surface integral that remains in the integration by parts, where x_n, y_n, and z_n are the directional cosines of the outward normal $\hat{\mathbf{n}}$ to the boundary Γ, and P, Q, and R are functions of u, v, and their derivatives, determined dependent upon the form of L (see, e.g., Courant and Hilbert, 1937).

Dirichlet Problem: A boundary-value problem of a differential equation that seeks a solution with a specified boundary value. These types of boundary conditions are called the Dirichlet condition.

Fredholm Integral Equation: For an unknown function $u(\mathbf{r})$ in the domain Ω, the following integral equation is called the Fredholm integral equation of the second kind:

$$u(\mathbf{r})-\int_\Omega K(\mathbf{r},\mathbf{r}')u(\mathbf{r}')d^3r'=f(\mathbf{r}),$$

$f(\mathbf{r})$ being a given function and K the integral kernel. The Fredholm integral equation of the first kind is the one with the first term $u(\mathbf{r})$ missing on the left-hand side.

Generalized Green's Formula: For the Laplacian operator the Green's formula is given by Eq. (4). It is generalized to an arbitrary second-order differential operator L and its adjoint M in the form shown in the definition of the adjoint operator.

Homogeneous Boundary Condition: The boundary condition such as $u(\mathbf{r})|_\Gamma=0$ or $(\partial/\partial n)u(\mathbf{r})|_\Gamma=0$ on the boundary Γ of the domain under consideration is a homogeneous boundary condition. In general, homogeneous boundary conditions consist of relations between the value of $u(\mathbf{r})|_\Gamma$ and its derivative $(\partial/\partial n)u(\mathbf{r})|_\Gamma$. If $u(\mathbf{r})$ satisfies the homogeneous boundary condition, so does $cu(\mathbf{r})$, c being an arbitrary constant. Boundary conditions for which this does not hold are called inhomogeneous boundary conditions. Examples are $u(\mathbf{r})|_\Gamma=f(\mathbf{r})$ or $(\partial/\partial n)u(\mathbf{r})|_\Gamma=g(\mathbf{r})$, with given nonzero $f(\mathbf{r})$ or $g(\mathbf{r})$ defined on the boundary.

Internal or External Boundary-Value Problem: When the solution of a boundary-value problem is sought inside the boundary on which a boundary condition is imposed, it is called the internal boundary-value problem. The problem for the outside region is the external problem.

Neumann Problem: The boundary condition specifying $\partial u/\partial n$, the derivative in the direction of the outward normal to the boundary, is called the Neumann condition. A boundary-value problem with a Neumann condition is a Neumann problem.

Vector Spherical Waves: Let Φ be a scalar function satisfying the scalar Helmholtz equation

$$(\Delta+k^2)\Phi=0.$$

From Φ one may construct three vector fields, $\mathbf{L}=\mathrm{grad}\Phi$, $\mathbf{M}=\mathrm{rot}(\mathbf{a}\Phi)$, and $\mathbf{N}=(1/k)\mathrm{rot}\mathbf{M}$, with $\mathbf{a}$ any constant vector. They all satisfy the vector Helmholtz equation. The two vectors $\mathbf{M}$ and $\mathbf{N}$ are solenoidal, while $\mathbf{L}$ is irrotational. For $\Phi=C_l(kr)Y_{lm}(\hat{\mathbf{n}})$, C_l being the lth cylindrical function and $Y_{lm}(\hat{\mathbf{n}})$ the spherical harmonic, the vectors $\mathbf{L}$, $\mathbf{M}$, and $\mathbf{N}$ are called the lth vector spherical waves.

Wick's Theorem: The theorem transforming the time-ordered product $T(\Psi(x)\Psi(x')\cdots)$ of any number of field operators in the interaction picture into a sum of products of simpler quantities (see, e.g., Fetter and Walecka, 1971). The expectation value of a product of field operators in the noninteracting state may be calculated by use of this theorem.

INTRODUCTION

Group theory is a mathematical technique for dealing with problems of symmetry. Such problems appear repeatedly in all branches of physics. The use of formal group theory is a very recent development, but notions of symmetry had been used extensively 1000 years ago. The design of ornaments with symmetries, the observation of periodic patterns, and the regular appearance of the Sun and other astronomical objects showed that symmetry was a useful concept. The first modern uses of symmetry were in crystallography. The first clear statement of the importance of symmetry was made by Pierre Curie around 1870. Since then group theory has become the principal tool for dealing with difficult problems in solid-state theory, relativity theory, atomic and nuclear spectroscopy, and the theory of elementary particles. In these problems we assert (or assume) that the laws describing the interactions of particles have some symmetry. In the simpler cases, such as the Coulomb field, the symmetry is easy to see. In nuclear physics the charge symmetry between neutrons and protons required a careful and bold extrapolation of experimental results. In elementary-particle physics we have very little clear understanding of the forces that determine the structure of the fundamental particles and their relations with one another. This has required us to assume some symmetry of the interactions, even though we know almost nothing about the details of the laws governing them. Once a symmetry is assumed we can then make predictions about the families of particles that are related to one another.

1. ELEMENTARY DEFINITIONS

1.1 Transformation Groups

We first give the definition of a transformation group, because these are the groups of direct importance for physics. For example, if we are considering the motion of a particle in a central field we realize that a rotation about any axis through the center will take a given orbit into another orbit with the same energy. So we want to study rotations around the center. Two successive rotations around the center again give a rotation to an orbit with the same energy. A reverse rotation would bring the orbit back to its original position. We see that the set of rotations of the three-dimensional space form a set of transformations that is closed under composition and contains all inverses. Now we give the rigorous definition. We have a *linear vector space* on which a set of transformations act. The transformations form a group if

1. The "product" of any two elements a and b of the set is also a transformation in the set: $ab=c$. By product we mean the transformation c that results from the sequence of transformations b followed by a.
2. The product is associative, i.e., $((ab)c)=(a(bc))$. The product of a whole sequence of transformations gives the same final result if we split the sequence into any clumps that preserve the order.
3. The set of transformations includes the identity transformation e, that leaves all the coordinates unchanged.
4. If the set includes the transformation a, it must also contain the inverse transformation b, such that $ab=ba=e$. We usually write the inverse element of a as a^{-1} so that $aa^{-1}=a^{-1}a=e$.

In the example given above we note that in general, if we reverse the order of rotations a and b around different axes we get different results. In general the multiplication is not commutative, i.e., $ab\neq ba$. If the product of any two elements of the set is commutative ($ab=ba$ for all a,b in the set), we say that the group is *Abelian* (the group is a commutative group). In general the transformations of a group will not all commute with one another. Then we say that the group is non-Abelian. If we take the product of an element a of the group with itself, i.e., we form aa, we write the product as a^2, the "square" of a. Similarly we write successive products of a with itself as a^3, a^4, etc.—powers of a. If we perform repeated transformations using the inverse a^{-1} of a, we get the negative powers a^{-2}, a^{-3}, etc. The total number of distinct elements in the group is called the *order g* of the group. If the order of the group is finite we say that the group is a *finite group.* An infinite discrete group is one in which the distinct elements can be labeled by the integers. Often the elements of the group can only be labeled by one or more continuous parameters. Then we say that the group is a *continuous group.* If we talk about a group of objects with some product that satisfies our definitions we have an *abstract group.* We give some examples of groups.

The numbers 0,1,2,3 form a group if the product is addition modulo 4: $2+1=1+2=3$, $2+3=3+2\cong 5-4=1$, $2+2\cong 4-4=0$, etc. The inverse of 2 is 2, the inverse of 1 is 3. This is the group Z_4, an Abelian group of order 4. Similarly the numbers $0,1,\ldots,n-1$ give the Abelian group Z_n of order n. If we take all the integers $\ldots,-2,-1,0,1,2,\ldots$ we get the infinite discrete Abelian group Z, in which the identity element is 0 and the inverse of s is $-s$.

Cyclic group. This is a group that consists of positive powers of some element a, for which there is a finite positive n such that $a^n=e$. Thus a^{n-1} is the inverse of a. So the group consists of $a,a^2,a^3,\ldots,a^n=e$. One example of a cyclic group is the set of rotations about some axis through angles $\theta=2\pi m/n$ where n is a fixed integer and $m=1,2,\ldots,n$. This is the cyclic crystal group C_n. Here the product of rotations with $m=r$ and $m=s$ is the rotation through the angle $(2\pi/n)(r+s)$. This group C_n has the same abstract structure as Z_n. Clearly cyclic groups are Abelian.

An example of an infinite Abelian group is the group of translations along the x axis given by $x'=x+n\delta$, where δ is fixed and n is an integer, positive or negative or zero (which is the identity translation). This group has the same abstract structure as the group Z.

Permutation groups. Another important class of groups comprises the permutation groups on n letters. In these groups each letter is replaced by some letter, while no two are replaced by the same letter. If each letter is replaced by itself, we get the identity permutation e. We first illustrate for the case of $n=6$. A permutation of the numbers 1 to 6 replaces each number by one of the six numbers, and no two numbers are replaced by the same number. A simple notation for a permutation is

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ i_1 & i_2 & i_3 & i_4 & i_5 & i_6 \end{pmatrix},$$

where each number in the upper line is replaced by the number appearing below it. For example, the permutation

$$\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 6 & 2 & 4 & 5 & 3 & 1 \end{pmatrix}$$

replaces 1 by 6 ($1\rightarrow6$), $2\rightarrow2$, $3\rightarrow4$, $4\rightarrow5$, $5\rightarrow3$, $6\rightarrow1$. Note that $2\rightarrow2$, so 2 is unchanged by this permutation. There are $6!=720$ different permutations. (If all the symbols are left unchanged we get the identity permutation with $1\rightarrow1$, $2\rightarrow2$, etc.). This same permutation can be written in *cyclic notation:* we start with any symbol, say 1. We record 1, and note that $1\rightarrow6$, so we write $1\rightarrow6$. $6\rightarrow1$, and we have a cycle (closed loop), so we put 1 and 6 in parentheses: (1 6). The number 2 is unchanged so we write (2). Next we start with 3 and find $3\rightarrow4\rightarrow5\rightarrow3$, giving the cycle (3 4 5) [which is the same as (4 5 3) or (5 3 4)]. Thus the original permutation is recorded as (16) (2) (3 4 5). The symbols inside a parenthesis are distinct. This particular permutation has the *cycle structure* [3,2,1]: it contains a cycle of three symbols, a cycle of two symbols, and a cycle of one symbol—a 3-cycle, a 2-cycle, and a 1-cycle. Often the permutation is written omitting its 1-cycles, so this would be (16) (345). Other examples are (134652) which consists of one 6-cycle, or (142)(365), with two 3-cycles (notation $[3^2]$), or (15)(26)(34) which contains three 2-cycles (notation $[2^3]$), or (135), where the three 1-cycles (unchanged symbols) are omitted, so its cycle structure is $[3\ 1^3]$. To find the inverse of a permutation expressed in cycle notation, we read the numbers from right to left, so the inverse of (142)(365) is (241)(563). The group that contains all the permutations on six symbols is called the symmetric group on six symbols S_6. We can form permutations on n letters and form the symmetric group S_n whose order is $n!$ This group S_n is very important in spectroscopy and especially when we consider identical (indistinguishable) particles, where the physical situation is unchanged when we make any permutation of the identical particles.

1.1.1 Subgroups. Suppose that we have a subset H of elements in the group G ($H\subset G$). If the elements of H form a group under the same product law as in G, we say that H is a *subgroup* of G. For example, the group S_6 contains all the permutations on five letters (e.g., we drop all permutations containing the number 6, or those that omit any single one of the six letters). Thus S_6 contains six subgroups that have the same structure as S_5. S_6 also contains many differently appearing subgroups that have the same structure as S_4. (We omit permutations that contain some two of the numbers 1–6). Such subgroups are isomorphic to one another. Clearly the group G is a subgroup of G. Also the group element e, the identity of G, is necessarily a subgroup. These two subgroups of G are said to be improper, while all other subgroups in G are called proper subgroups of G.

Suppose that H is a subgroup in G. If H does not exhaust G, take any element a not contained in H and form the set aH, which contains all elements of the form ah where h runs through H. The set aH contains no elements of H, since, if $ah=h'$ where h' is in H, applying h^{-1} on the right we would get $a=h'h^{-1}$, which says that a is a product of elements in H and is therefore in H. If the elements of G are not all included in H and aH, we choose one of the residual elements k of G and form kH. We continue this process until we have obtained all the elements of G. So G consists of the subsets of elements $H, aH, kH,\ldots,sH$, which have no elements in common and each contain m elements of G. We see then that the number m of elements in H (the order of H) must divide the order of G. This is called *Lagrange's theorem.* Note that the subgroups S_5 in S_6 have order $5!=120$, which divides the order $6!=720$ of S_6.

1.1.2 Cosets. The individual pieces in this decomposition of G are called the left cosets of H in G. We write this symbolically as $G=H+a_2H+a_3H+\cdots+a_rH$. If instead we formed the cosets by multiplying H from the right, giving disjoint sets Ha, we would get the right coset decomposition of G with respect to the subgroup H.

1.1.3 Conjugate Classes. If a and b are elements of the group G, the elements $bab^{-1}=c$, where b is any element of G, are said to be *conjugate* to a in G. We denote this by writing

$c \sim a$. If we let b run through all the elements of G, we get the set of *transforms* of a, the *conjugate class* of a in G. The determination of transforms gives a decomposition of G into conjugate classes that have no elements in common, i.e., the conjugation operation is an equivalence relation:

1. $a \sim a$.
2. If $a \sim b$ and $b \sim c$, then $a \sim c$.
3. If $a \sim b$, then $b \sim a$.

We prove 2. $a \sim b$ means that $a = kbk^{-1}$, where k is in G. Similarly $b \sim c$ means that $b = k'ck'^{-1}$, where k' is in G. So $a = kbk^{-1} = k(k'ck'^{-1})k^{-1} = (kk')c(k'^{-1}k^{-1}) = (kk') \times c(kk')^{-1}$, so $a \sim c$.

For geometrical transformations the conjugate has a simple interpretation. Suppose that a is a rotation through angle θ about a direction along the unit vector $\mathbf{n}$: $a = (\mathbf{n}, \theta)$. Let b be a rotation that turns the unit vector $\mathbf{n}$ into the direction of $\mathbf{n}'$. Then, since b turns $\mathbf{n}$ into $\mathbf{n}'$, in the conjugate bab^{-1}, b^{-1} first turns $\mathbf{n}'$ into $\mathbf{n}$, then a rotates about $\mathbf{n}$ through θ, then b brings $\mathbf{n}$ back to $\mathbf{n}'$, so the net result is a rotation through the angle θ about the unit vector $\mathbf{n}'$. Thus the conjugate of a rotation is always a rotation through the same angle θ about some other axis. Similarly, if a were a translation through a vector $\mathbf{s}$, the conjugate bab^{-1} would be a translation through the vector $\mathbf{s}'$, into which b takes $\mathbf{s}$.

For the permutation groups, the conjugate is also obtained simply. Suppose we want to find the conjugate c of the permutation a that results from taking $c = bab^{-1}$, where $a = (135)(24)$, $b = (325)$. Then $b^{-1} = (523)$, and we get $c = (325)(135)(24)(523) = (54)(123)$. We note that the conjugate of a has the same cycle structure as a; we get it by letting the permutation b act on the cycle symbol for a: apply (325) to a; it replaces 3 by 2, 2 by 5, and 5 by 3, so a is changed to $(123)(54)$, where 4 and 1 are untouched, since b does not contain 1 or 4. Another example would be the transform of $a = (142)(365)$ by $b = (16)(345)(2)$. Applying the permutation b to the cycle symbol for a replaces $1 \rightarrow 6 \rightarrow 1$, $3 \rightarrow 4 \rightarrow 5 \rightarrow 3$, giving $bab^{-1} = (652)(413)$.

We emphasize that the transforming element b must be in the group G. If the group is Abelian, then all its elements commute, and the conjugate class of an element a is just a itself. If an element a commutes with all the elements of the group G, its class consists of a alone. This is always the case for the identity element e for any group—the identity is a class containing the single element e. Suppose we consider the permutation group S_3 on three letters 1, 2, 3. There are six elements in this group: $e, (12), (23), (13); (123), (132)$. Only permutations with the same structure can be in the same conjugate class, so we have three classes: e; $(12), (23), (13)$; $(123), (132)$; with one, three, and two members, and cycle structures $[1^3]$, $[2\ 1]$, and $[3]$, respectively.

1.1.4 Invariant Subgroups. If H is a subgroup of G, we consider the set aHa^{-1}, containing all elements aha^{-1}, where h runs through the members of H. The elements of this set are all distinct, and the product of any two, $ah_1a^{-1}ah_2a^{-1} = ah_1h_2a^{-1}$, is also in aHa^{-1}, since h_1h_2 is in H. Clearly the set aHa^{-1} is a subgroup that looks like H in form. It is *a conjugate subgroup of H*. If all the conjugate subgroups of H in G are the same as H, we say that H is an invariant subgroup in G. But if $aHa^{-1} = H$ for all elements a, then multiplying on the right by a, we get $aH = Ha$, i.e., the sets of right and left cosets of H in G are identical. We also note that the invariant subgroup contains complete classes. Thus, in the example of the permutations on three letters, the group S_3 contains the proper subgroup e, $(123), (132)$. Since it consists of complete classes, it is an invariant subgroup. For the permutation group on four letters S_4, the group contains $4! = 24$ elements. The different classes are e; type (12), type (123), type (1234), and type $(12)(34)$, with numbers of elements 1,6,8,6,3, respectively. The classes correspond to the possible cycle structures given by the partitions of 4 into sums of positive integers. Thus e has four 1-cycles, partition $[1^4]$; (12) has one 2-cycle and two 1-cycles (partition $[21^2]$), (123) has one 3-cycle and one 1-cycle, (partition $[31]$), (1234) has one 4-cycle (partition $[4]$), and $(12)(34)$ has two 2-cycles (partition $[2^2]$).

As another example, we consider the group of all rotations and translations in a space with dimension m. We denote the elements by $(R \mid a)$, where this means that we first perform the rotation R and then the translation a. The translations a form a subgroup (Abelian), and we showed earlier that the transform of any a by a rotation R is again a translation. Thus the subgroup of the translations is invariant in the whole group.

1.1.5 Isomorphic Groups. Two groups G and G' are said to be *isomorphic* if their elements can be put into a one-to-one correspondence so that if $a \leftrightarrow a'$ and $b \leftrightarrow b'$ then $ab \leftrightarrow a'b'$. For example, consider the group consisting of the identity e and the inversion of coordinates i. Here $i^2=e$, so the group contains two elements. Now look at the group consisting of the numbers 1 and -1 with the product being ordinary multiplication, so that $(-1)(-1)=1$. We see that these groups can be put into one-to-one correspondence $e \leftrightarrow 1$, $i \leftrightarrow -1$, with $ii=e$ corresponding to $(-1)(-1)=1$. There can be many groups with the same abstract structure. They are isomorphic to one another.

1.1.6 Homomorphic Groups. Instead of a one-to-one correspondence, we may have two groups with a correspondence of products, but where several elements of the group G correspond to a single element of G'. We say that there is a *homomorphism* of the group G onto G'. For example, in the cyclic group of order 4, generated by an element a with $a^4=e$, the elements a^2 and $a^4=e$ are a subgroup H in G. If we take the odd powers a and a^3 and map them onto the number -1, and map the subgroup H onto 1, we have a two-to-one correspondence between the cyclic group and the two-element group.

1.1.7 Factor Groups. If the subgroup H is an invariant subgroup in G, we can write G as a "sum" of cosets of H in G: $G = H + a_2H + a_3H + \cdots + a_rH$, where $a_iH=Ha_i$. But then the product of cosets $(a_iH)(a_jH) = a_i(Ha_j)H = a_i(a_jH)H = (a_ia_j)H$, so the cosets themselves form a group, for which the identity is the coset H itself. This new group is called the factor group F of G by the (invariant) subgroup H. There is a homomorphism of the group G onto the subgroup H where all the elements in a coset are mapped on the same element of the factor group $F=G/H$.

1.1.8 Direct Product. If we have two groups, G and H, and the elements of one commute with all the elements of the other, we can form a new group, their direct product, by taking pairs (g,h) of elements g from G and h from H. The product of two elements (g_1,h_1) and (g_2,h_2) in this new group is the ordered pair (g_1g_2,h_1h_2). This group is called the direct product $G \otimes H$ of the two groups G and H. If we have a number of groups $G,H,K,\ldots$, and the elements of any one commute with all the elements of the others, we can form the direct product $G \otimes H \otimes K \otimes \ldots$, whose elements are obtained by taking one element from each group: $(g,h,k,\ldots)$. Clearly all the elements $(g,e_i,e_j,\ldots)$, where the $e_i,e_j,\ldots$ are the identity elements for the other factors, form a group isomorphic to G. This group can be identified with G and is an invariant subgroup of the direct product. The direct product is thus a product of the groups, $G,H,K\ldots$, and each of them is an invariant subgroup of the direct product.

For the crystal group that we described earlier, with elements $(R|a)$, the translations are an invariant subgroup, since RaR^{-1} is again a translation, while the subgroup of rotations is not invariant. Instead the rotations act on the translations and transform the translation vectors. Such a group is called the semidirect product of the groups R and A, where R contains all the pure rotations and A all the pure translations, and is written as $A \ltimes R$, where the invariant subgroup is the first symbol.

1.1.9 Finite Groups. For a finite group one can describe the group structure by recording the Cayley table for the group. We write the elements of the group as a matrix with each column headed by an element of the group, and similarly, each row. We then get a square matrix of products by placing the product g_ig_j at the i,j position.

The group formed by taking all products of r and s, where $r^3=s^2=(rs)^2=e$, is a group with six elements. Its Cayley table is shown in Table 1. Note that each row contains all six elements of the group, but they are rearranged. In other words, applying an element of the group from the left permutes the elements. We thus have a group of permutations that is isomorphic to the group in the table.

Table 1. A Cayley Table.

e	r	r^2	s	sr	sr^2
r	r^2	e	sr^2	s	sr
r^2	e	r	sr	sr^2	s
s	sr	sr^2	e	r	r^2
sr	sr^2	s	r^2	e	r
sr^2	s	sr	r	r^2	e

This is a group of permutations of six elements, and is a subgroup of the symmetric group S_6. In the same way, every finite group of order n is isomorphic to a subgroup of the symmetry group S_n. This result is called *Cayley's theorem.* An important collection of finite groups consists of the so-called point groups: rotations through submultiples of 2π that keep the origin fixed and reflections in planes passing through the origin (or inversion in the origin). These finite groups describe the point symmetry of crystals.

1.1.10 Infinite Discrete Groups. In three dimensions the translations through a displacement $\mathbf{r}=n_1\mathbf{a}_1+n_2\mathbf{a}_2+n_3\mathbf{a}_3$, where the n_i are integers and the vectors $\mathbf{a}_i$ are fixed, form an infinite discrete group. This is the translation group of a crystal lattice. Similar groups can be constructed for any space dimension. We can also have crystal space groups, that contain elements $(R|a)$ that preserve the crystal lattice. If the translations appearing in $(R|a)$ are always lattice vectors the crystal group is said to be *symmorphic.* There are some crystals in which there are additional symmetries which involve elements $(R|a)$ where the translation is some rational fraction of a lattice vector along the direction of the rotation axis, giving a screw motion. Or we may have glide motions where we translate parallel to some crystal plane through a rational fraction of a lattice vector and then reflect in the crystal plane. Crystals that have such symmetry elements are said to be *nonsymmorphic.* [For further information about space groups see Burns 1977, Chap. 11.] More detailed treatments of Sec. 1.1 can be found in Burns (1977), Chaps. 1, 2, and 13; Elliott and Dauber, (1979), Chaps. 1 and 2; and Hamermesh (1989), Chaps. 1 and 2.

1.2 Continuous Groups

When we consider continuous groups we combine the algebraic concept of "group" with the topological concept of "nearness." The law of combination of elements a, b of G now requires the product ab to depend continuously on its factors, and the inverse a^{-1} must depend continuously on a. We shall not discuss general topological groups but will assume that there is a metric (a measure of distance between group elements) on the group. So the group itself is a metric space on which the product and inverse are defined and continuous. We can look upon the group as a space in which the points are the elements of the group. We shall deal only with groups of transformations, so the group elements form a space whose points are the transformations of the group. Multiplying the element b on the left by some transformation a of the group moves the point b in the group space to the point ab. Thus the group elements can be regarded as operators that act on the group space itself and rearrange the points. The changed points also fill the space since any element of the group space c can be reached from b by applying the element cb^{-1} to it. Thus the group space looks the same everywhere. It is a homogeneous space, and we can obtain all our information by, e.g., working in the neighborhood of the identity e.

A group is said to be a mixed continuous group if the elements depend on discrete labels as well as continuous ones. For example, the translation group on the line G is the set of transformations $x'=x+a$, $(-\infty\leqslant a\leqslant\infty)$. If we adjoin the single transformation $x'=-x$ we also get the transformations $x'=-x+a$. The transformations $x'=x+a$ are in one piece and can be reached continuously from the identity. Thus this piece forms a group. The second piece, containing the transformations $x'=-x+a$, cannot be reached continuously from the identity, and is not a group. This piece is the coset of the first piece, obtained by multiplying elements of the first piece by the transformation $x'=-x$.

A *connected group* is a continuous group in which we can join any two points of the group by a continuous arc in the group space. Our last example showed a group consisting of two pieces (components). The piece that contains the identity is called the component of the identity. If a group is connected it consists of a single component. One basic theorem is the following: In a connected group G, every neighborhood of the identity generates the group. By taking products of elements near the identity we keep expanding the set of products and fill the whole connected piece containing the identity. For example, in the group of translations $x'=x+a$, if we take some neighborhood of the identity $a=0$, say $-\epsilon\leqslant a\leqslant\epsilon$, and keep applying these translations, we get the whole line.

1.3 Lie Groups

A Lie group is a group in which the neighborhood of the identity looks like (is homeomorphic to) a piece of an r-dimensional Euclidean space (an r-parameter Lie group). In other words, in the neighborhood of the identity the group elements can be parametrized using r parameters (coordinates on the group manifold). Thus each element can be labeled by r parameters $a_1,a_2,...,a_r$. Since we want continuity, this parametrization may not be possible over the whole group space, but we can use several maps that overlap to cover the whole space without singularities. (For example, to cover a sphere with continuous maps requires more than one map.) An element of the group is $R(a)=R(a_1,...,a_r)$ where the parameters $a_1,...,a_r$ are essential, i.e., all r parameters are needed to describe the space. The product of two elements with parameters a and b, respectively, $R(a)R(b)$, is the element $R(c)$ with parameters $c_1,...,c_r$ that are functions of $a_1,...,a_r$ and $b_1,...,b_2$, i.e.,

$$c_i=\varphi_i(a_1,...,a_r;b_1,...,b_r), \text{ or, symbolically,}$$

$$c=\varphi(a;b). \tag{1}$$

The simplest assumption is that the functions φ are analytic functions of the a's and b's. This was the original requirement for a Lie group. But this requirement is too strong. In fact, every parametric group is a Lie group. The group structure combined with continuity implies the analyticity of φ (Hilbert's "Fifth Problem").

For Lie groups with a finite number of parameters, the neighborhood of any point is bounded and contains all its limit points (the group is *locally compact*). If the parameter space is unbounded this may not be true as we move out to large distances in the parameter space. For most of the groups used in physics the group space is compact, but we shall see some cases of noncompact groups.

Consider transformations in n-space:

$$x_i'=f_i(x_1,...,x_n), \quad i=1,...,n, \tag{2}$$

or, symbolically, $x'=f(x)$. Suppose that we have a set of f's labeled by r parameters:

$$x_i'=f_i(x_1,...,x_n;a_1,...,a_r), \tag{3}$$

forming a Lie group. The transformation a is $x\to x'=f(x;a)$, and b is $x'\to x''=f(x';b)$. If we first apply a and then b, we get

$$\begin{aligned} x''&=f(x';b)=f(f(x;a);b)\\ &=f(x;\varphi(a,b))=f(x;c), \end{aligned} \tag{4}$$

where $c=\varphi(a,b)$ and φ is an analytic function of the parameters a and b. We give examples of Lie groups that comprise most of the groups of interest to physics.

1. The dilation group. In one dimension this is the group of transformations $x'=ax$, $a\neq 0$. The identity has $a=1$. All distances on the line are multiplied by the number a. The transformation with $a=-1$ reflects the line about the origin. The parameter a for the inverse is $\bar{a}=1/a$, and $c=\varphi(a,b)=ab$. The group space is the real line with the origin cut out, $\mathbb{R}\setminus\{0\}$. It consists of the two separate pieces $x\gtrless 0$. The group space for the dilations in two dimensions, $x'=ax$, $y'=ay$, is the real plane with the origin removed (the punctured plane $\mathbb{R}^2\setminus\{0\}$). In this case the group space remains a single connected piece. It is convenient to assign the parameter 0 to the identity. We write the group as $x'=(1+\alpha)x$, with $\alpha\neq -1$.
   The group $x'=ax, y'=a^2y$, with $a\neq 0$, has only one parameter, but now the transformations are in a space of dimension 2. We note that the number of parameters is not determined by the dimension of the space on which the transformations act.
2. GL(n), the general linear group in n dimensions, is the set of nonsingular linear transformations in n-dimensional space. For real entries we write GL(n,R), for complex entries GL(n,C): $x'=Ax$, or $x_i'=a_{ij}x_j$ ($i=1,...,n$), where we sum over the repeated index, and det $A\neq 0$ (the nonsingular transformations). The number of real parameters is n^2 for GL(n,R), and $2n^2$ for GL(n,C). $\bar{A}=A^{-1}$, $\varphi(A,B)=BA$. The elements a_{ij} vary over an infinite range ($-\infty\leqslant a_{ij}\leqslant\infty$), so the group is not compact. The elements of GL(n,C) are the subset of the $n\times n$ complex matrices with determinant $\neq 0$.
3. SL(n) is the special linear group (unimodular group) with det$=1$. SL(n,C) and SL(n,R) are subgroups of GL(n,C). Thus SL(2) is the collection of 2×2 matrices
   $$\begin{pmatrix} a & b\\ c & d\end{pmatrix} \text{ with } ad-bc=1.$$
4. $O(n)$ is the orthogonal group, a subgroup of GL(n), where we impose the requirement that the transformations leave scalar

products of any two vectors x,y unchanged; i.e., $(Ox,Oy)=(x,y)$, where the scalar product is

$$(x,y)=\sum_i x_iy_i.$$

Then $(x,y)=(Ox,Oy)=(x,\tilde{O}Oy)$, where $\tilde{O}$ is the transpose of the matrix O, so that

$$\tilde{O}O=1,\text{the unit matrix, or}\tilde{O}_{ij}O_{jk}=\delta_{ik}$$
$$=O_{ji}O_{jk}. \tag{5}$$

Taking determinants, $(\det O)^2=1$, or $\det O=\pm 1$. The column vectors of the orthogonal matrix are orthogonal unit vectors. Similarly $O\tilde{O}=1$, so the rows are orthogonal unit vectors. For $O(n,R)$, there are n conditions from the norm and $n(n-1)/2$ from the orthogonality, so the number of parameters is $r=n(n-1)/2$. The subgroup with positive determinant $+1$ is called $O^+(n,R)$ or $\mathrm{SO}(n,R)$, the special orthogonal group (or proper orthogonal group).

5. $U(n)$ is the unitary group that acts in a complex unitary space, where we have an inner product $(x,y)=\Sigma_i x_i^* y_i$, and the asterisk denotes the complex conjugate, so that $(x,y)=(Ux,Uy)=(x,U^\dagger Uy)$, where $U^\dagger=\tilde{U}^*$ is the adjoint of U, so $U^\dagger U=1=UU^\dagger$, $\Sigma_i U_{ij}^* U_{ik}=\delta_{jk}$, and $|\det U|^2=1$, so $\det U=\exp(i\epsilon)$. Note that for $j=k$ there are n conditions $\Sigma_i|U_{ij}|^2=1$, while for $j\neq k$ there are $2n(n-1)/2$ orthogonality conditions (real and imaginary parts both equal to zero). Thus the number of parameters is $r=n^2$. The sum of the absolute squares of all the matrix entries is n, so the group space is bounded and $U(n)$ is a compact group.
6. $SU(n)$ is the unitary unimodular group (special unitary group), a subgroup of $U(n)$ having $\det U=1$, so $r=n^2-1$.
7. The *Euclidean group $E(n)$* in real space, $x'=Ax+a$, where A is an orthogonal matrix and $\mathbf{a}$ is a translation vector, preserves the Euclidean distance, so $\tilde{A}A=1$, and the number of parameters is $r=n(n+1)/2$. For $n=3$, $r=6$. This group $E(3)$ can be regarded as a group of block matrices (A,a), where A is a 3×3 orthogonal matrix, O is the (1×3) null matrix,

$$\begin{pmatrix} & a_1 \\ A & a_2 \\ & a_3 \\ O & 1 \end{pmatrix},$$

and (A,a) acts on the column vectors

$$\begin{pmatrix} x_1 \\ x_2 \\ x_3 \\ 1 \end{pmatrix}.$$

This group describes the rigid-body displacements in 3-space.

In obtaining $O(n,R)$ we required the invariance of the scalar product (x,y). If we had required the invariance of any positive definite symmetric bilinear form $g_{ij}x_iy_j=(x,gy)$, with $g=\tilde{g}$, we could bring it back to the unit form by a change of basis. Thus the group $O(n,R)$ is obtained for all of these. If we extend this argument to include all nonsingular symmetric bilinear forms, a change of basis will bring them (Sylvester's law of inertia) to diagonal form with p 1's and q (-1)'s, where $p+q=n$. We get the pseudo-orthogonal groups $O(p,q)$, defined over the real numbers. If we define a matrix

$$S_{pq}=\begin{pmatrix} \mathbf{1}_p & 0 \\ 0 & -\mathbf{1}_q \end{pmatrix},$$

where the $\mathbf{1}_p$ and $\mathbf{1}_q$ are the unit matrices for dimension p and q, these groups are defined by the requirement that $(x,sy)=(Ox,sOy)=(x,\tilde{O}sOy)$ for arbitrary x and y, so that $\tilde{O}sO=s$. Again we have $(\det O)^2=1$, so by choosing those transformations with $\det=1$, we can define the special groups $\mathrm{SO}(n-q,q)$. An important example of this kind of group is the *Lorentz group*, where we require the invariance of $x^2+y^2+z^2-\tau^2$ (where $\tau=ct$) under the group.

What about skew-symmetric bilinear forms? Given a nondegenerate skew-symmetric bilinear form, with

$$\{x,y\}=g_{ij}x_iy_j \quad\text{and}\quad g_{ij}=-g_{ji}, \tag{6}$$

$g=-\tilde{g}$, $\det g=(-1)^m\det g$, so the form will be nondegenerate only for even dimension m. If we want the transformations to preserve $\{x,y\}$, we must have $\tilde{O}gO=g$, so $(\det O)^2=1$. By a change of basis we can bring g to the canonical form

$$g=\begin{pmatrix} 0 & \mathbf{1}_n \\ -\mathbf{1}_n & 0 \end{pmatrix},$$

where O is the $n\times n$ null matrix and $\mathbf{1}_n$ is the $n\times n$ unit matrix. These groups are the symplectic groups Sp(2*n*). For further details and examples, see Hamermesh (1989), p. 283ff.

2. LINEAR REPRESENTATIONS OF LIE GROUPS

In Sec. 1 we gave an introduction to group theory and a description of some of the important transformation groups that have application to physics. Now we want to show how groups can be used in the solution of physical problems.

2.1 Group Theory and Quantum Mechanics

In quantum mechanics the states of a system of n particles are described by wave functions (state vectors) Ψ that are functions of the time t, the coordinate vectors $\mathbf{r}_1,\mathbf{r}_2,\ldots,\mathbf{r}_n$ of the n-particle system, and any other internal coordinates of the particles. The changes of the system with time (the equations of motion) are governed by the Hamiltonian operator $H=T+V$, where T is the kinetic energy and V is the potential energy of the system, which includes the interaction of the particles with one another and with any external fields. V is a function of the coordinates, while T involves both the coordinates and derivatives with respect to the coordinates. The time behavior of the system will be given by the Schrödinger equation:

$$H\Psi=-\frac{\hbar}{i}\frac{\delta\Psi}{\partial t}, \tag{7}$$

where $\hbar=(1/2\pi)\times$(the Planck constant h). For most problems we look for the stationary states, i.e., states whose time dependence is given by an exponential factor $\exp(-iEt/\hbar)$:

$$\Psi(r_1,\ldots,r_n;t)=\psi(r_1,\ldots,r_n)\exp(-iEt/\hbar). \tag{8a}$$

E is the energy of this stationary state (energy eigenstate) and $H\psi=E\psi$. A particular problem will have many different solutions ψ_i with corresponding energies E_i. The set of all the eigenvalues E_i gives the spectrum of energy levels of the system. If there are several independent state vectors for a given energy level, we say that the state is degenerate. The theory is linear: we can superpose any states ψ_i to get a new state $\psi=\alpha\psi_r+\beta\psi_s$, where α and β are arbitrary complex numbers. If we assume that the state at time $t=0$ is given by

$$\psi=\sum_{i=1}^{m} c_i\psi_i,$$

then at time t, it will have developed into the function

$$\psi(t)=\sum_{i=1}^{m} c_i\psi_i(r_1,\ldots,r_n)\exp(-iE_it/\hbar). \tag{8b}$$

The quantities that are measured for a state ψ (the observables, such as position of the nth particle, the dipole moment of the system, etc.) are operators that act on the state vector, and in general change it to a new state. If the operator S leaves the state ψ unchanged except for a complex factor, so that $S\psi=s\psi$, we say that the state is an eigenstate of the operator with eigenvalue s. If we measure S on a state $\varphi=\Sigma_i b_i\varphi_i$, where the φ_i are normalized eigenstates of the operator S, the result will be one of the s_i, with a probability $|b_i|^2$, and the average value over many measurements (the expectation value of S in this state) will be

$$\langle S\rangle=|(\varphi,S\varphi)|^2=\sum_i |b_i|^2 s_i. \tag{9}$$

In addition to observables we can introduce other operators that act on the states of the system. For example, if the coordinates are changed by some transformation, there will be a corresponding change in the state vector $\psi(r)$. The new state vector ψ' will be obtained by acting on the state vector ψ with an operator related to the coordinate transformation. Some coordinate transformations may leave the physical situation unchanged. For example, for a particle in a central field, a rotation R about any axis through the center has no apparent effect on the physics, since the field depends only on the radius vector to the particle. The operator O_R corresponding to the rotation R acts on the state vector ψ to give a new state $\psi'=O_R\psi$ that looks the same in the rotated coordinates $r'=Rr$ as did the original ψ in terms of the coordinates r:

$$O_R\psi(r')=\psi(r),$$

$$O_R\psi(Rr)=\psi(r),$$

or

$$O_R\psi(r)=\psi(R^{-1}r). \tag{10a}$$

If the state ψ is an eigenstate of the Hamiltonian H with eigenvalue E, $H\psi=E\psi$, $O_R\psi$ will also be an eigenstate of H with the same energy E, i.e., $HO_R\psi=EO_R\psi$, so the states ψ and $O_R\psi$ will be degenerate (or differ by a phase). Applying the operator O_R^{-1} on the left, we get

$$O_R^{-1}HO_R\psi=E\psi=H\psi. \tag{10b}$$

Since this equation holds for any eigenstate, it holds for all states ψ, so the operators on both sides coincide:

$$O_R^{-1}HO_R=H; \quad HO_R=O_RH. \tag{10c}$$

Thus the operator O_R commutes with the Hamiltonian H. It is a symmetry operator for this Hamiltonian. If we choose some other rotation S we get a corresponding symmetry operator O_S that acts on the state vectors. The product of the operators O_SO_R is the operator O_{SR} that corresponds to the result of successive transformations by R and then by S. In general, if we have a collection of symmetry operators their products and inverses will also be symmetry operators. The identity operator is a symmetry operator and the operators satisfy the associative law. Thus the operators obtained by using Eq. (10a) for all the symmetry transformations will form a group of operators that is isomorphic to the group of symmetry transformations. The group of operators acting on some space of functions provides us with a representation of the symmetry group.

2.2 Construction of Representations

As a simple example of the construction of representations, we again consider the problem of a particle in a central field. The group of symmetry operators O_R will take an eigenfunction ψ into an eigenfunction $O_R\psi$ with the same energy E. If we apply all the rotation operators to the same ψ we will not always get a linearly independent $O_R\psi$ as the result. For example, if our $\psi(x,y,z)$ depends only on the radius r, $O_R\psi$ will leave ψ unchanged, since this state vector is spherically symmetric. If $\psi(x,y,z)=x$, the rotation operators will give only x,y,z or linear combinations of them. So this will be a representation in a three-dimensional carrier space, and we say that this is a three-dimensional representation of the rotation group. Calling these basis functions $\psi_i^{(1)}(i=1,2,3)$, $O_R\psi_i^{(1)}$ will be a linear combination of $\psi_i^{(1)}$:

$$O_R\psi_i^{(1)}=\sum_{j=1}^{3} D_{ji}^{(1)}(R)\psi_j^{(1)}, \quad (i=1,2,3), \tag{11}$$

where the superscript (1) labels the representation $D^{(1)}$, and $D_{ij}^{(1)}(R)$ is the matrix representative of the rotation in this representation. If we perform a second rotation S, we get

$$\begin{aligned} O_s(O_r\psi_i^{(1)}) &= \sum_j D_{ji}^{(1)}(R)O_s\psi_j^{(1)} \\ &= \sum_{k,j} D_{ji}^{(1)}(R)D_{kj}^{(1)}(R)\psi_k^{(1)} \\ &= \sum_k \left[\sum_j D_{kj}^{(1)}(R)D_{ji}^{(1)}(R)\right]\psi_k^{(1)} \\ &= \sum_k D_{ki}^{(1)}(SR)\psi_k^{(1)}. \end{aligned} \tag{12}$$

The matrices $D^{(1)}$ thus give a three-dimensional representation of the rotation group. If we take any linear subspace of this three-dimensional space, applying the rotation operators will automatically generate the rest of the three-dimensional space. There is no proper subspace that is invariant, i.e., is reproduced by the rotation operators. We say that the representation $D^{(1)}$ is an *irreducible* three-dimensional representation of the rotation group.

If we start with quadratic expressions in x,y,z: xy, yz, zx, x^2, y^2, z^2, we will obtain a six-dimensional carrier space on which the rotation operators will act, giving us a six-dimensional representation D. But this representation is *reducible:* we can find a proper subspace which is invariant. It is the one-dimensional subspace of the multiples of the function $\psi_{11}^{(0)}=x^2+y^2+z^2$, which is unchanged by rotations (orthogonal transformations). The remaining five-dimensional space with basis xy, yz, zx, x^2-z^2,y^2-z^2, contains no invariant subspace, so the matrices obtained by applying the rotation operators O_R to this subspace will give an irreducible five-dimensional representation of the rotation group. Thus by changing the basis we can decompose the representation into two independent irreducible representations.

In general, for any transformation group G with elements R, starting with some functions ψ, we can apply the corresponding operators O_R to the ψ's, find an independent basis set, and obtain an equation just like Eq. (11):

$$O_R\psi_i^{(\mu)}=\sum_{j=1}^{d_\mu} D_{ji}^{(\mu)}(R)\psi_j^{(\mu)},\quad (i,j=1,\ldots,d_\mu), \tag{13}$$

where μ labels the representation $D^{(\mu)}$, with dimension d_μ.

We mention again the two important steps:

1. We start with some functions and find the space of functions generated by the operator group.
2. We make changes of basis and look for invariant subspaces. If there are no invariant subspaces, the representation is irreducible. The basis functions must be degenerate with one another. If there are invariant subspaces, we check these separately. We finally end up with a collection of irreducible representations. The basis functions of each of these form a necessarily degenerate set.

In describing this process, it is convenient in general to use a "coordinate space" of dimension $d_\mu=m$, and call the basis set $y_1,\ldots,y_m$. The transformations R of the group G are represented by operators O_R that act on the coordinates $(y_1,\ldots,y_m)$ or by their matrix representatives $D^{(\mu)}(R)$.

An important method for constructing representations for transformation groups is to realize that the group supplies us with a representation of itself: each element R of the group is its own representative $D(R)$. If n is the dimension of the coordinate space on which the group acts, the representatives will be $n\times n$ matrices $D^{(1)}(R)$. This is the vector representation of the group G. Any quantity that transforms according to this representation is called a vector relative to the group G. The product of representatives of R and S is $D^{(1)}(RS)=D^{(1)}(R)D^{(1)}(S)$. We also sometimes refer to the basis of this representation as a tensor of rank 1 (relative to G). We can define tensors of higher rank relative to G as follows: If x and y are vectors we can form the n^2 products x_iy_j. Under the transformations of G these will transform so that $x_i'y_j'=D_{ik}^{(1)}(R)D_{jl}^{(1)}(R)x_ky_l$, where we always use the convention of summing over any repeated index. (Note that the same transformation R is applied to each factor.) Any set of quantities T_{ij} that transform like this product is called a second-rank tensor: $T_{ij}'=D_{ik}^{(1)}(R)D_{jl}^{(1)}(R)T_{kl}$. Similarly we can construct tensors of any rank:

$$T'_{i_1,\ldots,i_n}=D^{(1)}_{i_1j_1}(R)D^{(1)}_{i_2j_2}(R)\ldots D^{(1)}_{i_mj_m}(R)T_{j_1,\ldots,j_m}. \tag{14}$$

These representations will be reducible, but can be reduced by the methods described in Hamermesh (1989), Chap. 10.

2.2.1 Equivalent Representations. If we have a representation $D(R)$ of the group G and make a transformation of basis in the space of the representation, using some matrix P, we can form matrices $PD(R)P^{-1}=D'(R)$, and it is easy to verify that these also form a representation of G with the same dimension as D. We also see that $D'(E)=1$, and $D'(R)D'(S)=D'(RS)$, since $PD(R)P^{-1}\times PD(S)P^{-1}=PD(R)D(S)P^{-1}=PD(RS)P^{-1}$. We say that the two representations D and D' are equivalent. They are isomorphic and represent only a change of basis. Equivalent representations have the same set of eigenvalues. The diagonal sum (trace) is the same for $D(R)$ and $D'(R)$. We call this quantity which is the same for any two equivalent representations the character $\chi(R)$ of R in the representation D: $\mathrm{Tr}\,D'=D'_{ii}=D_{ii}=\mathrm{Tr}\,D$. If two elements R and S of the group G are in the same conjugate class, so that there is an element P of the group such that $S=PRP^{-1}$, then $D(S)=D(P)D(R)D(P^{-1})$ and, taking the trace, we get $\chi(S)=\chi(R)$. Thus all elements in the same class in G have the same character.

2.2.2 Addition of Representations. Reducibility and Irreducibility. Suppose that we have two representations $D^{(1)}$ and $D^{(2)}$ of the same group G, where $D^{(1)}$ has dimension n_1 and acts on coordinates x_i, $i=1,\ldots,n_1$, and $D^{(2)}$ has dimension n_2 and acts on some other space with coordinates x_i, $i=n_1+1,\ldots,n_1+n_2$. Thus the matrices $D^{(1)}(R)$ are $n_1\times n_1$ matrices and the $D^{(2)}(R)$ are $n_2\times n_2$. For each R in G, we construct a new representation D that has dimension n_1+n_2,

$$D(R)=\begin{pmatrix} D^{(1)}(R) & 0 \\ 0 & D^{(2)}(R)\end{pmatrix}$$

and acts on the column vectors

$$\begin{bmatrix} x_1 \\ \vdots \\ x_{n_1} \\ x_{n_1+1} \\ \vdots \\ x_{n_1+n_2} \end{bmatrix},$$

and $D(R)=D^{(1)}(R)\dot{+}D^{(2)}(R)$. The two representations act separately in the two subspaces. If we make a change of basis in the (n_1+n_2)-dimensional space so that the x's mix, the equivalent representation will no longer have this block form, and it will not be evident that the representation is actually a "sum" of two independent representations. Now we proceed in the reverse directions. Given a representation of the group in some space of dimension N, we ask whether it is possible to find a simultaneous decomposition of the matrices for all R into invariant subspaces of dimensions n_1, n_2 such that $n_1+n_2=N$, so that $D(R)$ acting on vectors in subspace 1 gives vectors in that subspace, and similarly for subspace 2. If this is true for all R in G we say that the representation D of dimension N is reducible and has been decomposed into the sum of $D^{(1)}$ and $D^{(2)}$. Next we try to find decompositions of the subspaces 1 and 2 into invariant subspaces. This process must end in a finite number of steps, and we finally have a decomposition of the original representation space into a sum of subspaces, and $D=D^{(1)}\dot{+}D^{(2)}\dot{+}\cdots\dot{+}D^{(r)}$, where none of the representations $D^{(i)}$ has an invariant subspace. Then we say that the original representation $D(R)$ has been *fully reduced.* If the carrier space of D contains no proper invariant subspace, we say that the representation is irreducible. Note that the character of the representation $D(R)$ is the sum of the characters of its irreducible component representations: $\chi(R)=\Sigma_i\chi^{(i)}(R)$. The same irreducible representation can occur several times in the decomposition, so that, in general, $D=\dot{\Sigma}_i a_i D^{(i)}$, and $\chi=\Sigma_i a_i\chi^{(i)}$, where a_i are positive integers.

2.2.3 Invariance of Functions and Operators. We found earlier that $O_R\psi(x)=\psi(R^{-1}x)$, so $O_R\psi$ is not the same as ψ. If $O_R\psi$ is the same as ψ, so that $\psi(Rx)=\psi(x)$, we see that the function ψ is invariant under the transformations. To test for invariance we replace the arguments x of any function $\psi(x)$ by Rx and see whether we get the same expression. If an operator T acts on a function ψ we get a function $\varphi=T\psi$, and applying the operator O_R to $T\psi$ we get

$$O_RT\psi(x)=\varphi(R^{-1}x)=T(R^{-1}x)\psi(R^{-1}x), \quad (15)$$

$$\begin{aligned} O_RT(x)O_R^{-1}O_R\psi(x)&=T(R^{-1}x)O_R\psi(x)\\ &=T'(x)O_R\psi(x), \end{aligned} \quad (16)$$

where $T'(x)=T(R^{-1}x)$. In general the operators T and T' are different. If they are the same, i.e., if

$$O_RT(x)O_R^{-1}=T(x), \quad (17)$$

the operator T is invariant under the transformation. In other words the operator T commutes with O_R. For example, the function x^2+y^2 is invariant under rotations around the z axis, and also under inversion. The operator $\partial^2/\partial x^2+\partial^2/\partial y^2$ is also invariant under these transformations. A function describing the state of a system of identical particles is invariant under any permutation of the particles.

Now we can see the connection of group theory with physics. The Hamiltonian H of a physical problem may be invariant under some operators T. The collection of these operators and all possible products form a group G—the symmetry group of the Hamiltonian H. The basis functions for an irreducible representation of this symmetry group must be transformed into vectors in this same space by the operators $D^{(\mu)}(R)$. This m-dimensional space provides us with an m-fold degeneracy of the particular energy level. For a reducible representation of the symmetry group G more states seem to be transformed among themselves, but we can reduce the representation by finding the irreducible components. The basis functions for an irreducible representation *must* transform into one another under the operations of the symmetry group. It may happen that a problem gives degeneracies that are greater than expected from the assumed symmetry group. We must then search for some symmetry operation beyond those assumed. Often this occurrence is labeled as "accidental" degeneracy. Note that the basis function $\psi_i^{(\mu)}$ for the irreducible representation $D^{(\mu)}$ is said to belong to the ith row of the representation.

2.3 General Theorems

We now list without proof the general theorems that enable us to reduce any representation of a group G into its irreducible constituents.

Schur Lemma 1. If D and D' are two irreducible representations of a group G, having different dimensions, and the matrix T satisfies $D(R)T=TD'(R)$ for all R in G, then the matrix T must be the null matrix $T=0$.

Schur Lemma 1a. If D and D' have the same dimensions and are irreducible representations of G, and if $D(R)T=TD'(R)$ for all R, then either D and D' are equivalent or $T=0$.

Schur Lemma 2. If the matrices $D(R)$ are an irreducible representation of G and if $TD(R)=D(R)T$ for all R, then T is a multiple of the unit matrix: $T=\text{const }1$. This lemma gives an easy test of irreducibility.

Next we present the orthogonality relations. The quantities $D_{ij}^{(\mu)}(R)$ for fixed μ, i, j form a vector (whose components are labeled by R) in a g-dimensional space (where g is the order of G). If $D^{(\mu)}$ and $D^{(\nu)}$ are two nonequivalent irreducible representations of G, then

$$\sum_R D_{il}^{(\mu)}(R)D_{mj}^{(\nu)}(R^{-1})=\frac{g}{n_\mu}\,\delta_{\mu\nu}\delta_{ij}\delta_{lm}, \tag{18}$$

where n_μ is the dimension of the representation $D^{(\mu)}$. If $D^{(\mu)}$ and $D^{(\nu)}$ are the same D, then

$$\sum_R D_{il}(R)D_{mj}(R^{-1})=\frac{g}{n}\,\delta_{ij}\delta_{lm}. \tag{19}$$

If the representations are unitary, we replace $D_{mj}(R^{-1})$ by $D_{jm}^{*}(R)$. Thus each irreducible representation $D^{(\mu)}$ gives us n_μ^2 vectors $D_{ij}^{(\mu)}(R)$ $(i, j=1,\dots,n_\mu)$ that are orthogonal to one another and to all such vectors formed from nonequivalent representations. Since the number of orthogonal vectors in a g-dimensional space cannot exceed g, we must have $\Sigma_\mu n_\mu^2\leqslant g$. We can obtain similar formulas for the characters $\chi^{(\mu)}$ by setting $i=l$ and $j=m$ and summing over i and j:

$$\sum_R \chi^{(\mu)}(R)\chi^{(\nu)}(R^{-1})=g\delta_{\mu\nu}\,, \tag{20}$$

or

$$\sum_R \chi^{(\mu)}(R)\chi^{(\nu)*}(R)=g\delta_{\mu\nu} \tag{21}$$

if the representation is unitary. We saw earlier that all the group elements in the same class have the same character. We label the classes K_1 to K_r, and denote by g_i the number in the class K_i. Then the last equation becomes

$$\sum_{i=1}^{r} \chi_i^{(\mu)}\chi_i^{(\nu)*}g_i=g\delta_{\mu\nu}, \tag{22}$$

where $\chi^{\mu}(R)=\chi_i^{(\mu)}$ for all elements in the class K_i.

2.4 Kronecker Product of Representations

If we have two irreducible representations $D^{(\mu)}$ and $D^{(\nu)}$ of the symmetry group, we can take products of their basis functions and get the Kronecker product representation $D^{(\mu\times\nu)}(R)$ with matrices

$$[D^{(\mu\times\nu)}(R)]_{ik,jl}=D_{ij}^{(\mu)}(R)D_{kl}^{(\nu)}(R). \tag{23}$$

The character of $D^{(\mu\times\nu)}$ can be found by setting $j=i$, $l=k$, and summing over i and k:

$$\chi^{(\mu\times\nu)}(R)=\chi^{(\mu)}(R)\chi^{(\nu)}(R). \tag{24}$$

All elements R in the same class K_i will have the same character $\chi_i^{(\mu\times\nu)}$. The scalar product of the basis functions is

$$(\psi_i^{(\mu)},\varphi_j^{(\nu)})=\int d\tau\, \psi_i^{(\mu)*}\varphi_j^{(\nu)}. \tag{25}$$

For unitary representations this expression is identical with $(D^{(\mu)}(R)\psi_i^{(\mu)},D^{(\nu)}(R)\varphi_j^{(\nu)})$ for any R. If we use Eq. (13) and the orthogonality relation of Eq. (18) we find

$$(\psi_i^{(\mu)},\varphi_j^{(\nu)})=\frac{1}{n_\mu}\sum_k (\psi_k^{(\mu)},\varphi_k^{(\nu)})\delta_{\mu\nu}\delta_{ij}. \tag{26}$$

The scalar product is zero for $i\neq j$, i.e., basis functions belonging to different rows are orthogonal. Setting $\mu=\nu$ and $i=j$, we find that $(\psi_i^{(\mu)},\varphi_i^{(\mu)})$ is independent of i. This means that the scalar product of two functions belonging to the same row of an irreducible representation is independent of the row. We shall see that this result is the basis of the use of perturbation theory and selection rules throughout the applications of group theory.

2.5 Analysis of Representations

If we know the characters of the irreducible representations of the group G, we can use the above theorems to find how a given representation decomposes into irreducible constituents. We found (see p. 376) the equation

$$D(R)=\sum_{\mu} a_\mu D^{(\mu)}(R). \tag{27}$$

Taking the trace for an element R in the class K_i, we get

$$\chi_i=\sum_{\mu} a_\mu \chi_i^{(\mu)}. \tag{28}$$

Next we multiply by $\chi_i^{(\nu)*}g_i$ and sum over i. Using the orthogonality relations found earlier, this gives

$$a_\nu=\frac{1}{g}\sum_{i} g_i \chi_i^{(\nu)*}\chi_i. \tag{29}$$

Thus the number of times a given irreducible representation is contained in D is given by this formula. In particular this shows that if two representations have the same set of characters, they are equivalent. Again, if we multiply Eq. (29) by g times its complex conjugate equation and sum over i, we find

$$\sum_{i} g_i|\chi_i|^2=g\sum_{\mu} a_\mu^2. \tag{30}$$

If the representation is irreducible, all the a_μ must be zero, except for one which is equal to 1. So if the representation is irreducible, its characters must satisfy the equation

$$\sum_{i} g_i|\chi_i|^2=g, \tag{31}$$

which gives a simple test for irreducibility. Finally one can show that the number of inequivalent irreducible representations is precisely equal to the number of conjugate classes in the group, and that

$$g=\sum_{\mu=1}^{r} n_\mu^2, \tag{32}$$

i.e., the sum of the squares of the dimensions of all the nonequivalent irreducible representations is equal to the order of the group.

We give some examples of finding characters for some groups.

1. Cyclic groups: $a,\ldots,a^n=e$. These groups are Abelian, so all irreducible representations have dimension 1. The matrices are 1×1 and the representative is just the character, a complex number. Since $a^n=e$, the nth power of the character $D(a)$ must equal 1, so $D(a)=\exp(2\pi im/n)$, $m=1,\ldots,n$, and $D(a^r)=\exp(2\pi imr/n)$.
2. General Abelian group. Again all irreducible representations are one-dimensional. We choose any element and take its powers. This gives a cyclic subgroup of G. We repeat this process with some other element. We see that the group is a direct product of cyclic subgroups. For example, if $G=C_2\otimes C_3\otimes C_5$, with $g=30$, we have generators a,b,c, with $a^2=b^3=c^5=e$, and the character of any element $a^m b^n c^p$ is $\exp[2\pi i(mr/2+ns/3+pt/5)]$.
3. Point groups. These are the groups of rotations about a fixed point (the origin) and reflections in planes through the origin. For crystals, only the rotations through multiples of $2\pi(\frac{1}{2};\frac{1}{3};\frac{1}{4};\frac{1}{6})$ are permitted, i.e., only cyclic subgroups C_2, C_3, C_4, C_6. As a typical example, we treat the octahedral (cubic) group O. This is the group of rotations about axes through the center of the cube that take the cube into itself. It consists of 24 rotations in 5 classes: 6 rotations C_4,C_4^3 around lines joining the midpoints of opposite faces; 3 rotations C_4^2 around these same axes; 6 rotations C_2 around lines joining the midpoints of opposite edges; 8 rotations C_3,C_3^2 around lines joining opposite vertices of the cube; and the identity E. There are five nonequivalent irreducible representations. Using Eq. (32) we find

$$24=\sum_{\mu=1}^{5} n_\mu^2$$

which has the unique solution $n_\mu=3,3,2,1,1$. The character table for this group is

	E	$C_3,C_3^2(8)$	$C_4^2(3)$	$C_2(6)$	$C_4,C_4^3(6)$
Γ_1	1	1	1	1	1
Γ_2	1	1	1	-1	-1
Γ_3	2	-1	2	0	0
Γ_4	3	0	-1	1	-1
Γ_5	3	0	-1	-1	1

where $\Gamma_1,\ldots,\Gamma_5$ label the irreducible representations. The column vectors are orthogonal:

$$1(1)+1(1)+2(-1)+3(0)+3(0)=0, \text{ etc.,}$$

and normalized to $g=24$:

$$1^2+1^2+2^2+3^2+3^2=24,$$
$$8[1^2+1^2+(-1)^2]=24, \text{ etc.}$$

The row vectors are also orthonormal when we include the factors g_i:

$$1(2)+8(1)(-1)+3(1)(2)+6(-1)(0)$$
$$+6(-1)(0)=0,$$
$$3^2+8(0)(0)+3(-1)^2+6(1)^2+6(-1)^2$$
$$=24, \text{ etc.}$$

4. The permutation groups S_n. These finite groups are important for dealing with identical particles, construction of irreducible tensors, and finding states in atomic or nuclear shell models. Earlier we described the conjugate classes in S_n. We found that there is a class corresponding to each partition of n. For example, for $n=3$, we have $r=3$ and $g=3!$, so $6=\Sigma_i n_i^2$, so $n_i=2,1,1$. There are two one-dimensional and one two-dimensional irreducible representations. The character table is

	E	$(12)_3$	$(123)_2$
Γ_1	1	1	1
Γ_2	1	-1	1
Γ_3	2	0	-1

For large n, the simple procedure becomes impractical. Instead we use Young diagrams. For each partition of $n=n_1+n_2+\cdots+n_r$, with $n_1 \geqslant n_2 \geqslant \ldots \geqslant n_r$, we draw a diagram with n_1 dots in the top row, n_2 in the second, etc. For example, for $n=5=3+1+1$ we get the Young diagram

• • •
•
•

Each such partition gives an irreducible representation of the group S_n. Next we enter the digits 1–5 in the boxes in all possible ways that keep the entries increasing to the right in rows and down in columns. These arrangements are the standard Young tableaux:

$$\begin{array}{cccccc} 123 & 124 & 125 & 134 & 135 & 145 \\ 4 & 3 & 3 & 2 & 2 & 2 \\ 5 & 5 & 4 & 5 & 4 & 3\,. \end{array}$$

There are six standard tableaux so the dimension of this irreducible representation is 6. The use of the symmetric group S_n and the construction of irreducible representations is discussed in Hamermesh (1989), Chaps. 7 and 10.

5. SO(3) is the group of pure rotations in three dimensions. All rotations through a given angle θ about any axis **n** are in the same class (see p. 368), so if we choose the z axis for **n** the rotation matrix is

$$\begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix},$$

and the character for the vector representation is $\chi^{(1)}(\theta)=1+2\cos\theta=e^{i\theta}+e^0+e^{-i\theta}$. One can show that there is a single irreducible representation for each integer $l=0,1,\ldots$ with

$$\chi^{(l)}(\theta)=\sum_{m=-l}^{+l} e^{im\theta}, \tag{33}$$

and the dimension of the representation is $\chi^{(l)}(0)=2l+1$. There are also irreducible representations of SO(3) for $l=\frac{1}{2}, \frac{3}{2}$, etc. These are double-valued representations that can be derived by using the group SU(2), which is homomorphic to SO(3) with two elements corresponding to each element of SO(3). These irreducible representations give all information needed about states in a central field. For a detailed treatment of group representations, see Elliott and Dauber (1979), Chaps. 4 and 7; Hamermesh (1989), Chaps. 3, 4, and 5.

3. APPLICATIONS

3.1 Atomic Structure

The application of group theory to most physical problems requires the use of some model. It should be evident that we cannot consider the quantum problem exactly if we have more than two entities interacting with one another. We must find some method of successive approximations that enables us finally to get satisfactory agreement with experimental results. In atomic physics our procedure is first to consider the individual electrons to be moving in the field of the nucleus and some spherically symmetric averaged field of the other electrons in the atom. In this central field the Hamiltonian for the individual electron has the symmetry group SO(3), so the states of a single electron have quantum numbers l and $m=-l,\ldots,+l$. A single-particle level with quantum number l has degeneracy $2l+1$. There will be many states with a given lm, with energies $E=b/n^2$ approximately, where $n=1,2,\ldots$ giving us a triple of labels n, l, m, with $n\geqslant l+1$, and $l=0,1,\ldots$, where l is the orbital angular momentum. Often we use letters in place of l:

$l=$	0	1	2	3	4
state label	s	p	d	f	g.

For $l=0$, we have 1s, 2s, 3s,...; For $l=1$, we have 2p, 3p,...; For $l=2$, we have 3d, 4d,...,etc. The energy levels are given approximately by $E=b/n^2$, so the level ns is nondegenerate ($m=0$), the level np has $m=\pm 1,0$, etc. In addition we know that each electron carries an internal angular momentum (spin) with $s=\frac{1}{2}$. In light atoms the spin results in there being two states (with $m=\pm\frac{1}{2}$). This results in doubling the occupancy of each level. Thus we have a level sequence

Level	1s	2s	2p	3s	3p	3d	4s	4p	4d	4f
Degeneracy	2	2	6	2	6	10	2	6	10	14 ,

etc., where the atomic shells are labeled by n, and have a total number of electrons=2, 8, 18,... . The order of the levels goes with n, but some changes occur when the 3d and 4f levels become partly filled.

To study the spectrum of levels for an atom with atomic number Z, we fill the single-particle levels successively. For example, for $Z=16$, the only unfilled shell would be 3p, with two electrons. This state would be described by $(1s)^2(2s)^2(2p)^6(3s)^2(3p)^2$. The closed inner shells have spherical symmetry, so we consider only the two electrons in the 3p shell. The orbital states of the two electrons have $l_1=l_2=1$, while the spin states are $s_1=s_2=\frac{1}{2}$. For light atoms we use Russell-Saunders coupling, in which we first find the Kronecker product of all the space functions, and separately of all the spin functions, and then couple the two resultants. To keep the Coulomb force between the electrons unchanged requires that the same rotation R be applied to both electrons, so that we are taking the product representation $D^{(l_1)}(R)D^{(l_2)}(R)$. The basis functions are $\psi^{(1)}_{m_1}(1)\psi^{(1)}_{m_2}(2)$, giving nine coupled wave functions. This reducible representation can be decomposed into $L=2,1,0$. The two spins will couple to $S=1,0$. Finally we include the weaker coupling of orbit and spin to give the states of total angular momentum $J=L+S$, and find states $^3D,^3P,^3S$ and $^1D,^1P,^1S$. But we must also consider that the electrons are identical particles (fermions), and so the Pauli principle requires that the total wave function must be antisymmetric under the interchange of all coordinates of the two electrons. For this simple case of two electrons the nine functions $\psi^{(1)}_{m_1}(1)\psi^{(1)}_{m_2}(2)$ can be split into a symmetric second-rank tensor (with trace zero), an antisymmetric second-rank tensor, and a scalar. The orbital states with $L=2,0$ are symmetric while the state with $L=1$ is antisymmetric. The spin states with $S=1$ are symmetric (triplet states) while the $S=0$ singlet states are antisymmetric. Thus the Pauli principle allows only the states $^3P,^1D,^1S$. Note that this argument would not apply to the case of $(3p)(4p)$ because then the states of the two electrons are not the same, so the Pauli principle has no effect.

This simple procedure fails if there are more than two electrons in the same subshell. For example, for the case of $(3p)^3$ we would have 27 product functions $\psi^{(1)}_{m_1}(1)\times\psi^{(1)}_{m_2}(2)\psi^{(1)}_{m_3}(3)$ while the spin part would be the product of three spin-$\frac{1}{2}$ functions. The general procedure requires the use of irreducible tensors. If we have r electrons in a subshell with angular momentum l our spatial wave function for one electron is $\psi^{(l)}_m$, and for the r electrons the product is $\Psi=\psi^{(l)}_{m_1}(1)\times\ldots\psi^{(l)}_{m_r}(r)$ with $m_i=-l,\ldots,+l$. Thus Ψ is an rth-rank tensor in a space of dimension $2l+1$.

Since all these functions are degenerate, the transformations of the group SU$(2l+1)$ act on these ψ's. We then must classify them according to the irreducible representations of SU$(2l+1)$ with their particular symmetries. Similarly, for the spins we have tensors $\varphi^{(1/2)}_{\mu_1}(1),\dots,\varphi^{(1/2)}_{\mu_r}(r)$ of rank r in the space of dimension 2. Again we must find the irreducible pieces. Finally, to satisfy the Pauli principle we must assure that the total wave function is antisymmetric. For the detailed treatment, see Hamermesh (1989), Chap. 11, or Elliott and Dauber (1979), Chap. 8.

3.2 Nuclear Structure

In the case of atoms, we know that the interactions are electromagnetic, and we have just one type of identical particle, electrons. In the case of the nucleus we have two constituents, neutrons and protons, which have approximately equal masses and can transform into one another in β-ray processes. The Coulomb force between protons is small compared with the specific nuclear force, so we use a model in which we disregard the differences between n and p, and deal with a single type of identical particles, nucleons, in two charge states. This looks like the case of two possible spin states for electrons. Both n and p have an intrinsic angular momentum $s=\frac{1}{2}$, but now there is another intrinsic feature, the isospin $t=\frac{1}{2}$. The other important difference is that we have little basis for choice of a model. We start with no knowledge of the interaction and must try various shapes for its radial dependence and its dependence on spin and isospin.

The most successful model requires the use of j-j coupling. In such models we first couple (i.e., take the product of) the $\psi^{(l)}$ and $\psi^{(s)}$ for an individual nucleon to give a resultant $\psi^{(j)}$ and then couple the $\psi^{(j)}$s (i.e., take products of $\psi^{(j)}_m$ for the nucleons). Since the nuclear force is attractive, the state with lowest j for a given l,s will have the highest symmetry (since the particles can get closest to one another). The order of the levels will also depend on the choice of the radial dependence of the potential. One model is shown in the following diagram of single-particle levels and their degeneracies:

Nucleon states		Occupation	Total
$1g_{9/2}$		10	50
	$2p_{1/2}$	2	
$1f_{5/2}$		6	
	$2p_{3/2}$	4	
$1g_{7/2}$		8	28
$1d_{3/2}$		4	20
	$2s_{1/2}$	2	
$1d_{5/2}$		6	
$1p_{1/2}$		2	8
$1p_{3/2}$		4	
$1s_{1/2}$		2	2

The numbers in the right-hand column are the magic numbers corresponding to the closed shells.

As in the atomic case, we look only at the partially filled shells. If we consider a level $(j)^3$, the single-particle state has a wave function $\psi^{(j)}$ that is a vector in a space of dimension $2j+1$. Since the js are halves of odd integers, $2j+1$ is even. The wave function for $(j)^3$ is $\psi^{(j)}_{m_i}(1)\psi^{(j)}_{m_2}(2)\psi^{(j)}_{m_3}(3)$, a third-rank tensor in a space of dimension $2j+1$. Next we take the product of the three isospin functions which are vectors in a space of dimension 2. Just as in the atomic case, we must find the irreducible parts of each tensor. For the isospin tensor we get $T=\frac{3}{2},\frac{1}{2},\frac{1}{2}$. The completion of the problem would be the same as in the atomic case [see Hamermesh (1989), Chap. 11-9].

3.3 Solid State and Crystal-Field Theory

In discussing atomic structure we used a central-field model in which the Hamiltonian had the symmetry group SO(3). If we study the energy levels of electrons in a crystal, this is no longer the correct symmetry group. Now the electron moves in the periodic field of the crystal lattice. In the neighborhood of a lattice point the field is no longer spherically symmetric. It now has the symmetry of one of the crystal point groups. For example, the wave function of an electron in a cubic crystal will belong to an irreducible representation of the cubic point group O. Thus the possible degeneracy of a level will be 1, 2, or 3. (See the character table on p. 378.) If the crystal is distorted, the point symmetry group will be reduced from O to some lower symmetry and the levels may split. Or we may consider what happens to a level in a free atom when the atom is put at a crystal site. In the free atom the levels correspond to irreducible representations of the symmetry group SO(3). When the atom is placed in the crystal, we must use the crystal-field symmetry. The level with a given l may split into levels belonging to the symmetry group of the crystal ("crystal-field theory"). We illustrate this for the octahedral group. A level belonging to the irreducible representation $D^{(L)}$ of SO(3) has the character

$$\chi^{(L)}_{(\theta)} = \sum_{m=-L}^{+L} e^{im\theta}.$$

In the crystal this representation will be reducible. The cubic field has only rotations through angles $\theta=0$, $\pi/2$, π, and $2\pi/3$. In the crystal we need to record only the $\chi^{(L)}(\theta)$ for these values of θ. We repeat the character table of O from p. 376 and enter below the characters for $L=0$, 1, etc. Then we decompose using Eq. (29):

	E	$C_3,C_3^2(8)$	$C_4^2(3)$	$C_2(6)$	$C_4,C_4^3(6)$
Γ_1	1	1	1	1	1
Γ_2	1	1	1	-1	-1
Γ_3	2	-1	2	0	0
Γ_4	3	0	-1	1	-1
Γ_5	3	0	-1	-1	1
$L=0$	1	1	1	1	1
$L=1$	3	0	-1	-1	1
$L=2$	5	-1	1	1	-1
$L=3$	7	1	-1	-1	-1
$L=4$	9	0	1	1	1

For example, we see that $L=0$ gives Γ_1. $L=1$ is just Γ_5 so the vector does not split in a cubic field. For $L=2$ we find $\Gamma_3+\Gamma_4$, so the level splits into a doublet and a triplet. $L=3$ splits into $\Gamma_2+\Gamma_4+\Gamma_5$, while $L=4$ gives $\Gamma_1+\Gamma_3+\Gamma_4+\Gamma_5$. For details and applications to various point groups and the construction of wavefunctions, see Hamermesh (1989), Chap. 9; Elliott and Dauber (1979), Chap. 14; or Burns (1977), Chaps. 8, 11, and 12.

4. SUMMARY

Group theory has developed in the last 60 years to become an essential tool in many branches of physics and chemistry. After a mathematical introduction to the subject, we have given examples of its application to atomic and nuclear structure, and to crystal-field theory.

INTRODUCTION

Thermodynamic devices that convert heat into work are called *heat engines*; these work producers require both a heat source and a heat sink and, to be useful, should operate in a cyclic manner. Examples are steam power plants, internal combustion engines, and gas turbines. On the other hand, thermodynamic devices that use work to transfer heat from a lower temperature to a higher temperature are also heat engines but are referred to as *refrigerators*. In addition to traditional kitchen refrigerators, cold rooms, and air conditioners, whose purpose is to transfer heat out of a space so as to lower its temperature, the term refrigerators also includes *heat pumps*, whose purpose is to transfer heat into a space so as to increase its temperature. The term heat engine is used at times to denote both work producers and refrigerators and at others to denote work producers only.

Each heat engine has its own descriptive cycle that has losses, and thus is irreversible, and that does not lend itself to simple modeling and analysis. Fortunately, however, it is possible to approximate an actual cycle by an ideal cycle, a cycle with reversible (lossless) processes that can be analyzed to yield insight into the performance and design of the actual cycle, particularly with respect to the influence of various parameters on the cyclic performance. Furthermore, the performance of the ideal cycle is a measure of the best performance that can be expected from the actual cycle and can therefore be used as a figure of merit when comparing different configurations of an actual cycle. This article is limited to a description of each major heat engine (and refrigerator) in terms of its ideal cycle and associated performance; several of the actual cycles and their associated hardware are discussed in separate articles. Since the reader is assumed to have some knowledge and understanding of engineering thermodynamics (see THERMODYNAMICS, EQUILIBRIUM), only a brief review of those elements deemed necessary to an understanding of the ideal cycles is presented in this article.

1. THERMODYNAMIC CONSIDERATIONS

1.1 Thermodynamic Definitions

Engineering thermodynamics deals primarily with thermodynamic systems containing pure substances (and gaseous air) whose composition is the same whether a solid, liquid, or gas. A thermodynamic system is defined by boundaries that must be carefully drawn so as to identify the problem of interest; for example, the thermodynamic behavior of an automobile engine cylinder with the boundaries drawn just inside the cylinder walls differs from the behavior with the boundaries drawn so as to include the cylinder walls. Heat and work can cross the boundaries of a thermodynamic system; although input heat and output work are generally considered to be positive, other sign conventions may be encountered. If mass does not cross the boundaries (a *closed system*), any work, in or out, is accomplished by movement of the boundaries. If, on the other hand, mass does cross the boundaries (an *open system*), the boundaries remain stationary and any work is shaft or indicated work.

The condition of a system at any instant of time or location is called the *state* of the system and is established by a minimum number of independent properties. A change in one or more of these properties results in a change of state, and one or more changes of state constitute a *process*. When a system undergoes one or more changes of state and returns to its original state, the series of processes forms a *cycle*. A *reversible process* is one with no losses, and the processes of a reversible cycle are all individually reversible.

The three fundamental thermodynamic properties are pressure P, temperature T, and specific volume v (the inverse of the density). Other properties of interest are the specific internal energy u, the specific enthalpy h, and the specific entropy s. Enthalpy and entropy are both derived properties, enthalpy for convenience in analyzing open systems and entropy as a measure of the reversibility (or irreversibility) of a process. The differentials of the properties are exact and can be integrated without regard to the path traveled in going from one state to another. Heat and work, on the other hand, are not properties since their differentials are inexact and cannot be integrated without a knowledge of the path traveled. Heat and work cannot be stored, only transferred or transformed.

Pure substances can have different molecular structures, with clearly identifiable boundaries, which are known as *phases*. The three principal phases are solid, liquid, and vapor (at high temperatures a vapor is usually referred to as a superheated vapor or a gas), and there may be phases within a principal phase. The three principal phases of water, for example, are known as ice, water (the liquid phase), and steam (or vapor). When more than one phase is present, as with ice in water, the phases are separated from each other by boundaries. There is a single combination of temperature and pressure (the *triple point*) where all three phases can simultaneously exist in equilibrium.

In thermodynamic systems, the two phases of primary interest are the liquid and vapor phases and their combination, referred to as a (two-phase) mixture. Figure 1 is a typical (not to scale) T-v phase diagram that shows these phases and the lines of demarcation. The region labeled SMR is called the *saturated-mixture region* and is a two-phase combination of liquid and vapor; the boundaries of the SMR define what is known as the *vapor dome*. The *compressed-liquid region* (CLR) lies to the left of the SMR, and the line of demarcation is known as the *saturated-liquid line*, the combination of P-v-T at which a liquid begins to vaporize. The region to the right of the vapor dome labeled SHV is the *superheated-vapor region* (which blends into the gaseous region) and this line of demarcation is the *saturated-vapor line*. Within the SMR, the composition of the two-phase (saturated) mixture ranges from all liquid (the start of vaporization or boiling) to all vapor (no liquid remaining) and is described in terms of its *quality*, the percentage of vapor mass present.

The saturated-liquid and saturated-vapor lines come together at the *critical point* at the top of the vapor dome. At temperatures above the critical point, there is no distinction between the liquid and vapor phases; the substance becomes a *supercritical fluid*. Two isobars (lines of constant pressure) have been drawn to show the nature of the isobars in the various regions.

Tables of thermodynamic properties in these various regions are available for substances commonly used in thermodynamic

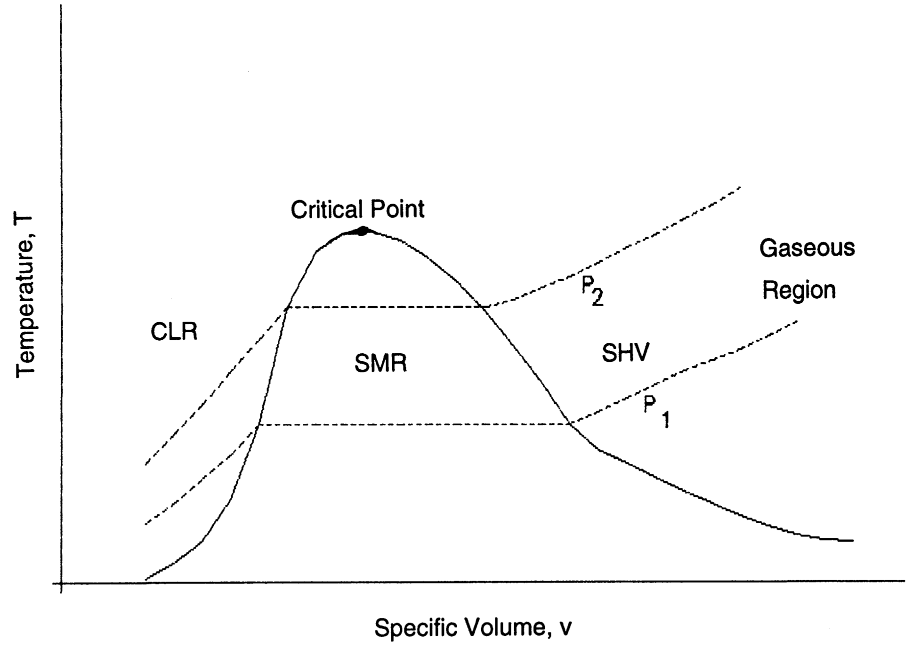

FIG. 1. A typical *T-v* diagram (not to scale) showing the regions of thermodynamic interest.

systems; for example, there are extensive tables for water (the steam tables) along with tables for such substances as ammonia, nitrogen, mercury, and the various Freon refrigerants. These tables have been constructed primarily from experimental data that have been correlated with and verified by thermodynamic relationships.

Tables are not needed for *ideal* or *perfect gases*, which are gases at high temperatures and low pressures whose intermolecular forces and molecular size can be neglected. Their properties can be found from relationships such as the *P-v-T* relationship,

$$Pv=RT, \tag{1}$$

where P is the pressure, v the specific volume, T the absolute (thermodynamic) temperature, and R the gas constant for the gas of interest. R can be found from tables or from the relationship that $R=R_u/M$, where R_u is the universal gas constant and M is the molecular mass of the gas.

Equation (1) is known as the *ideal-gas law* or the *equation of state for a perfect gas.* Although Eq. (1) may be used with acceptable error (along with other relationships) to determine the properties of many gases, including air, property tables should be used for the denser gases, such as water and refrigerant vapors in the vicinity of the SMR. The specific heats (C_p and C_v) are especially useful when dealing with changes of state of ideal gases as is the *ratio of specific heats k*, where $k=C_p/C_v$ and is always greater than unity.

1.2 Thermodynamic Laws and Equations

The continuity equation and the first law of thermodynamics are expressions of the conservation of mass and of energy, respectively. As for the mass balance of the continuity equation, the system mass is constant for a closed system; for an open system with steady-state flow the sum of the mass entering the system must be equal to the sum of the mass leaving the system.

As for the energy balance, the first law states that the net heat transferred across the boundaries is proportional to the net work done during a cycle (with SI units the constant of proportionality is unity). For a process, on the other hand, the net energy crossing the boundaries (the work and heat) will be equal to the change of the energy (internal, kinetic, and potential) of the system itself. For a closed system, the first law can be written on a per-unit-mass basis as

$$q=u_2-u_1+w=\Delta u-w, \tag{2}$$

where the values of q and w (the actual heat and work) are functions of how the change of state was accomplished (the path) whereas Δu, the change in internal energy, is a function only of the two states 1 and 2.

There is a large and important class of steady-state applications in which there is only one flow entering and leaving the system. They are known as *single-flow systems*, and the first law can be written as

$$q=(h_e-h_i)+(v_e^2/2-v_i^2/2)+w, \tag{3}$$

where h is the enthalpy per unit mass and the subscripts i and e denote the inlet and outlet states.

When the change in kinetic energy is negligible (as it is for well-designed systems, other than nozzles), Eq. (3) becomes

$$q=h_e-h_i+w=\Delta h+w. \tag{4}$$

Notice that Eq. (4) is similar in form to Eq. (2), the first law for a closed system, but with several differences. Whereas the closed system deals with the change in internal energy (Δu) over an interval of time, the open system deals with the change of enthalpy (Δh) between two locations, a spatial interval; in addition, the nature of the work involved differs, one being moving-boundary work and the other shaft work.

Although very useful, the first law has its shortcomings. For example, it does not indicate any limitations on the transformations between heat and work, such as the fact that all of the input heat cannot be transformed into work; the Kelvin-Planck statement affirms that some portion of the input heat must be transferred out of the system in order to complete a cycle (this "rejected heat" is commonly referred to as the *waste heat*). Neither does the first law show, in accordance with the Clausius statement, that work is required to transfer heat from a cooler body to a warmer body in order to complete a refrigeration cycle, nor does it indicate which processes can proceed in one direction only and may even be impossible.

These two statements, along with the inequality of Clausius, constitute what is known as *the second law of thermodynamics*. The second law leads to the derivation of a new property called *entropy*; the specific entropy can be used as an independent property to define a thermodynamic state. Since ds, the exact differential of the specific entropy, is defined as $\delta q/T$ for a reversible process, the amount of heat per unit mass that is transferred in a *reversible process* can be determined from the expression

$$q=\int_1^2 T\,ds, \tag{5}$$

where the limits of integration represent the start and end of the process and the relationship between T and s must be known.

Equation (5) shows that if a process is both reversible and adiabatic ($q=0$), the change in entropy will be zero; i.e., the process is *isentropic.* [If a reversible process is isothermal, then ${}_1q_2=T(s_2-s_1)$.]

Space does not permit a detailed discussion of the various expressions of the second law and their use, along with the entropy, to determine the nature (reversible, irreversible, or impossible)of cycles and processes, to determine a missing property, to serve as a baseline for evaluating process efficiencies, or to develop useful thermodynamic relationships.

1.3 Cycle Performance and Efficiency

The performance of a heat engine is described in terms of its *cycle (thermal) efficiency,* which is defined as the ratio of the net work output of the cycle to the input heat. Remembering that the first law for a cycle states that the net work is equal to the net heat transferred, the thermal efficiency of the cycle can be expressed on a per-unit-mass basis as

$$\eta_{\text{th}}=\frac{w_{\text{net}}}{q_{\text{in}}}=\frac{q_{\text{in}}-q_{\text{out}}}{q_{\text{in}}}=1-\frac{q_{\text{out}}}{q_{\text{in}}}, \tag{6}$$

where q_{out} includes the rejected (waste) heat (required by the second law) that keeps the efficiency less than 100%, as well as all other heat losses.

A refrigeration cycle is essentially a reversed heat-engine cycle whose objectives are to maximize the desired heat transfer and to minimize the required work input. Since the ratio of the transferred heat to the required work is greater than unity, the *coefficient of* *performance* (COP) is used to avoid efficiencies that would be greater than 100%.

With a refrigerator (or air conditioner) the desired heat transfer is that removed from the refrigerated space and is given the symbol q_L to denote transfer at the lower temperature; q_H denotes the necessary transfer of heat at the higher temperature. Consequently, the COP of a refrigerator is defined as

$$\mathrm{COP}=\frac{q_L}{w_{\mathrm{in}}}=\frac{q_L}{q_H-q_L}=\frac{1}{q_H/q_L-1}. \tag{7a}$$

With a heat pump, q_H, the heat transferred into the heated space, is the desired heat transfer, and the coefficient of performance $(\mathrm{COP})_{\mathrm{HP}}$ is given by

$$(\mathrm{COP})_{\mathrm{HP}}=\frac{q_H}{w_{\mathrm{in}}}=\frac{q_H}{q_H-q_L}=\frac{1}{1-q_L/q_H}. \tag{7b}$$

Note that there is a definite relationship between the two COP's, namely,

$$(\mathrm{COP})_{\mathrm{HP}}=1+\mathrm{COP}. \tag{7c}$$

This relationship should be considered when selecting a heat pump to be used as an air conditioner as well as a space heater.

1.4 The Carnot Cycle

The Carnot cycle serves as a baseline for evaluating cycle performance in that it has the highest efficiency (COP) of all heat engines (and refrigerators) operating between two temperatures and in that the Carnot efficiency is independent of the working substance. The Carnot cycle is distinguished by the fact that its processes are totally reversible in that, in addition to the absence of internal losses, all transfers of heat are isothermal and therefore externally reversible processes.

Figure 2 is the *T*-*s* diagram of a heat engine (work producer or refrigerator) operating in a Carnot cycle between two temperatures T_H and T_L and involving four totally reversible processes. This Carnot cycle is a work producer if traveled in a clockwise direction and a refrigerator if traveled in a counterclockwise (reversed) direction. For operation as a work producer, the first process, 1–2, is an isothermal transfer of heat q_H into the system from a high-temperature thermal reservoir; from Eq. (5) q_H is the area under the line connecting states 1 and 2. The second process, 2–3, is an isentropic ($ds=0$) expansion from T_H to T_L that produces work. The third pro-

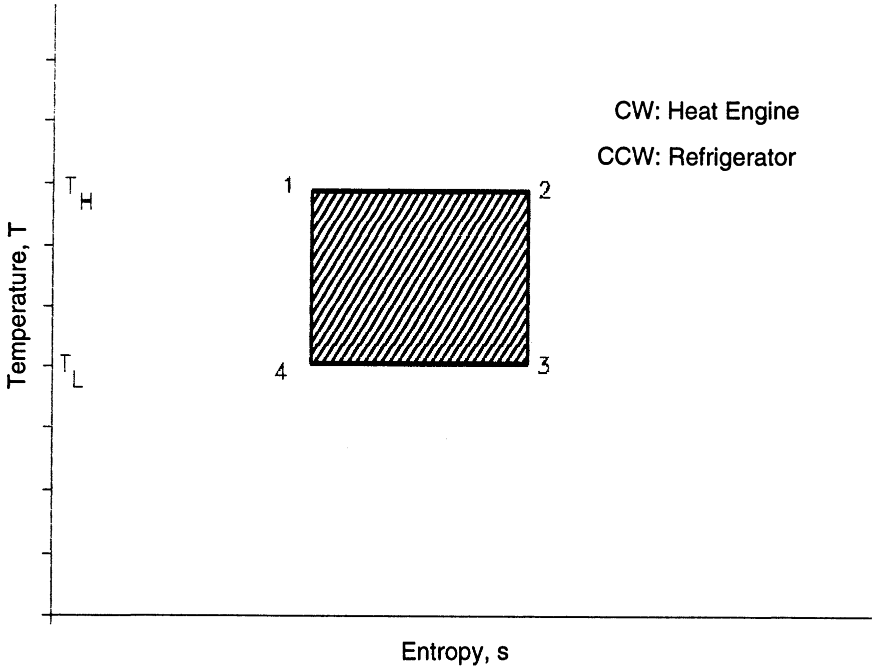

FIG. 2. The *T*-*s* diagram of a heat engine operating in a Carnot cycle.

cess, 3–4, is another isothermal transfer of heat, q_L, from the system to the low-temperature reservoir; q_L is the area under the line from 3 to 4. The fourth, and final, process is an isentropic compression, requiring a work input, that increases the temperature from T_L to T_H and completes the cycle. (The reversed cycle, 1–4–3–2–1, is that of a Carnot-cycle refrigerator.)

Since the thermal efficiency and COP expressions of Eqs. (6) and (7) are valid for all cycles, they are also valid for Carnot cycles but can be further defined in terms of the cycle temperatures, T_H and T_L. The relevant expressions are

$$\eta_{\text{th}}=\frac{w_{\text{net}}}{q_H}=\frac{T_H-T_L}{T_H}=1-\frac{T_L}{T_H}, \tag{8a}$$

$$\text{COP}=\frac{q_L}{w_{\text{in}}}=\frac{T_L}{T_H-T_L}=\frac{1}{T_H/T_L-1}, \tag{8b}$$

$$(\text{COP})_{\text{HP}}=\frac{q_H}{w_{\text{in}}}=\frac{T_H}{T_H-T_L}=\frac{1}{1-T_L/T_H}. \tag{8c}$$

Some words of caution are in order. These temperature relationships are valid for Carnot cycles only, and the net work is *not* the temperature difference nor is the heat transfer equal to the temperature; only the temperature *ratios* are valid, and the temperatures must be absolute (thermodynamic) temperatures.

The cross-hatched area in Fig. 2 represents the net work of the system: the output work for a heat engine and the required work for a refrigerator. The cyclic performance is improved by increasing the area for a heat engine and minimizing the area for a refrigerator when the heat transfer of interest is specified.

In the discussion of the cycles to follow, the appropriate Carnot cycle will serve as a starting point in developing an ideal cycle as well as providing a criterion for evaluating its performance. Since a real cycle is irreversible, its cycle efficiency or COP must be less than that of the Carnot cycle; if it is equal to or greater than the Carnot efficiency or COP, the cycle is not possible.

2. VAPOR (POWER) CYCLES

The isothermal heat transfers of the Carnot cycle can be approached by isobaric phase changes of a pure substance, by adding heat to a vaporizing liquid and removing heat from a condensing liquid while holding the pressure constant, i.e., by operating in the two-phase region (SMR). Such a vapor–liquid cycle is commonly referred to as a *vapor cycle* and is the basis of the Rankine cycle in its various forms. Rankine cycles can be used to generate power and, in a reversed mode, to provide refrigeration. Vapor cycles are characterized by a phase change of the working medium, by operation in the saturated-mixture (two-phase) region (the SMR of Fig. 1), and at times in the CLR.

Since the Rankine cycle has been used extensively in the past in steam power plants, this discussion of power-generation cycles will be limited to steam (see STEAM ENGINE). However, other fluids are under consideration along with other energy-conversion systems using geothermal energy, ocean thermal gradients, and solar energy.

2.1 The Vapor Carnot Cycle

The simplest steam plant has four major components; a steam generator (boiler), a turbine, a condenser, and a pump—two heat exchangers and two work devices. The vapor Carnot cycle represented by this steam plant is sketched in Fig. 3. The cycle remains within the SMR and starts with saturated (liquid) water entering the steam generator at state 1. The water is heated reversibly, isothermally, and isobarically until all of the water has turned to dry steam (vapor) at state 2, which is at the edge of the saturated-mixture region (SMR). This dry steam is then expanded isentropically in the turbine to state 3, producing work (and partially condensing) during the process. At state 3 this wet steam is further condensed reversibly, isothermally, and isobarically to state 4, where the still wet steam enters a pump that isentropically raises the pressure and temperature to state 1 and the cycle is complete.

Although this Carnot cycle has the highest possible cycle efficiency for the specified boiler and condenser pressures (and corresponding temperatures), it also has several serious practical drawbacks. The first drawback deals with

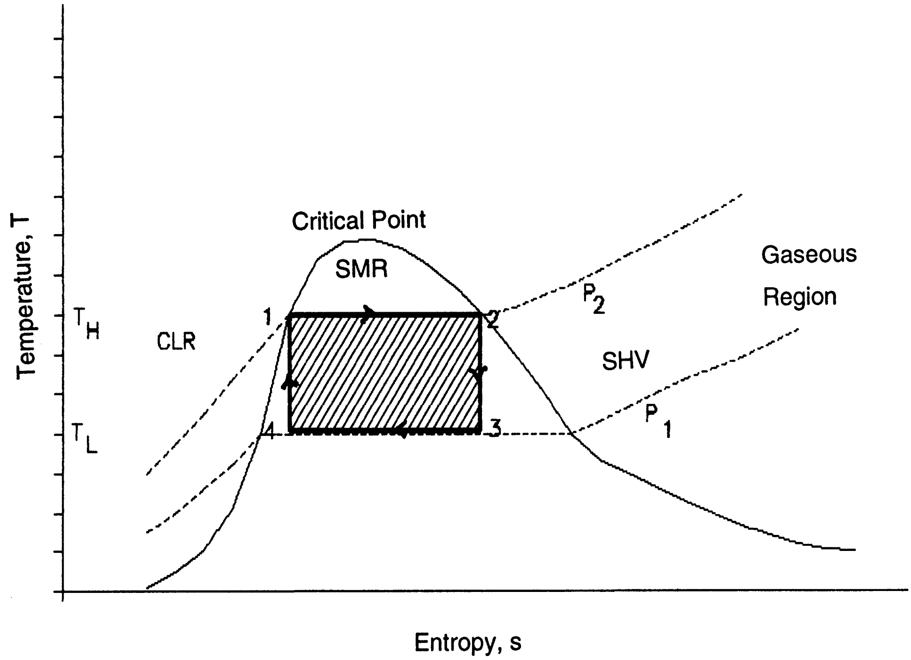

FIG. 3. The *T-s* diagram of a vapor (phase-change) Carnot cycle.

the turbine and pump, devices that work best with single-phase substances. In the turbine, for example, the drops of liquid water in the wet steam damage the blades and collide with the faster moving vapor particles for a loss in kinetic energy and a reduction of the turbine efficiency. In the pump, on the other hand, compressing a wet vapor to a liquid is not an efficient process, and the presence of the vapor leads to cavitation. Furthermore, in addition to the problem of stopping the condensation precisely at state 4, the net work per unit mass, as represented by the area 1–2–3–4–1, is small, requiring a large mass-flow rate and large power plant if the power output is to be of reasonable size.

2.2 The Rankine Cycle

The basic Rankine power cycle is the SMR Carnot cycle with modifications to correct its deficiencies. Referring to Fig. 4, where the Carnot-cycle states are indicated by primes, the first modification is to continue the condensation until all of the water vapor has been condensed and the water is a saturated liquid at state 4. The isentropic pump now compresses the liquid (with no vapor) to the boiler pressure at state 1. At this point heat transfer, which is isobaric and internally reversible but obviously not isothermal, commences. The isobaric addition of heat raises the temperature of the liquid water until the start of vaporization at state 1′, but heating does not stop at the saturated vapor line (state 2′); it continues isobarically into the superheated region to T_2, which normally is the highest allowable turbine inlet temperature. The additional heat, from 2′ to 2, is called ***superheat***, and its transfer is internally but not totally reversible since it is not isothermal; isothermal heat transfer in the superheated region (and in the CLR) requires a continuous change in the steam generator pressure, a difficult and impractical process. The superheated steam is then expanded isentropically in the turbine from state 2 to state 3, which is still in the SMR but is dryer than state 3′.

This additional heat, the superheat, and the higher average temperature accomplish three things: increase the net work, increase the thermal efficiency by increasing the average temperature at which heat is added, and reduce the amount of liquid water in the turbine and at state 3. Although the thermal efficiency with superheat can be greater than that of the

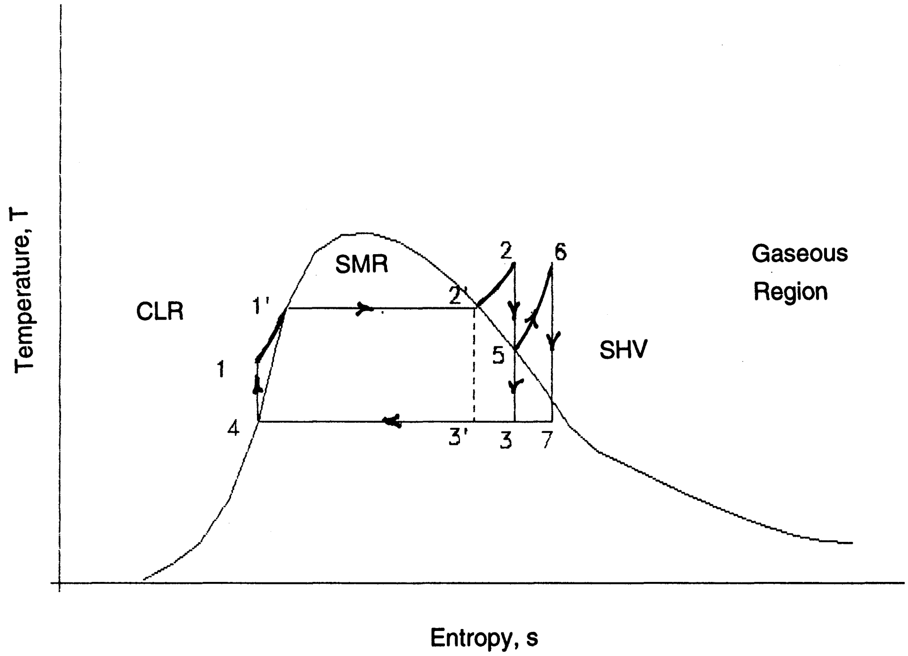

FIG. 4. The *T-s* diagram of an ideal Rankine power cycle.

Carnot cycle within the SMR, it is less than that of a Carnot cycle operating between T_2 and T_3, if such a cycle were possible.

The cycle efficiency with superheat can be evaluated from Eq. (6) with w_{net} and q_{in} determined from the appropriate use of Eq. (4). Neglecting the pump work ($h_4 \cong h_1$) and referring to Fig. 4 yield the expression

$$\eta_{\text{th}} = \frac{w_{\text{net}}}{q_{\text{in}}} \cong \frac{h_2 - h_3}{h_2 - h_1}. \tag{9}$$

Both the net work and thermal efficiency can be improved by increasing the temperature at which heat is added to the water and by decreasing the temperature at which the heat is removed in the condenser.

2.3 Reheat and Regeneration

The performance of the Rankine cycle can be further improved by adding what is known as *reheat* involving a two-stage turbine in which, as is shown in Fig. 4, the exhaust steam of the first (the high-pressure) stage is reheated isobarically but at a lower pressure from state 5 (usually still superheated) to state 6, the maximum turbine inlet temperature of state 2. This reheated steam is then expanded isentropically in the low-pressure stage to the condenser pressure at state 7, which usually is just within the SMR. This reheat cycle increases the net work per unit mass significantly, increases the thermal efficiency slightly, and reduces the moisture content of the turbine exhaust significantly. There may be more than one reheat cycle, particularly when the steam generator pressure is very high.

A second modification to the basic Rankine cycle is the addition of regeneration (not shown in Fig. 4) in which steam from the turbine is used to preheat the condensate before it reenters the steam generator. The simplest and commonly used device is the open *feedwater heater* in which steam extracted from the turbine is mixed directly with the condensate, whose pressure has been raised to that of the steam by an additional pump. The closed feedwater heater, on the other hand, resembles the more conventional heat exchanger in that the steam and condensate do not mix, eliminating the need for an additional condensate pump. A feedwater heater increases the thermal efficiency (reducing the fuel required for a given power output) and reduces the amount of coolant required for the condenser, both desirable results.

2.4 Other Vapor Cycles

Although reheat and regeneration have improved the thermal efficiency of steam power plants, the upper limit is restricted by the relatively low boiling temperature of water, even at high pressures, so that heat cannot be added at as high a temperature as desirable. In order to increase the temperature differential, the *binary vapor cycle* has been considered and even tested on a small scale using mercury in a Rankine cycle with a mercury-vapor generator, a mercury-vapor turbine, and a condenser (heat exchanger) that serves as the steam generator of a conventional steam cycle. The complications, costs, and complexities of using mercury (or other liquid metals such as potassium and rubidium) as well as the improvements in steam power plants have dampened interest in the binary vapor cycle.

There is, however, interest in using liquid metals in Rankine vapor cycles to produce auxiliary power in space. Since heat is rejected by radiation from the condenser, a high condenser temperature is needed in order to reduce radiator weight. This requirement in turn calls for supplying the vapor generator with higher-temperature heat from isotopes or solar panels.

At the other end of the power spectrum are Rankine vapor cycles in which the heat is supplied at relatively low temperatures from such "free" sources as geothermal energy, unfocused solar energy, ocean thermal energy, and waste heat. The resulting low thermal efficiencies require large mass-flow rates if the power output is to be significant. Since the specific volume of steam is large at the low pressures and temperatures of such systems, other fluids such as ammonia, isobutane, and possibly some of the Freons are more suitable than steam.

3. REFRIGERATION (AND HEAT-PUMP) CYCLES

Reversing the direction of the processes in a work-producing heat engine results in a refrigerator in which work is the input and a desired heat transfer is the output. Consider the two-phase Carnot cycle of Fig. 3, which when traveled in a clockwise direction (1–2–3–4–1) produces work with a heat input and a heat rejection. When traveled in a counterclockwise direction, however, this same cycle with a suitable working medium (the refrigerant) and a work input can produce two heat transfers. The cross-hatched area is the net work required whereas the area under the upper temperature line, 2–1, represents q_H, the heat transferred to the high-temperature reservoir, and q_L, the area under the lower-temperature line, 4–1, is the heat transferred from the low-temperature source. If the cooling of a space is the objective, q_L is to be maximized with respect to the net work input (the traditional refrigerator or air conditioner), whereas q_H is to be maximized if the heating of a space is the objective (the heat pump). The process from 3 to 2 is the isentropic compressor work, the work required to raise the pressure (and temperature) of the refrigerant from P_3 (T_L) to P_2 (T_H), and the process from 1 to 4 is the work produced by expanding the saturated liquid refrigerant through an appropriate device so as to reduce the pressure and temperature to that of the two-phase mixture at state 4.

This two-phase Carnot cycle provides the basis for the two major liquid-refrigerant refrigeration cycles, vapor-compression and absorption, as well as other lesser-known cycles such as the water-vapor, adsorption, and resorption refrigeration cycles. The vapor-compression cycle is favored for domestic and smaller-scale refrigeration and heating applications, whereas absorption refrigeration systems are better suited for larger, generally commercial, applications.

3.1 The Vapor-Compression Refrigeration Cycle

The vapor-compression refrigeration cycle, which is essentially a reversed Rankine power cycle without reheat or regeneration, is shown in Fig. 5. The two-phase refrigerant enters the evaporator at state 1, absorbs heat from the space to be cooled (q_L), and vaporizes until it reaches the saturated-vapor line (no liquid) at state 2 and enters a single-phase compressor. The vapor is compressed isentropically until it reaches the condenser pressure at state 3 and enters the condenser, where the heat of condensation (q_H) is transferred isobarically to the surroundings or to some other thermal

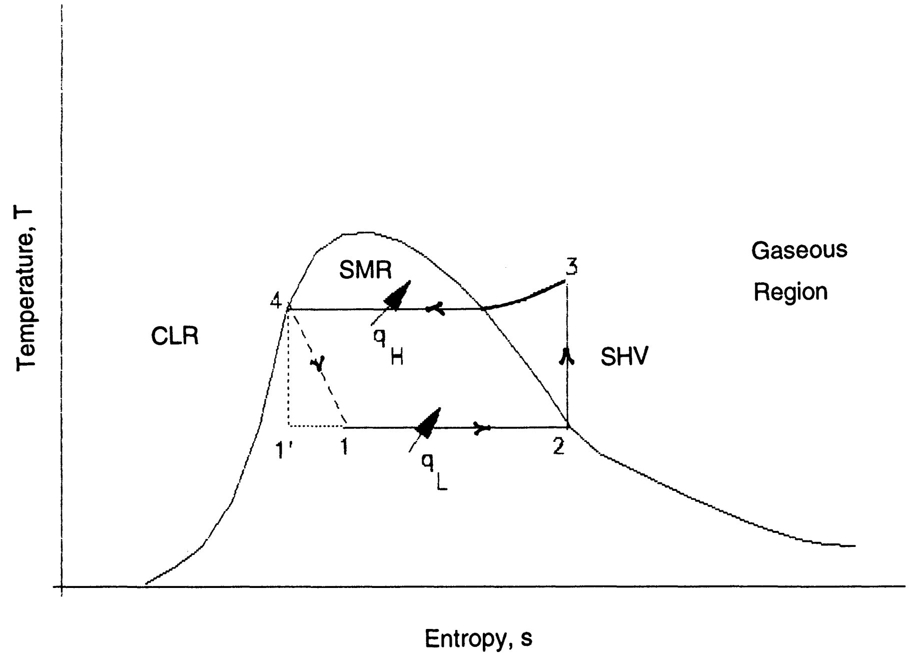

FIG. 5. The *T-s* diagram of an ideal vapor-compression refrigeration cycle.

reservoir. The liquid refrigerant of state 4 flows through an expansion valve (or capillary), changing phase and arriving back at state 1, the beginning of the cycle. The flow from 4 to 1 is a constant-enthalpy throttling process that is irreversible, as indicated by the dashed line. Although such a throttling device is lossy and has no work output, it has the advantages of simplicity and low cost when compared with an isentropic expander such as a two-phase turbine or a piston–cylinder combination whose work output would be small with respect to the required compressor work.

Referring to Fig. 5 and making use of Eqs. (7a) and (4) and the fact that $h_1 = h_4$, the COP for an ideal vapor-compression refrigerator can be written as

$$\mathrm{COP} = \frac{q_L}{w_{\mathrm{in}}} = \frac{h_1 - h_2}{h_2 - h_3} = \frac{h_4 - h_2}{h_2 - h_3}. \tag{10}$$

The cycles for space cooling and heating are identical; only the COP's and locations of the condenser and evaporator are different. For cooling (a refrigerator or air conditioner), the evaporator is located in the space to be cooled and the condenser usually discharges q_H into the atmosphere. This heat could be utilized, however, rather than be wasted—for example, to provide domestic hot water by using water rather than air in the condenser.

For heating (as a heat pump) the condenser is so located that q_H is transferred into the space to be heated and the evaporator obtains q_L from the surroundings, which might be ambient air, air from underground pipes, water from various sources, such as a well, a pond, or a swimming pool, or any other convenient thermal reservoir whose temperature is higher than that of the refrigerant, such as a solar collector or waste heat from another process.

Since heat pumps and air conditioners have the same components and operate in the same cycle, it is a common practice to use a heat pump as an air conditioner by adding a reversing valve to the cycle so that the condenser of the heat pump becomes the evaporator of the air conditioner and the evaporator of the heat pump becomes the condenser of the air conditioner. Sizing the heat-pump–air-conditioner combination to satisfy the cooling load sets the COP for the heating load and thus the temperature at which any supplementary heating will be required to maintain a desired space temperature.

The simple vapor-compression refrigerator cycle may be modified to improve its effectiveness and efficiency for large commercial applications. In *cascade refrigeration* systems two or more refrigeration systems are connected in series by a heat exchanger that contains the condenser of one system and the evaporator of the other; since there is no mixing in these cascaded systems, different refrigerants may be used in each stage. A second modification is the *multistage compression* system, which is in essence a cascaded system using a single refrigerant in which the heat exchanger connecting the stages is replaced by a mixing (flash) chamber in which part of the liquid refrigerant vaporizes.

With respect to refrigerants for vapor-compression cycles, any fluid that can be made to evaporate at pressures between 1 and 20 atm at reasonable temperatures is a possible candidate. However, there are other considerations that limit the choices, such as toxicity, corrosiveness, and environmental effects.

3.2 The Absorption Refrigeration Cycle

The *absorption refrigeration cycle* (not shown) is a variation of the vapor-compression refrigeration cycle in which the compressor is replaced by an absorption process in which a refrigerant vapor (such as ammonia) is absorbed in a liquid medium (such as water) and pumped as a liquid (sometimes referred to as a strong liquor) into a heat exchanger (called a generator), where heat (q_{gen}) is applied to vaporize most of the refrigerant along with some of the absorbent. This high-pressure vapor then passes through the condenser, the expansion valve, and the evaporator, as before, and returns to the absorber as a weak liquor, and the cycle is completed. Since the absorption process is exothermic, a coolant, such as water, is required to control the absorber temperature.

Since the specific volume of the liquid mixture to be pumped is a very small fraction of the specific volume of the refrigerant vapor, the pump work is also very small in comparison with that required for a vapor compressor, so small that it is often neglected in the cycle analysis. However, the amount of external heat required by the generator is quite large, and the COP is lower than that of the vapor-compression refrigerator. The COP can be improved somewhat, with added cost and complexity, by such techniques as adding a regenerator and an expansion valve to the absorption subsystem. In spite of a low COP, such absorption systems have certain operational advantages and can be very cost effective when a large source of inexpensive heat is available, such as waste heat from a power station or a process steam plant, geothermal energy, or solar energy.

Absorption refrigeration on a small scale is also attractive when electrical power is either limited or expensive as in isolated regions and campsites. If no electrical power is available, the pump can be replaced by the addition of hydrogen to maintain the total system pressure; this Electrolux absorption system, as it is known, has no moving parts or valves.

3.3 Other Refrigeration Cycles

There is a variation of the absorption refrigeration cycle known as the *resorption refrigeration cycle*, in which the condenser is replaced by a *resorber* where the vapor is not condensed to a pure liquid but is absorbed by a special weak solution while condensing. As the vapor is condensed and absorbed in the resorber, heat is transferred to and removed by the cooling water, and the solution flows through an expansion valve to the evaporator. As the refrigerant (ammonia) boils in the evaporator, the heats of vaporization and dissociation both contribute to the refrigerating effect. Greater cooling can be achieved than in the usual absorption system at the cost of an extra pump and some piping. Combination absorption and resorption cycles may be suitable for special applications.

Although chilled water can be provided from an evaporator heat exchanger, the *water-vapor refrigeration cycle* is used to provide large quantities of chilled water for cooling. The key element is an evaporator whose pressure has been lowered, by a vacuum pump, to the saturation pressure corresponding to the desired temperature of the chilled water. When the intake water is sprayed into the evaporator, the low pressure causes a portion of this water to flash into vapor, reducing the temperature of the resulting two-phase mixture to the saturation temperature for the evaporator pressure. The chilled water is easily drawn off from the bottom of the evaporator and pumped to its destination.

Removal and condensation of the vapor, however, are much more of a problem because of its large volume and high volume flow rate; the latter can easily be of the order of thousands of cubic meters per minute, and velocities can become supersonic if the cross-sectional area of the pipes is not large enough. Such large flow rates require large axial flow or centrifugal compressors (and large amounts of power) to move the vapor through the condenser. When steam at moderate pressures and low cost is available, a *steam jet compressor* may be used to provide a straightforward and low-cost alternative, simple to operate and maintain, to rotating compressors and blowers.

Even though the concept and system elements of an *adsorption refrigeration* system are similar to those of an absorption refrigeration system, adsorption refrigeration is not as well known and is still in the study and developmental phases and not in commercial use. Whereas in the absorption refrigeration cycle the refrigerant and absorbent form a liquid solution that can be pumped and from which the refrigerant can be vaporized, in the adsorption refrigeration cycle the refrigerant is adsorbed on the surface of a solid; otherwise the ideal cycles are identical.

4. GAS CYCLES

Although the vapor cycles involve phase changes and two-phase mixtures of the working fluid, the working fluid in a gas cycle remains in the gaseous phase throughout the cycle; there is no condensation or evaporation. Furthermore, many of the gas cycles are *open cycles* in that some or even all of the working fluid leaves the system and enters the surroundings during the cycle to be replaced by additional fluid entering the system at the same original state as the departing fluid. (The vapor cycles discussed in the previous sections were, with the possible exception of the water-vapor refrigerator, closed cycles.)

Although some of the vapor power cycles are reversed to operate as refrigerators (and heat pumps), the gas cycles are predominantly heat engines (work producers). An additional measure of performance for the piston–cylinder (reciprocating) engines is the *mean effective pressure* (mep), which is defined as the net cycle work divided by the volume change during one stroke; it can be an indicator of the size of an engine.

4.1 The Carnot Cycle

The *T-s* diagram for a gas-cycle engine operating in a Carnot cycle is shown in Fig. 6. Although this cycle has the highest thermal efficiency possible, it also has practical limitations that restrict its use. First of all, the isothermal heat transfers (from 1 to 2 and 3 to 4) are not isobaric so that some means of varying the pressure appropriately is required if the heat transfers are to be totally reversible; as mentioned earlier, maintaining an isothermal heat transfer without a phase change is not a simple task. Second, the net work per unit mass is small and the volume change is high. Consequently, the mep is quite low—so low that a Carnot engine might have trouble overcoming the starting friction.

Although the Carnot cycle is still a standard for performance evaluation, these two limitations are sufficient to preclude using the Carnot cycle as the basis for the ideal cycles to be used in the analyses of internal combustion engines, analyses that also assume air-standard cycles. External combustion devices with regenerators, however, such as those using the Stirling or Ericsson cycles, can approximate isothermal heat transfers and can have efficiencies approaching that of the Carnot cycle.

4.2 The Air-Standard Cycle

Many gas-cycle engines are classified as *internal combustion engines* (see AUTOMOTIVE PROPULSION SYSTEMS) because they obtain their thermal energy by compressing and then burning a mixture of fuel and air within the system boundaries. Although all of the combustion products comprise the working fluid, the predominant component is air and it is convenient to assume that the working fluid is dry air. Other convenient assumptions are that the air is an ideal gas with constant specific heats, that any combustion may be replaced by an equivalent heat transfer from an external thermal reservoir, and that any open cycles are thermodynamically closed by the transfer of heat to the surroundings. In addition, all processes are assumed to be

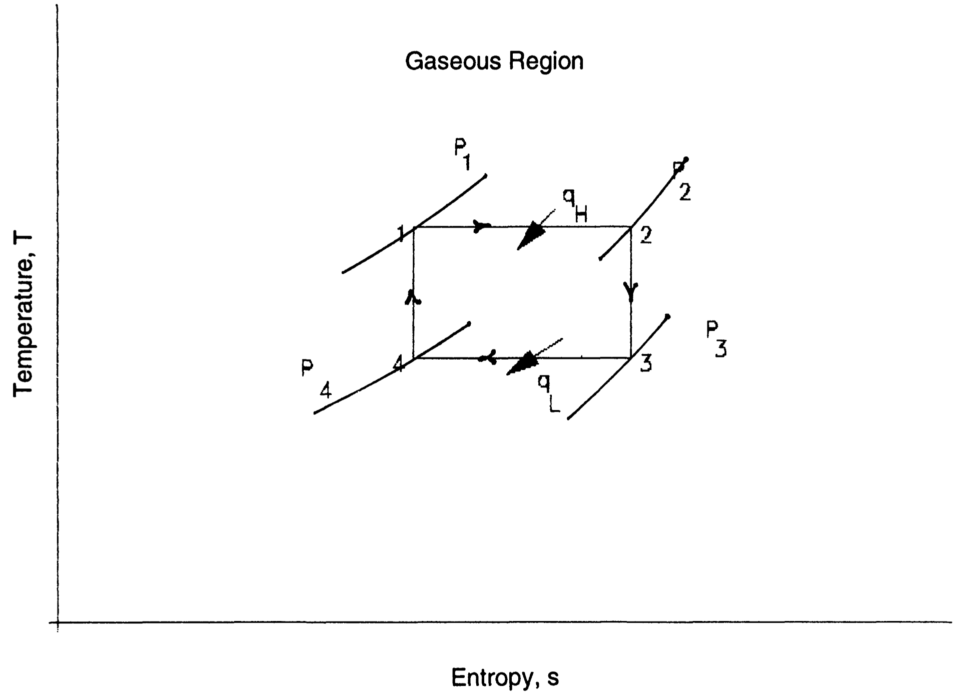

FIG. 6. The *T-s* diagram of a gas Carnot cycle (no phase change). The arcs labeled P_n are portions of isobars.

internally reversible. This collection of assumptions constitutes the *air-standard cycle,* which is incorporated in the analyses of the various ideal gas cycles that follow.

Since the specific heats are assumed to be constant, this set of assumptions may be thought of as the *cold-air-standard cycle* to distinguish it from the *hot-air-standard cycle* in which the variations in the specific heats that occur within an engine are taken into account.

4.2.1 The Otto Cycle. The air-standard *Otto cycle* is used to predict the performance of a *spark-ignition* (SI) gasoline piston–cylinder (reciprocating) engine. Referring to the *T-s* diagram of Fig. 7, the fuel–air mixture enters the cylinder at state 1 (with the piston at bottom dead center) and is compressed isentropically to state 2 (with the piston at top dead center) where ignition and combustion take place. With the assumption of insignificant piston movement during combustion, heat is added at constant volume from states 2 to 3 followed by an isentropic expansion to state 4, where the piston is again at bottom dead center. The process from states 4 to 1 is a constant-volume rejection of heat through the exhaust of the combustion products to the surroundings.

The piston–cylinder combination is a closed system, and the Otto-cycle efficiency can be expressed as

$$\eta_{\text{th}} = 1 - \frac{T_1}{T_2} = 1 - \frac{1}{r^{k-1}}, \qquad (11)$$

where k is the ratio of specific heats (1.4 for air) and r, the *compression ratio,* is the ratio of the cylinder volume before compression to the volume after compression (V_1/V_2); r is a volume ratio, *not* a pressure ratio.

Equation (11) shows that the efficiency of the ideal air-standard Otto cycle depends only on the compression ratio and the value of k and is independent of such factors as the heat added per cycle and the conditions at the start of compression. In addition to a reasonably high efficiency, this cycle has a high mep, i.e., a high net work output for a given displacement volume.

4.2.2 The Diesel Cycle. In *compression-ignition* (CI) engines, the intake air is so highly compressed that the temperature of the air is sufficiently high for self-ignition to occur

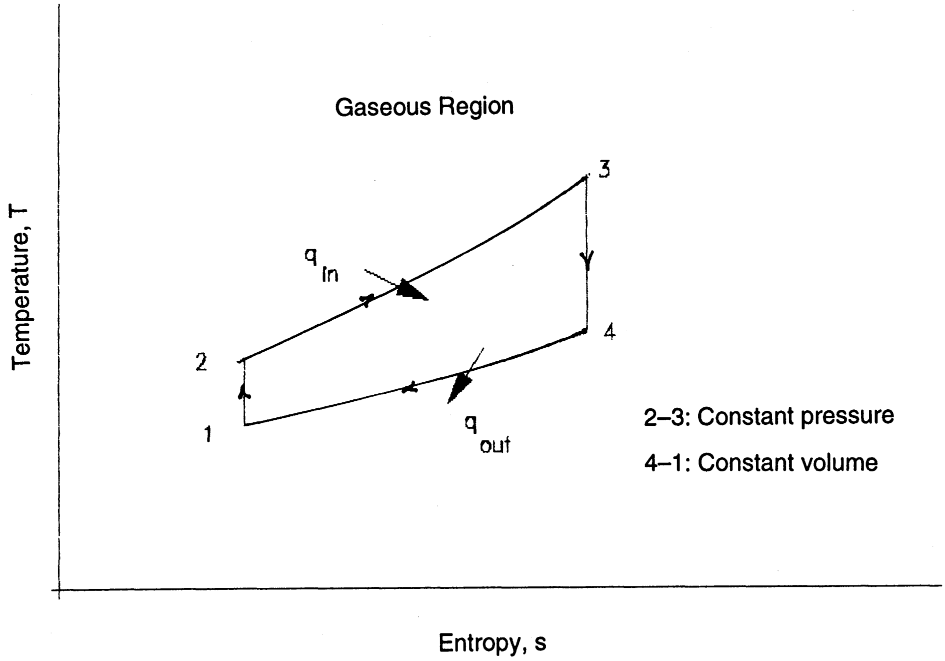

FIG. 7. The *T-s* diagram of an ideal Otto cycle.

when fuel is injected into the cylinder. The air-standard *Diesel cycle* is the model for low-speed (and usually large) compression-ignition engines. Referring to the *T-s* diagram of Fig. 8, the intake air is compressed isentropically from state 1 to 2, at which point fuel is introduced and self-ignites. Since the duration of combustion is longer than that for the Otto cycle, constant pressure is a more appropriate assumption; thus the heat is added isobarically in moving from state 2 to 3. Isentropic expansion from 3 to 4 (the power stroke) is followed by constant-volume rejection from state 4 back to 1, completing the cycle.

Notice the similarity to the Otto cycle; the only difference is the heat input process: constant volume in the Otto cycle and constant pressure in the Diesel cycle. The procedure for finding expressions for the thermal efficiency is similar to that used with the Otto cycle with the exception that q_{in} now involves moving-boundary work because of the volume change. At this point it is convenient to define two new parameters: the *expansion ratio*, $r_e = V_3/V_4$, and the *cutoff ratio*, $r_c = V_3/V_2$. Note that r_c, which is always greater than unity for the Diesel cycle, is also equal to the ratio of the compression ratio to the expansion ratio: $r_c = r/r_e$. (Since the expansion ratio of the Otto cycle is equal to the compression ratio, the cutoff ratio for the Otto cycle is unity.)

The Diesel-cycle efficiency expression can be written as

$$\eta_{\text{th}} = 1 - \frac{1}{r^{k-1}}\left[\frac{r_c^k - 1}{k(r_c - 1)}\right], \tag{12}$$

showing the efficiency to be a function of both the compression ratio and the cutoff ratio as well as of the ratio of specific heats. A comparison of Eq. (12) with Eq. (11) shows that only the bracketed term differentiates the efficiency of the Diesel cycle from that of the Otto cycle. With $r_c > 1$, this term is also greater than unity so that with identical compression ratios the thermal efficiency of the Otto cycle will always be greater than that of the Diesel cycle; increasing the cutoff ratio further decreases the Diesel efficiency. Note that when $r_c = 1$, the Otto-cycle value, the bracketed term becomes unity and the two efficiencies are identical.

As the rpm of a diesel engine is increased to increase the horsepower-to-weight ratio, the

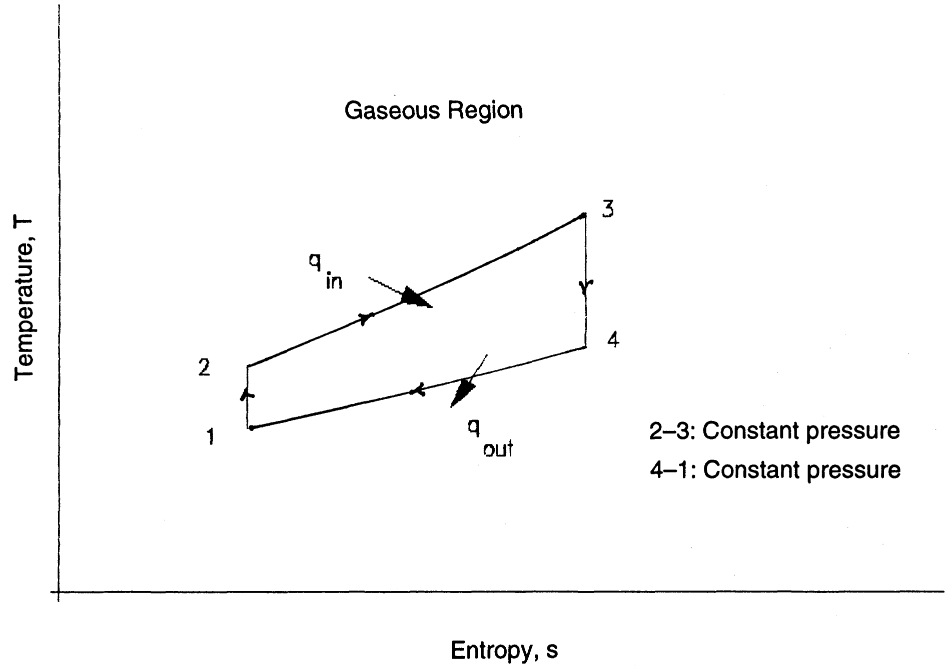

FIG. 8. The *T-s* diagram of an ideal Diesel cycle.

validity of the approximation of a constant-pressure heat input process becomes less valid. A more realistic representation is one in which heat is added in two steps, a constant-volume addition followed by a constant-pressure addition; the corresponding cycle is known as an *ideal dual cycle.* As the rpm increases, the constant-volume input increases and the constant-pressure input decreases so that the small high-speed compression-ignition engines used in automobiles today, although called diesel engines, approach the Otto cycle in their performance. This dual cycle is applicable to modern SI engines as well as CI engines, and the relative amounts of heat transferred during each process can be adjusted to approximate better the actual cycle. The ideal Otto and Diesel cycles are special cases of the dual cycle.

4.2.3 The Brayton Cycle. The air-standard *Brayton cycle,* also known as the *Joule cycle,* is the ideal cycle of the simple gas-turbine cycle; it can be an open cycle with internal combustion as the heat source and with heat rejection to the surroundings, or a closed cycle, utilizing an external heat source and transferring heat with heat exchangers. Either type of cycle can be represented by the *T-s* diagram of Fig. 9, where an isentropic compression from 1 to 2 is followed by an isobaric heat addition (in the combustion chamber for an open cycle) to state 3, which for best performance is the maximum allowable turbine inlet temperature. Process 3–4 is an isentropic expansion (through the turbine), and 4–1 is an isobaric heat rejection (to the surroundings for an open cycle).

Whereas the processes of the Otto and Diesel cycles represent closed systems, those of the Brayton cycle are open (single-flow) systems, and the cycle efficiency can be written as

$$\eta_{\text{th}} = 1 - \frac{T_1}{T_2} = 1 - \frac{1}{(P_2/P_1)^{(k-1)/k}}, \tag{13}$$

where P_2/P_1, the *pressure ratio* during compression (and expansion), is the parameter used to determine the efficiency of a Brayton-cycle engine; it should not be confused with the compression ratio r (V_1/V_2) used with the Otto and Diesel cycles. Note that the pressure ratio determines the cycle efficiency, not the maximum cycle temperature T_3.

Not only is the efficiency of a typical Brayton-cycle engine less than that of a comparable Otto-cycle engine, but the mep is also

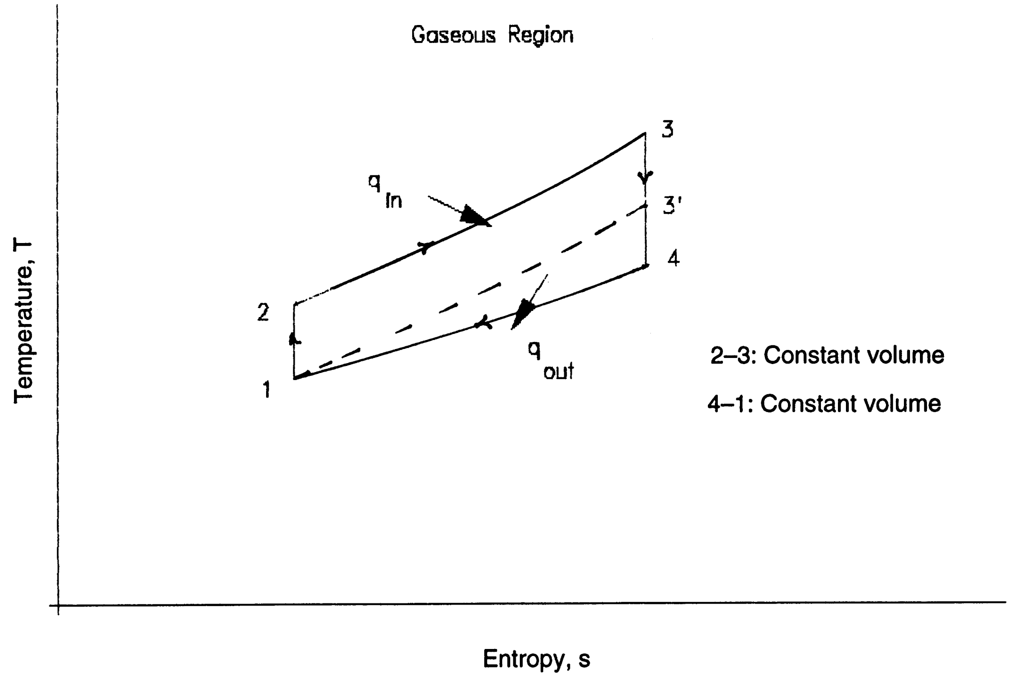

FIG. 9. The *T-s* diagram of an ideal Brayton cycle.

considerably lower, requiring the movement of large volumes of gases to obtain a useful amount of net work. The volume and weight of reciprocating compressors and expanders associated with a closed Brayton cycle are so large as to be impractical. Rotating machinery, on the other hand, can handle the large volumes of gases in a small volume of machinery so well that the open Brayton cycle has become the model for the various forms of gas-turbine engines, engines that have higher power-to-weight ratios than comparable SI and CI engines.

A large percentage of the turbine work output is required to drive the compressor (the *back work*). Whereas only 1% or 2% of the turbine work is required to drive the pump of a Rankine cycle, the compressor of a Brayton cycle can require from 40% to even 80% of the turbine output. The startling difference in the back-work ratios arises because the specific volume of the liquid being pumped in the Rankine cycle is very low compared with that of the gas being compressed in the gas turbine cycle.

Referring to Fig. 9, state 3′ represents the amount of the expansion in the turbine required to drive the compressor so that the area 1–2–3–3′–1 represents the compressor work and the remaining area, 1–3′–4–1, represents the net work, the available output work. Note that while an increase in T_3, the maximum turbine inlet temperature, does not improve the efficiency, it does increase the net work and reduce the back-work ratio, both desirable, since the divergence between the isobars increases with increasing temperature.

The energy remaining in the turbine at state 3′ is available to be used in various ways. It may be completely expanded in a nozzle to produce thrust (a *turbojet*), partially expanded in another turbine to drive a propeller (a *turboprop*) or a multibladed fan (a *turbofan*) with the residual energy transformed into jet thrust in a nozzle, or completely expanded in another turbine (a *turboshaft engine*) to drive a pump, an electrical generator, a helicopter rotor, a marine propeller, or a tank track.

In a closed Brayton cycle, heat is received and rejected via heat exchangers so that the working fluid is not limited to air (combustion products). One possible application of the closed cycle might be in a nuclear power plant using a gas with a higher C_p, such as helium.

As with the Rankine cycle, there are add-ons to improve the performance of the open gas-turbine cycle. A *regenerator* can be used when the temperature of the exhaust gases is higher than the temperature of the air leaving the compressor ($T_4 > T_2$). The exhaust gases enter a counterflow heat exchanger to preheat the air leaving the compressor before it enters the combustor. If the regenerator were ideal, the temperature entering the combustor would be T_4, and the ideal thermal efficiency with a regenerator is

$$\eta_{\mathrm{th}} = 1 - \frac{w_c}{w_t} = 1 - \left(\frac{T_1}{T_3}\right)\left(\frac{P_2}{P_1}\right)^{(k-1)/k} . \qquad (14)$$

Equation (14) shows that the thermal efficiency with regeneration depends not only upon the pressure ratio but also upon the ratio of the minimum to the maximum temperatures, and that the efficiency decreases with an increasing pressure ratio to the point where regeneration is no longer effective.

The efficiency of the Brayton cycle, either open or closed, can be further improved by the addition, in conjunction with a regenerator, of *multistage compression with intercooling between stages* and *multistage expansion with reheat between stages.* Although there is no theoretical limit to the number of stages, the economic and practical limit in view of the declining payoff and increasing complexity, cost, and losses is usually two or maybe three stages. It is interesting to note that with an unlimited number of stages, the thermal efficiency would approach that of the Ericsson cycle (discussed in Sec. 4.4) and therefore that of the Carnot cycle.

4.3 The Gas Refrigeration Cycle

The ideal *gas refrigeration cycle* is essentially a reversed Brayton cycle and may be referred to as *air-cycle refrigeration* or as the *air-standard refrigeration cycle* when air is used as the refrigerant. The gas cycle differs from the vapor-compression refrigeration cycles in that the condensation and evaporation of a liquid refrigerant are replaced by the sensible cooling and heating of a gas. In addition, the irreversible expansion valve is replaced by an isentropic expansion engine or turbine so as to achieve a greater drop in the gas temperature.

The air-standard refrigeration cycle, originally known as air-cycle refrigeration, was one of the earliest forms of cooling and was operated in either an open or closed (dense-air) cycle. Although air is a safe and inexpensive refrigerant, air-cycle refrigeration became obsolete for general use because of its low COP and high operating costs; it could not compete with vapor-compression refrigeration with its higher-performance refrigerants. It does, however, still have two specialized applications: to provide open-cycle cooling for pressurized aircraft and, in a closed cycle with regeneration, to liquefy air and other gases.

Referring to the ideal Brayton cycle of Fig. 9, in a closed cycle air enters the compressor at state 4 and is isentropically compressed to state 3. After being cooled isobarically from T_3 to T_2, the air expands in an isentropic process (doing work in the process) to the compressor inlet pressure at state 1. Heat is then transferred isobarically from the space to be cooled to raise the temperature of the air to T_4 at the compressor inlet. The amount of work done by the expander (the turbine) is significant and can be used, for example, to drive a circulating fan or to provide a portion of the compressor work if appropriate.

The COP of the ideal gas refrigeration cycle is related to the compressor pressure ratio by the expression

$$\mathrm{COP} = \frac{1}{(P_3/P_4)^{(k-1)/k} - 1} , \qquad (15)$$

where $P_3/P_4 = P_2/P_1$.

With regeneration, gas-cycle refrigeration can be used for the *liquefaction* of gases. With a simple gas cycle (without regeneration) the lowest possible turbine inlet temperature T_2 is the temperature of the cooling medium, the ambient temperature when ambient air is the coolant. With one or more regenerators [counterflow heat exchangers] between the compressor and the turbine, however, the inlet temperature can be lowered further so that the turbine exit temperature is below the critical temperature of the air (−140 °C) and the air enters the liquid phase. Since the critical temperatures of the major components of air (nitrogen and oxygen) are different (−147 and −119 °C, respectively), they can be removed separately from the liquid air by fractional distillation, as can the other components such as argon, helium, and neon.

The regenerative gas cycle can be applied to the liquefaction of other gases, such as helium, and to the solidification of carbon dioxide (dry ice). There are other techniques with varying configurations and complexities for the liquefaction of gases, such as the Linde, Claude, Collier, and Heylandt processes, and they all involve compression of a gas to a high temperature, successive cooling with regeneration, and then expansion through a turbine, an expansion valve, or a reciprocating expander.

4.4 The Stirling and Ericsson Cycles

The Stirling cycle (see STIRLING ENGINE) and the Ericsson cycle are ideal-gas cycles with external heat sources that make use of a regenerator to accomplish isothermal heat transfers into and out of the working fluid. Since the regenerator is an essential element of these closed cycles, they are often referred to as the regenerative cycles. The regenerator in these cycles is a thermal energy-storage device that has the capability of storing and releasing thermal energy on demand. It might, for example, be a porous plug with a high thermal mass through which the gas flows, or a counterflow heat exchanger. The porous plug is appropriate for intermittent devices, such as reciprocating expanders and compressors, whereas the heat exchanger is appropriate for continuous-flow devices, such as turbines and rotary compressors.

Consider Fig. 10, the *T*-*s* diagram of a Stirling cycle. Starting with the gas at T_H at state 1, heat from an external source is supplied during the process 1–2 to an isothermal expander (a turbine or a piston–cylinder combination); work must be done if the temperature is to remain constant. Then while the volume is kept constant, the hot gas is forced through the regenerator, transferring heat to the regenerator and cooling the gas to T_L at state 3. The cooled gas now enters an isothermal compressor, rejecting heat to an external sink to state 4, where $V_4 = V_1$. The gas is passed through the regenerator again in another constant-volume process (from 2 to 3), this time picking up the heat stored in the regenerator and raising the temperature back to T_H at state 1.

It can be shown that the heat transferred from the gas to the regenerator (the area

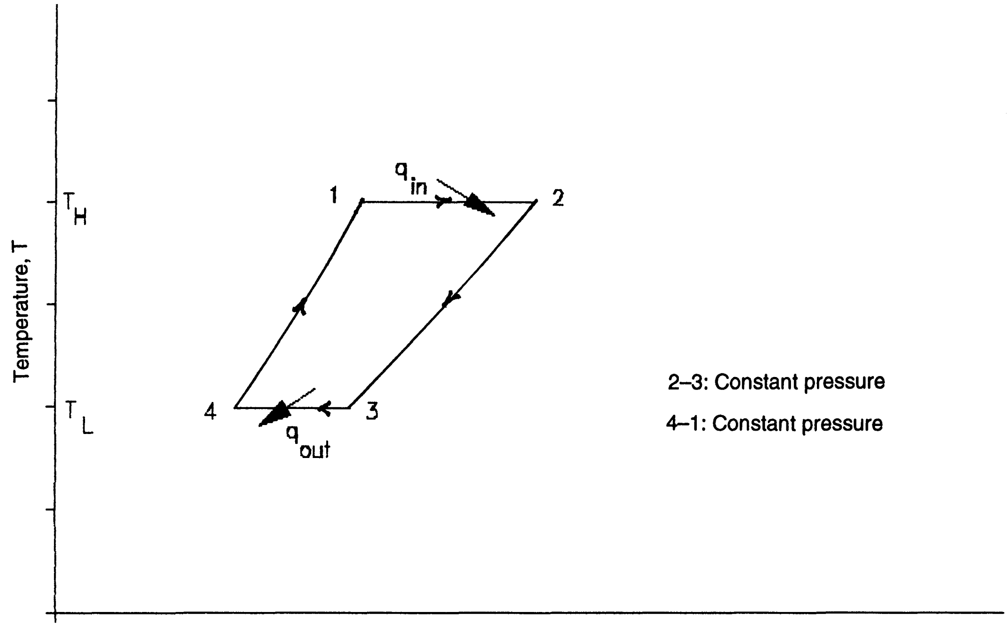

FIG. 10. The *T*-*s* diagram of an ideal Stirling cycle.

under the line from 2 to 3) is exactly equal to the heat transferred from the regenerator to the gas (the area under the line from 4 to 1). Therefore the transfer of heat from the external source to the gas takes place in the isothermal expander at T_H, and all of the heat rejected to the sink takes place in the isothermal compressor at T_L. Since these isothermal heat transfers are the conditions for a Carnot cycle, the efficiency of the ideal Stirling cycle will be that of a Carnot cycle operating between the same temperatures, namely

$$\eta_{\text{th}} = 1 - T_L/T_H. \tag{16}$$

The ideal Ericsson cycle is similar to the Stirling cycle, as is its *T-s* diagram, except that the heat exchanges with the regenerator take place at constant pressure rather than at constant volume. Since heat is transferred isothermally between the gas and the external heat source and the external sink, as in the Stirling cycle, the ideal thermal efficiencies are equal, namely, that of a Carnot cycle. These cycles provide an excellent example of the beneficial effects of regeneration upon thermal efficiency, as was seen with the Rankine cycle and with the Brayton cycle with multistage compression and expansion and intercooling, reheat, and regeneration.

The Stirling and Ericsson cycles share with the Carnot (and the Brayton) cycle the disadvantage of low mep's that lead to bulky reciprocating engines, which was the case with early *hot-air engines*. As with the Brayton cycle, the total work can be increased in spite of the low mep's by the use of rotating turbines and compressors.

The actual thermal efficiencies of these cycles are much less than the ideal values for several reasons. First of all, isothermal heat transfer is not practical as, without a temperature differential, it would require infinitely large surface areas or infinite transfer times. Furthermore, all four processes involve heat transfer through gas-surface films with large thermal resistances that lower the mean cycle temperatures and thus the efficiency. There are, as well, pressure drops in the components and the problems associated with achieving isothermal expansion and compression.

In spite of these drawbacks, there are advantages associated with external combustion and a closed cycle that have led to a renewed interest in Stirling and Ericsson cycles. With external combustion, any source of heat (combustion, solar, isotopes, nuclear, etc.) can be used. In the case of combustion, there is a greater choice of fuels, and the duration of the combustion process can be longer, leading to more complete combustion with greater energy output and less pollution. The closed cycle offers the opportunity to select a working fluid with the most suitable characteristics for the application of interest (in addition to air, gases such as hydrogen, nitrogen, and helium are suitable candidates) and does not require a reservoir of the working fluid to replace that exhausted in an open cycle.

These cycles can be reversed to be used as refrigerators; Stirling refrigerators, for example, are already being used in laboratories and in small-scale commercial applications to provide cooling, to liquefy air, and to recondense evaporated cryogens. Stirling and Ericsson engines and refrigerators can be combined to form heat pumps, such as a Stirling–Stirling heat pump. The *Vuilleumier cycle* is a related cycle that combines a Stirling engine and an Stirling refrigerator in a single device that cools and heats, and is characterized by three operating temperatures.

5. COGENERATION AND ENVIRONMENTAL CONSIDERATIONS

In a heat-engine cycle the major portion of the input heat is not transformed into work and is transferred out of the working fluid and out of the engine. If the residual energy in this rejected (waste) heat is not utilized in another heat engine or in some other manner but is merely rejected to the surroundings, it is truly wasted. Not only is this rejected energy wasted, but it also pollutes the environment, thermally if the cycle is closed and both thermally and with combustion products if the cycle is open and internal combustion provides the input heat. It should be noted that the external heat source of a closed cycle is also a source of environmental pollution, the type of pollution depending on the nature of the source, combustion or nuclear.

An ideal solution to the waste heat problem would be to extract all of the available energy from the input heat so that there would be no residual energy to affect the environment. Since this an impossibility under the second law, a realistic agenda calls for the maximum practicable reduction in the energy of the rejected heat and for the utilization of the lower-quality residual thermal energy in a meaningful and economic manner. If these two objectives can be met, then the rejected heat is no longer waste heat.

If the term "waste heat" is retained to identify the heat rejected from a cycle, waste heat can be categorized as *high-quality waste heat* when its temperature exceeds 93 °C (200 °F) and as *low-quality waste heat* when its temperature is less than 93 °C. If the temperature of the high-quality waste heat is sufficiently high, it can be used directly to provide all or a portion of the input heat for lower-temperature systems, to provide steam or power; if not, a heat pump can be used to raise the temperature to a useful level to generate steam or high-temperature liquids. The low-quality waste heat, particularly that represented by condenser cooling water, can be used for agricultural (greenhouses and soil warming), aquacultural (fish farming), and other similar purposes.

Before defining and discussing cogeneration, it should be noted that improving the combustion processes, both internal and external, so as to increase the energy extracted from the fuels not only improves the efficiency of the combustion process and the economics of the heat engine but also, by reducing the temperature of the combustion products, reduces the environmental pollution.

The major industrial needs are for heat (usually in the form of steam) for processes and heating, and for electrical and mechanical power. Consequently, *cogeneration* is generally defined as the use of a single integrated plant to generate both process steam and electrical power; such a cogeneration plant may also be described as a combined heat and power (CHP) plant. Actually, any multipurpose plant whose objectives are to increase the extraction of energy from the input heat and to reduce the amount of waste heat is a cogeneration plant. For example, a steam plant that provides steam for *district heating* (community space heating and domestic hot water), for an absorption refrigeration system, and to drive a turbine to generate electrical power to operate the plant is a cogeneration plant. Although the electrical power production in this particular plant, and in many like it, may be limited to that needed for plant operation, there is a growing trend for cogeneration plants to produce more electrical power than needed for plant operation and to use the excess or sell it to the public utilities when the utilities are willing to buy it.

Depending on how cogeneration is integrated into a system, particularly a CHP plant, the cogeneration technologies may be grouped as topping cycles and as bottoming cycles. In a *topping cycle*, the high-temperature input energy is first used for power generation and then the lower-temperature residual energy is used to produce process steam. In a *bottoming cycle*, the sequence is reversed; the high-temperature energy is used first to produce steam with the remaining energy used to produce power. Most currently available cogeneration technologies are not new and have been used in one form or another for many years.

There are many cogeneration configurations involving various combinations of steam and gas turbines and even large diesel engines with electrical generators and heat exchangers that maximize the extraction of energy and minimize the effect on the environment.

GLOSSARY

Adiabatic: Without heat transfer (thermally insulated).

Carnot Cycle: Ideal cycle with maximum efficiency or COP.

COP (Coefficient of Performance): Measure of the thermal performance of refrigerators and heat pumps.

Cycle: Series of processes with identical initial and end states.

Enthalpy: A derived property; sum of internal energy and the product of pressure and volume.

Entropy: A derived property related to the second law, and a measure of losses.

First Law: Thermodynamic statement of the principle of conservation of energy.

Heat Engine: Cyclic system with only heat and work crossing its boundaries. Often used to describe a system that receives and rejects heat and produces work.

Ideal Gas: A gas whose P-v-T relationship is determined by the ideal-gas equation of state, $Pv=RT$.

Isentropic: Adiabatic and reversible; taking place at constant entropy.

Isothermal: Taking place at constant temperature.

Process: Change in one or more properties.

Refrigerator: Heat engine that uses a work input to transfer heat from a lower to a higher temperature so as to cool or heat a space.

Reversible: Ideal with no losses.

Second Law: Complex set of relationships and equations that deal with the quality and direction of a process.

INTRODUCTION

The transmission of heat between bodies at different temperatures, or between regions of the same medium at different temperatures, can take place without the movement of material, either by conduction through a body (solid or fluid) or by radiation through a transparent medium from one body to another. In addition, there can be heat transfer in fluids associated with the movement or circulation of matter. This process, convection, is often more effective than conduction in large bodies of fluid.

After discussing each mode of heat transfer individually, their combined effect will be discussed. Finally these principles will be illustrated by some applications.

1. THERMAL CONDUCTION

This is the transfer of heat within a continuous body, without overall or bulk motion of matter. It is through the motion of atoms or molecules that pass energy from regions of higher to lower temperature. According to the empirical Fourier law, which preceded a full understanding of the nature of heat, the local heat current density **J** (heat energy flowing per unit area per unit time) is proportional to the local temperature gradient grad$T$, T being the temperature, so that

$$\mathbf{J} = -\lambda \cdot \mathrm{grad} T. \qquad (1)$$

This relation defines the thermal conductivity. In the most general case λ is a symmetric tensor with six independent components. In crystals of cubic symmetry it has only three diagonal components, equal to each other, so that **J** and grad$T$ are parallel and λ appears isotropic, even though its tensor nature becomes apparent in derivatives such as the stress dependence of the thermal conductivity. Also λ is isotropic in materials without preferred direction (simple fluids, most amorphous solids, and solids composed of small crystallites arranged completely at random). In the case of isotropy, λ is replaced by a single parameter.

Measuring heat in units of energy and T in kelvins, the SI unit of thermal conductivity is $\mathrm{W\,m^{-1}\,K^{-1}}$. Older units are cgs ($\mathrm{erg\,cm^{-1}\,K^{-1}\,s^{-1}}$) and the convenient hybrid unit $\mathrm{W\,cm^{-1}\,K^{-1}}$, which frequently appears in the older literature and has not yet disappeared completely. Even older is the unit $\mathrm{cal\,cm^{-1}\,{}^{\circ}C^{-1}\,s^{-1}}$. Two practical British units are also used: $\mathrm{BTU\,ft^{-2}\,in.\,h^{-1}\,{}^{\circ}F^{-1}}$ and $\mathrm{BTU\,ft^{-1}\,h^{-1}\,{}^{\circ}F^{-1}}$. The reciprocal of the former defines

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

the R value of insulations. Table I lists some conversion factors.

An excess of heat flowing into a small region increases the local temperature, so that

$$\mathrm{div}\mathbf{J} = -C\rho\ \partial T/\partial t. \qquad (2)$$

Here $\partial T/\partial t$ is the rate of temperature increase at a fixed location, C is the specific heat, ρ is the density, and div**J** is the net rate of heat outflow per unit volume. For isotropic conductivity Eqs. (1) and (2) lead to

$$\mathrm{div}(\lambda\cdot\mathrm{grad}T) = C\rho\ \partial T/\partial t. \qquad (3)$$

Here λ may be a function of position (inhomogeneous medium). If λ is a constant, independent of position, and its T dependence can be neglected, Eq. (3) is a linear partial differential equation. The temperature T is a function of position and time. This equation can then be solved in terms of Fourier coefficients. Each Fourier component decays with a characteristic time that varies as the square of the wavelength, so that the spatial variation of the temperature field becomes progressively smoother with increasing time. Numerous special cases have been treated (Carslaw and Jaeger, 1959).

The conduction equation (3) is more complicated when λ is not constant. If it depends on T, the equation is no longer linear and numerical methods must be used to solve it. In the steady state when $\lambda(\mathbf{r})$ is a specified function of position, the problem is the same as for electrical conduction in inhomogeneous media, and various approximations have been proposed, as reviewed by Landauer (1978). For a medium that is inhomogeneous but globally uniform, the effective conductivity has upper and lower bounds given, respectively, by the volume average of $\lambda(\mathbf{r})$ and by the reciprocal of the volume average of the resistivity $1/\lambda(\mathbf{r})$.

The Fourier equation for thermal conduction is formally the same as that for diffusion. This is not surprising when one considers the microscopic picture of thermal conduction; heat transport can be considered as due to the random motion of carriers of thermal energy, with net transport in the direction toward the lower energy density due to such carriers.

It is thus useful in time-dependent problems to define thermal diffusivity by

$$\alpha = \lambda/C\rho. \qquad (4)$$

It has the same dimensions as ordinary diffusivity (length squared divided by time). It is an indicator of how long it takes for a temperature inhomogeneity to decay if that inhomogeneity extends over some given distance.

Table 1. Conversion of Units. Various units of heat and thermal conductivity converted to SI (MKS) units.

Units	SI
Heat	
1 cal	4.187 J
1 BTU	1055 J
Thermal Conductivity	
1 cal $\mathrm{s^{-1}\,cm^{-1}\,K^{-1}}$	418.7 $\mathrm{W\,m^{-1}\,K^{-1}}$
1 BTU $\mathrm{ft^{-2}}$ in. $\mathrm{h^{-1}\,{}^\circ F^{-1}}$	0.1442 $\mathrm{W\,m^{-1}\,K^{-1}}$
1 BTU $\mathrm{ft^{-1}\,h^{-1}\,{}^\circ F^{-1}}$	1.731 $\mathrm{W\,m^{-1}\,K^{-1}}$
1 W $\mathrm{cm^{-1}\,K^{-1}}$	100 $\mathrm{W\,m^{-1}\,K^{-1}}$
Thermal Resistance[a]	
1 R	0.176 $\mathrm{W^{-1}\,m^2\,K}$

[a] The R value of an insulation is the reciprocal of the conductance per square foot per °F, expressed in $\mathrm{BTU^{-1}\,ft^2\,h\,{}^\circ F}$.

2. THERMAL CONDUCTIVITY

On a microscopic or atomic basis, thermal conduction is due to the random diffusive motion of carriers of heat, moving with speed v and with a mean free path l. The net heat transport is proportional to the temperature gradient, and the thermal conductivity has the form

$$\lambda = \tfrac{1}{3}\,C'vl, \qquad (5)$$

where $C' = C\rho$ is the specific heat per unit volume of the material, ρ being the density. The factor $\frac{1}{3}$ accounts for the random direction of motion of the carriers. The concept of mean free path requires some elucidation. In a Boltzmann-equation approach, which examines the steady-state distribution of carriers in momentum space, one equates $l = v\tau$, where τ is the relaxation time that describes the approach of a perturbed distribution toward equilibrium as a result of the various random interactions between the carriers. When τ or l is a function of carrier energy, Eq. (5) is replaced by an appropriate integration over that energy. When there are several types of carriers, each type contributes additively to the conductivity. However, the mean free path of each carrier is possibly reduced by interaction with carriers of other types. For example, both electrons and phonons contribute a component each to the thermal conductivity of solids, but the electronic component is reduced by the interaction with phonons, while the phonon component is reduced by interaction with electrons, especially at low temperatures.

2.1 Gases

Here the atoms or molecules are themselves the carriers of heat. The heat energy is their kinetic energy and also the vibrational and rotational energy of molecules. The mean free path is comparable to the average distance traversed by a particle from an average initial position to the next collision, but not exactly so, because the relaxation time is really derived from the solution of an integral equation. If the gas consists of particles of only one kind, l is still a function of energy. However, the gas is subject to the conditions that pressure does not vary with local temperature and that there is no net flow of particles. This requires that τ is to a good approximation independent of energy, irrespective of the energy dependence of the collision cross section. Also C' in Eq. (5) is the specific heat per unit volume at constant pressure.

The average mean free path, when limited by interparticle collisions, is of the order of 0.1 μm at normal temperature and pressure. It varies inversely with pressure, but C' is proportional to pressure at fixed T, so that the thermal conductivity is practically independent of pressure. However, at sufficiently low pressures, particularly when the gas is confined in small spaces, the mean free path is also terminated by collisions with the walls and does not increase further with decreasing pressure. Then the thermal conductivity decreases with decreasing pressure (Knudsen effect). Also in that case the pressure in the presence of a temperature gradient is no longer constant, since $\tau = l(E)/v$ is no longer constant. In the extreme limit when l is limited only by boundaries and is independent of E, pressure varies as $T^{1/2}$ in a temperature gradient. This thermomolecular pressure can cause errors in gas thermometry or other pressure measurements when the gas space at one temperature is connected to the pressure sensor at another temperature by a narrow tube. A similar pressure variation would exist in a temperature gradient when the gas fills the interstices of a fine powder.

A more complex situation arises in gas mixtures. The mean free path of each species is limited by collisions with its own and with the other species. The total pressure stays constant in large spaces, but the partial pressure of any one component can vary with temperature, so that the composition varies with temperature. This thermal diffusion effect depends on the various collision cross sections and their energy dependence.

In molecular gases the internal degrees of freedom contribute to C', and for each such component there is, in principle, a different mean free path; collisions tend to bring all degrees of freedom into mutual equilibrium, but at different rates.

Thermal conductivity of gases is discussed, for example, by Hirschfelder *et al.* (1954) and more compactly by McLaughlin (1969).

2.2 Liquids

Liquids range in their properties from gas-like, but at high densities with strong interaction, to similar to solids, but with vanishing shear modulus over long times. The behavior of their thermal conductivity can correspondingly vary between these two extremes. Solids are discussed below. Hirschfelder *et al.* (1954) and McLaughlin (1969) also deal with liquids.

2.3 Solids

One can picture a solid as a uniform background that contains excitations; these behave like a gas of particles and carry thermal energy. The principal excitations are lattice vibrations, free electrons in electrically conducting solids, and electromagnetic radiation in transparent solids. The energy of electromagnetic waves consists of discrete quanta or photons, which can be regarded as particles, carrying energy and moving with the group velocity of the underlying wave. Similarly, the atomic vibrations can be represented by elastic or lattice waves; their quanta (phonons) carry energy with the group velocity of the waves. Each mobile excitation of type α makes a contribution C'_α to the specific heat per unit volume, and a corresponding contribution λ_α

to the thermal conductivity. If the excitations move with speed v_α and have a mean free path l_α, the thermal conductivity has the form

$$\lambda = \sum_\alpha \lambda_\alpha = \sum_\alpha \tfrac{1}{3} C'_\alpha v_\alpha l_\alpha. \tag{6}$$

The various mean free paths are limited by interaction processes. These include scattering of the mobile excitations or heat carriers by various defects of the crystal lattice and by boundaries, both external boundaries and internal or grain boundaries of polycrystalline aggregates. Phonons, and to a lesser extent electrons, do interact with each other. Also, when carriers of more than one type are present, they not only contribute additively to the conductivity, but they may interact with each other and limit each other's mean free path, as mentioned above.

In metals there are contributions from both electrons and phonons, but the electronic component frequently swamps the phonon or lattice component. The electronic component of the specific heat C_e is proportional to the absolute temperature T. In pure metals the electron mean free path is limited by interaction with lattice vibrations and varies as $1/T$; thus the thermal conductivity is almost independent of temperature from room temperature up. In the case of alloys with several-percent solute content, the mean free path is independent of T and $\lambda_e \propto T$, decreasing with increasing solute content. As a rough rule, one can regard the thermal resistivity $W = 1/\lambda_e$ as composed of an intrinsic component W_i independent of T, and a component W_0 that varies as $1/T$ and depends on solute content c, in continuous solid solutions varying as $c(1-c)$. Typically 1%–2% solutes make W_0 equal to W_i at room temperature. At low temperatures W_i decreases with decreasing temperature.

An equivalent and useful way of looking at the electronic thermal conductivity is to compare it to the electrical conductivity σ. Since the electrical conductivity is also proportional to the electron mean free path, and to the number of electrons per unit volume and to C_e, λ_e and σ are proportional to each other (Wiedemann-Franz law), and related by

$$\lambda_e = L_0 \sigma T, \tag{7}$$

where $L_0 = (\pi^2/3)(k/e)^2$ is the Lorenz ratio. Here k is the Boltzmann constant and e is the electronic charge. In mks units, $L_0 = 2.45 \times 10^{-8}\ \mathrm{V^2\,K^{-2}}$. At low temperatures, however, the mean free paths for thermal and electrical conduction are not equal and λ_e is often less than given by Eq. (7).

Equation (7) refers to the electronic component only; there is also a lattice component. If the electrical resistivity is high enough, λ_e is reduced and the lattice conductivity can become a significant fraction of the total. At room temperatures this may be the case when the electrical resistivity exceeds $10^{-3}\ \Omega\,\mathrm{m}$; below 90 K the resistivity needs only to exceed $10^{-4}\ \Omega\,\mathrm{m}$ for this to occur. The thermal conductivity of metals and alloys has been discussed by Klemens (1969) and by Klemens and Williams (1986).

In insulators and in most intrinsic semiconductors the electronic component is absent or negligible, and heat is carried by lattice waves or phonons. The phonon conductivity is

$$\lambda_p = \tfrac{1}{3} C'_p v_p l_p, \tag{8}$$

where C'_p is the vibrational specific heat per unit volume, v_p the group velocity of elastic waves, and l_p the phonon mean free path. When v_p and l_p depend significantly on frequency, this expression must be replaced by an integral over frequencies. The mean free path is limited by various processes:

1. the intrinsic interaction between the elastic waves due to the anharmonic nature of the interatomic forces;
2. the scattering of the elastic waves or phonons by various imperfections of the crystal lattice; and
3. the limitation due to the finite size of crystals, or of grains in the case of polycrystalline solids.

All these processes contribute additively to $1/l$, the scattering probability per unit path length.

Since these scattering probabilities depend on phonon frequency, with different processes having different frequency variations, one should add the contributions to $1/l_p$ for each frequency in turn, and consider the spectral distribution of C'_p to obtain the integral in the generalization of Eq. (8). While at ordinary and high temperatures the largest contribution to C'_p comes from the highest frequencies (with wavelength of about $\frac{3}{2}$ of the interatomic distance), the intrinsic mean free path increases with decreasing frequency, so that equal frequency intervals make equal contributions to the intrinsic phonon conductivity. Also $l_p \propto 1/T$, so that the intrinsic phonon conductivity λ_p varies as $1/T$. Point defects such as impurities or vacancies reduce mainly the high-frequency contribution; grain boundaries and extended defects, such as colloidal inclusions, reduce the low-frequency contribution.

At low temperatures the maximum contribution to C_p' shifts to lower frequency, and the temperature dependence of λ_p is also dependent on the frequency dependence of l_p. At very low temperatures the mean free path approaches a constant value, that of the smallest linear dimension of the specimen, when λ_p becomes proportional to C_p', and attains a T^3 dependence and a size dependence in many cases. This is the phonon-gas analog of the Knudsen effect in real gases.

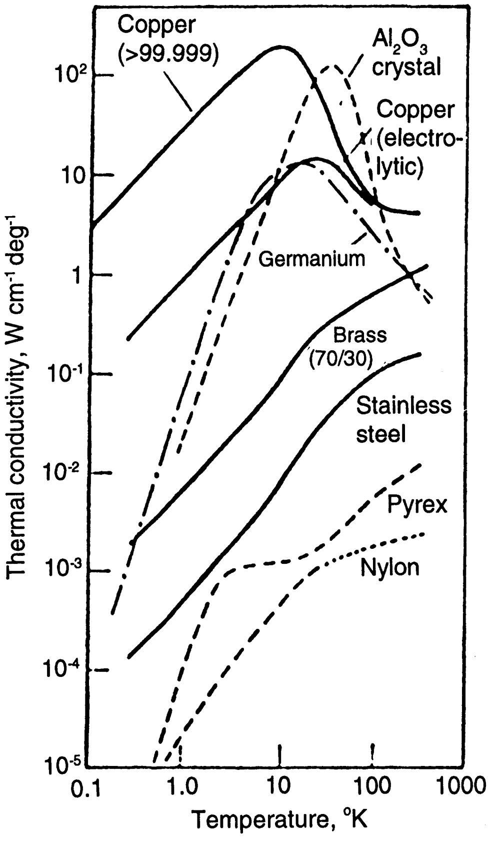

FIG. 1. Wide variability of the thermal conductivities of solids as functions of temperature for metals (full curves), semiconductors (dot-dashed curve), and insulators (dashed curves). From White (1969).

For a review of lattice thermal conductivity see Klemens (1969) and Berman (1976).

Figure 1 shows the thermal conductivities of several solids as functions of temperature, illustrating the variability of that property, which results from two conducting mechanisms, each subject to several different processes limiting the carrier mean free path.

3. RADIATION

Heat can be exchanged between solid bodies by electromagnetic radiation, even over great distances, if the intervening space is empty or filled with transparent material. The capacity of space to carry radiative energy increases rapidly with the temperature of the emitting body; also the energy peak of the emitted spectrum shifts to higher frequency as the temperature is increased. For room-temperature emission the peak lies in the far infrared, but moves to the visible at higher temperatures. The solar surface, at 6000 K, has its radiation maximum in the yellow, and this is also where the human eye has its peak sensitivity. Radiative heat transfer between bodies at different temperatures can be important even at ordinary temperatures; radiation from hot surfaces or to cold surfaces plays a part in human comfort. Radiation can also form a significant component of the thermal conductivity of condensed matter at high temperatures, provided the material has a sufficient spectral range of transparency.

The amount of radiant energy leaving unit surface area of a body varies with absolute temperature T and is given by

$$E = \sigma_{SB} \epsilon T^4, \qquad (9)$$

where $\sigma_{SB} = 5.670 \times 10^{-8}\ \mathrm{W\,m^{-2}\,K^{-4}}$ is the Stefan-Boltzmann radiation constant while the emissivity ϵ, a parameter generally less than 1, depends on the material, on surface roughness, and on the dominant wavelength of the radiation, hence on temperature. For a perfect blackbody, approximately realized by a small hole leading into a cavity, $\epsilon = 1$.

While radiation leaves every surface, other radiation reaches that surface from surrounding bodies, and a fraction ϵ is absorbed. While emissivity and absorption efficiency of a surface are the same at each wavelength, the average values depend on the spectral nature of the incoming radiation. The net energy transfer depends on the solid angle subtended by the other bodies, on the temperatures, and on the effective emissivity and absorptivity. For two bodies at temperature T_1 and T_2 the net energy transfer varies as $T_1^4 - \beta T_2^4$, where β depends on spectral differences and on geometry. When one body completely encloses another and their temperatures are equal, the net energy transfer must be zero.

In a partially transparent medium the photon mean free path, or the attenuation length of electromagnetic waves, is limited by absorption, by scattering from inhomogeneities, and by external boundaries. For moderate temperature differences one can define a radiative component of the thermal conductivity λ_r analogously to the phonon thermal conductivity, except that the specific heat per unit volume of space is smaller, and the mean free path is larger. As in the case of phonons, one must consider the frequency dependence of the mean free path, so that

$$\lambda_r = 4\sigma_{\mathrm{SB}} \frac{T^3}{26} \int n^2(f) l(f) x^4 e^x (e^x - 1)^{-2} dx. \tag{10}$$

Here $x = hf/kT$ is the reduced frequency and h is Planck's constant. Also $n(f)$ is the refractive index, generally a function of frequency f, and $l(f)$ is the mean free path of photons of frequency f. In general $1/l(f)$ is composed of contributions from absorption, from scattering, and from the limitation on the mean free path by external dimensions.

For a constant mean free path the peak in the radiative conductivity is at frequencies for which $x = 4$. In vacuum ($n = 1$) this corresponds to a wavelength of $2.898 \times 10^{-3}/T$ m, where T is in kelvins. In the presence of matter $n > 1$, and the wavelength is reduced by n. If $l(f)$ increases with decreasing frequency, the peak is shifted to lower frequencies. In extreme cases of strong and frequency-dependent scattering, λ_r can be size dependent with most of the heat transferred at those frequencies where $l(f)$ equals the smallest external dimension.

4. CONVECTION

Heat can be transported across a temperature gradient by fluid flow. In forced convection the flow arises from an external cause; in free convection the sources of the flow are density changes due to temperature differences in the presence of gravity. Convection transports heat within a body of fluid, and also transports heat from or to a solid body by conduction, through a boundary layer, into or out of the moving fluid.

When convection occurs, it is much more effective as a mode of heat transport over large distances than conduction. In conduction the heat current per unit area scales as $\Delta T/L$, where ΔT is the temperature difference over a distance L. In convection the heat current scales as $h\Delta T$, where the convection coefficient h is either independent of L or increases with L. It also depends on the flow rate and on local flow conditions at the interface. In free convection h varies roughly as L^3, but depends also on other factors.

An extreme example is heat transport in the mantle of the Earth, which is solid but flows with very high viscosity over geological time scales. Heat flow to the surface is primarily by free convection; conduction and radiation are unimportant and are dominant only in the thin crustal layer.

4.1 Forced Convection

The hydrodynamic equations that govern fluid flow are nonlinear, so that mathematical solutions can be obtained only in a few special cases, and the equations must be solved numerically. Many cases of engineering interest have also been investigated by scale models. For either case one can use dimensional analysis, and can scale solutions with similarities based on nondimensional parameters. The Reynolds number $Re = VL/\nu$ describes the transition between laminar and turbulent flow, being the ratio between inertial and viscous forces. Here V is the flow speed, L a linear dimension of the confining surface, and ν the kinetic viscosity (viscosity/density) that has the dimensions of diffusivity. A high value of Re results in turbulence, since laminar flow is stabilized by viscosity. Critical values of Re range from 10^3 to 10^4, depending on geometry and surface roughness.

Fluid flows parallel to a surface, with a boundary layer of laminar flow and regions of turbulence away from the surface. Within the boundary layer, heat is transferred by conduction. In the turbulent region a uniform temperature is reached by mixing, and the overall flow transports both turbulence and heat. Whether heat flow is limited by the boundary layer or by the rate of flow depends on the Prandtl number $Pr=\nu/\alpha$, where α is the thermal diffusivity. The Nusselt number is $Nu=hL/\lambda_f$, where h is the convection coefficient (heat flow per unit area and unit temperature difference). Now h/λ_f is the temperature gradient at the surface, where λ_f is the thermal conductivity of the fluid, since heat transfer in the boundary layer is by conduction; also $1/L$ is the average temperature gradient for unit temperature difference. Thus Nu is a dimensionless temperature gradient, relative to the average temperature gradient, and describes the relative importance of convection to conduction, or the inverse of the relative width of the thermal boundary layer to the laminar flow region. Finally, in the case of very poorly conducting solids, it is possible for heat flow to be limited by the thermal resistance within the solid. This is described by the Biot number $Bi=hL/\lambda_s$, where λ_s is the thermal conductivity of the solid.

All these dimensionless parameters define physically similar cases of heat transfer for the appropriate limiting mechanism.

4.2 Free Convection

Here the flow responsible for heat transfer is caused by differences in buoyancy due to thermal expansion. Since heat transfer varies as the product of flow velocity V and temperature difference ΔT, and V is caused by ΔT, the heat transfer by free convection would vary as ΔT^2, except for departures from that variation due to changes in the flow pattern with flow speed, e.g., from laminar to turbulent.

Free convection is the result of an instability of a horizontally layered structure of density variations. It thus occurs most easily when a heated surface or other heat source is near the bottom of the fluid.

For similarity considerations, the relevant dimensionless parameter is the Grashof number

$$Gr=g\rho_1(\rho_2-\rho_1)L^3/\nu^2$$
$$=g\rho_1^2\beta(T_1-T_2)/\nu^2, \qquad (11)$$

where g is the gravitational acceleration, β is the coefficient of volumetric thermal expansion, ρ is the density, and suffixes 1 and 2 refer to the hot and cold regions, respectively. The first version is preferable near the critical point, but the second one is the one frequently used. The Grashof number plays a role similar to the Reynolds number in forced convection.

The Rayleigh number $Ra=Gr\nu/\alpha$ describes whether free convection is more important than conduction; for $Ra<10^3$, free convection can be ignored. Apart from buoyancy, free convection depends sensitively on the linear dimension L. For $Ra>10^3$, an instability sets in and fluid motion consists of roll cells that, between parallel horizontal plates, are regularly spaced as shown in Fig. 2. This mode (Bénard-Rayleigh instability) persists for Ra values up to between 10^4 to 10^5, when the fluid motion becomes turbulent. Convection can be suppressed by dividing up the available space into smaller units, as is done in insulations.

Both forms of convection depend, of course, on the geometrical arrangement. For a fuller discussion see Burmeister (1983), or books on heat transfer. Free convection is also discussed by Ziebland (1969).

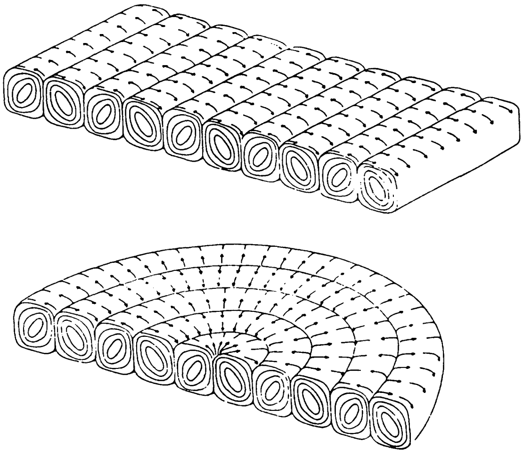

FIG. 2. Roll cells (Bénard-Rayleigh instabilities) in a fluid heated from below, for rectangular and circular symmetry. The fluid is confined at top and bottom by parallel plates. From Velarde and Normand (1980).

5. INTERACTION BETWEEN TRANSFER MODES

There are three basic mechanisms of heat transfer, conduction, radiation, and convection, and it is relatively rare that only one mode is important in any given situation. To a first approximation one treats the heat transfer modes as additive, though for large temperature differences this is unlikely to be true.

Thus, for small ΔT, radiative heat transfer is a linear function of ΔT, and it can be added to transfer by conduction. This holds particularly for radiative heat transport within a translucent solid, where radiation is important at higher temperatures and can be regarded as a component of the conductivity. However, when the attenuation length becomes comparable to the linear dimension and ΔT is no longer small compared to the absolute temperature T, conduction and radiation are no longer additive Also, in transient situations absorption and scattering of radiation play different roles.

Heat transport by phonons in dielectric crystals at very low temperatures, where at least part of the phonons can pass right through the specimen, shows similarity to radiation. The relative amounts of heat thus transported are in the ratio $T^3c^2v^{-2}$, where v and c are the phonon and light speeds, respectively. Phonons transport more heat. In the case of phonons it is also strictly speaking not possible to speak of a true conductivity (Klemens, 1969).

In fluids, free convection does not behave like conduction, since it depends strongly on the linear dimension of unbroken space. Thus the two modes are not additive in their action. In partially transparent fluids all three modes are present. The absorption of radiation in the fluid can cause local heating and enhance the onset of convection.

6. MEASUREMENT OF THERMAL CONDUCTIVITY

There are difficulties in the measurement of thermal conductivity that are often not fully appreciated and that have led in the past to substantial errors in reported values. In principle all that is needed is a measurement of heat current in a specimen of known geometry, together with a measurement of the temperature difference between two specified surfaces normal to the heat flow. Heat flow is known from the heat generated at one end by a heater, if one can be sure that all heat does indeed flow through the specimen. This, of course, is where errors can occur, because convection and radiation do cause some heat to bypass the specimen, at the same time also distorting the isothermal surfaces.

In the case of solid specimens, convection can be eliminated by placing the specimen in an evacuated container. When this is not possible, one should at least have the specimen mounted vertically with the heater on top. Evacuation is used at low temperatures, where one can use rod-shaped specimens. However, radiation can bypass the specimen. Depending on the conductivity, the rod diameter, and the emissivity, radiation becomes important above about 100 K. There is radiation from the sides of the specimen, and also from the heater and from the attached thermometers. Attempts to correct quantitatively for that radiative heat flow have usually not been successful. Packing the space between the specimen and the outer shield with evacuated powder or fiber insulations, using radiation baffles, and matching the temperature gradient of the specimen and that of an outer shield do mitigate the problem. However, as one goes to higher temperatures the geometry of the specimen must be changed, ideally platelike rather than rod-shaped. It is best to surround the plate with temperature-matched guard rings, so that edge effects may be minimized. This geometry is the most suitable for low-conductivity materials. However, it becomes difficult to measure the temperature gradient, since small errors in the effective position of the thermometers become important. Nevertheless this arrangement is currently the best way to measure the overall conductivity of insulations and other low-conductivity materials.

As one goes to high temperatures, radiation effects become increasingly troublesome, and it also becomes difficult to anchor thermometers to the specimen. Pyrometry has been used, sighting into small holes in the specimen. In recent years, however, transient techniques have been preferred. There are several versions. The most widely used one is the flash diffusivity method. A heat pulse is deposited on one side of a disk-shaped specimen, and the temperature rise on the back face is measured as a function of time, using a rapid-response thermometer or pyrometer. This yields the thermal diffusivity $\alpha=\lambda/\rho C$, where λ is the thermal conductivity, ρ the density, and C the specific heat. One still needs to know the specific-heat per unit mass and the density at the required temperature. High-temperature specific-heat measurements are far from trivial, but in general the specific heat and the thermal expansivity are less specimen dependent than the thermal conductivity, so that literature values can be used where available. The heat can be deposited by means of a laser, a flash lamp, or a pulsed current in a thin-film resistor. The temperature rise can be monitored by attached thermocouples or by infrared detectors. Nonlinearity in response can become important, and in some cases one must go beyond the one-dimensional conduction problem to consider spreading and edge effects. The technique is not sensitive to incomplete absorption or to heat losses at the front surface, or to small thermometer errors; the measurement of thermal diffusivity is mainly one of specimen thickness and response time. The fact that a small specimen can be used is often a great advantage. For transparent specimens one must place a thin absorbing film on the front face, and this can cause complications.

Transient methods can also be used to measure thermal conductivity and specific heat, but then one must pay careful attention to measure absolute temperature changes and the deposited heat.

Measurements of the thermal conductivity of fluids present all the problems just discussed, and in addition it is necessary to confine the fluid, both gases and liquids, in a container. Also, one must suppress free convection. A cylindrical geometry is often used, with a central wire that serves both as heater and as thermometer, and an outer cylindrical sheath. End effects are corrected for either by using two cells of different length, or by guard cylinders. The size must be chosen so as to make the Grashof number small enough. The hot-wire method can be adapted to conductivity measurements as function of pressure, and has also been used for powders. The main problem is accurate alignment. Experimental techniques to measure the thermal conductivity of fluids have been reviewed by Ziebland (1969).

The appreciation of the experimental difficulties in thermal conductivity measurements has led to a series of conferences on thermal conductivity, where these problems have been discussed in depth (Cremers and Fine, 1990; also earlier conferences in that series).

7. APPLICATIONS

Problems in heat transfer can be divided into two groups, either to obtain a maximum heat transfer between two bodies or regions, or to keep the heat transfer as low as possible. The applications given here divide into these two classes.

7.1 Enhanced Transfer

7.1.1 High-Conductivity Substrates. Although the amount of heat generated in electronic circuit elements is not large, the development of integrated circuits of high packing density does require high current densities and low temperature differences. Cooling by forced or free convection is not possible directly at these elements, but only at the far side of a solid substrate, often loosely called a heat sink. The development of electrically insulating solids of high thermal conductivity has thus become a priority. These substrates must have a high phonon conductivity, even in the form of thin plates or films.

High phonon conductivity at room temperature requires single crystals or large-grained polycrystalline materials. The basic material should be composed of light atoms, strongly bound, and should be free of lattice defects and impurities (to better than 3×10^{-3} per atom), and in the case of a polycrystalline aggregate the porosity or the amount of binder should be small. For a volume fraction c of pores or other low-conductivity inclusions the conductivity is reduced by a factor of $1-nc$, where n varies between $\frac{4}{3}$ and $\frac{5}{3}$. Candidate materials include boron nitride, beryllium oxide, and diamond. Oxides of the next row in the periodic table (MgO, Al_2O_3, SiO_2) have a lower thermal conductivity but are more readily available as single crystals. There is usually a 10%–15% difference between single crystals and polycrystalline aggregates of the same material (Touloukian *et al.*, 1970).

Natural diamond crystals have been considered as substrates for special applications, but only pure crystals have a high conductivity of 3000 W m^{-1} K^{-1} at room temperature. Their availability and cost would be a limitation. However, in recent years it has become possible to grow diamond films and free-standing thin plates by chemical vapor deposition. The key to the process is the removal of incipient graphite inclusions, using atomic hydrogen as an etchant. These films are composed of small grains, random or columnar, and also the lattice is not perfect but contains both point defects of atomic dimensions and large imperfections of 100-Å scale. All these depress the thermal conductivity substantially below 100 K, while at room temperature it has been possible to approach the conductivity of bulk diamond to within a factor of 2.

Diamond crystals can also be grown in pressure vessels using metals as pressure-transmitting media. These crystals are pure, but may contain traces of impurities. A surprising result was that the use of monisotopic carbon led to a significant increase in thermal conductivity. To what extent the room-temperature thermal conductivity is influenced by the natural 1% content of ^{13}C, and to what degree it is influenced by residual impurities, is still a matter of debate (Anthony *et al.*, 1990).

7.1.2 Hot Isostatic Pressing of Metal Powders. Many metal alloys are best prepared in the form of powders, as this allows rapid cooling of small droplets and retention of metastable phases. These powders are then compacted by pressing at temperatures high enough for plastic flow but low enough to retain the desired structures. Isostatic pressing allows control of the final shape. The powder is filled into a container that is evacuated and sealed, and hot gas is used to apply external pressure to the container and to the powder mass within it. One problem is to ensure that the powder has reached the desired temperature everywhere, particularly in the center of the container. Each particle is at one temperature, as a result of the high conductivity of the alloy, but the contact between particles has a small area, which varies as the hydrostatic pressure of the powder itself, and inversely as the yield stress. Gas conductivity is absent, and radiation transport is inhibited by the small photon mean free path in the interstices, so that the overall conductivity is very low. Preheating thus requires long times. One cannot directly measure but one can only estimate theoretically the time required, which can be of the order of a day for moderate sizes. Usually the last place to reach the pressing temperature is near the top of the powder mass, where contact areas are smallest, about as deep down as the horizontal radius of the form. This is indeed the region where pressing defects are most frequently found.

7.2 Reduced Transfer

In the following applications, one aims to reduce the heat transfer.

7.2.1 Thermoelectric Energy Conversion. A thermoelectric element can be used as a heat engine. The temperature difference causes a thermoelectric voltage that generates a current to deliver external work. Similarly an applied current can lift heat energy from the cold to the hot junction. The efficiency depends on the Carnot efficiency and a reducing factor that increases with a coefficient of performance $ZT = S^2\sigma T/\lambda$. Here S is the thermoelectric power, σ the electrical conductivity, T the absolute temperature, and λ the thermal conductivity. Until now it has been possible to obtain ZT values around 1. An increase in the coefficient of performance would widen the applicability of thermoelectric converters and refrigerators. Robustness and long life, so important in space applications, are achieved as a compromise at the expense of efficiency; here too an improvement in ZT is desirable. For a recent discussion see Allred *et al.* (1991).

Apart from external parasitic effects, the main limitation is the phonon component of the thermal conductivity, λ_p. In these conductors, which are between semiconductors and semimetals, $\lambda = \lambda_e + \lambda_p$, and the electronic component λ_e depends on both σ and S. If it were not for the phonon component, the quantity to be maximized, $S^2\sigma/\lambda_e$ would be the larger the lower the carrier concentration, since a small concentration of electrons or holes increases the magnitude of S. If $\lambda_p > \lambda_e$, one aims to increase $S^2\sigma$, which means increasing the carrier concentration. The actual optimum occurs for carrier concentrations such that λ_e is comparable to λ_p. The smaller one can make λ_p, the higher is the value of ZT for optimum carrier concentration. The aim is then to reduce λ_p without reducing σ for fixed S, i.e., without reducing the carrier mobility.

An obvious step is to make the semiconductor an alloy, replacing atoms by solutes from the same column of the periodic table, so that the mass and size difference scatters phonons, while electron scattering is minimized by the similarity in the ionic charge. However, this phonon scattering depends strongly on frequency, scattering high-frequency phonons but allowing low-frequency phonons to pass unimpeded. At those carrier concentrations that optimize performance, the phonons of lowest frequency are scattered by the carriers. This still leaves a frequency range or window in which phonons are only weakly scattered. This limits the attainable reduction in λ_p. Current research aims to close this window by introducing extended defects, which scatter phonons in that frequency range without degrading the mobility of the carriers.

7.2.2 Thermal Insulations. Efficient insulations consist of an array of solid particles of low conductivity or other elements, of small size, making contact with each other only over small areas, so that solid conduction takes a tortuous path and is reduced. At the same time the spaces between the particles are small, reducing convection. This still leaves gas conduction and radiation as important components.

The insulations can be powders, fibers, or foams. The last are cells of space separated by thin solid walls. The solid material should have a low bulk thermal conductivity.

The best insulations are those where gas has been removed from the interstices. These are the most expensive to produce, requiring prolonged pumping and vacuum-tight enclosures. The enclosures, in turn, require some form of mechanical support that act as conducting bridges; without spacers the enclosure walls could press onto the solid filler and increase the contact areas. In such evacuated insulations the solid filler still plays an important role, because the particles cut down the radiation. Unless the particles are very fine or the fibers extremely thin, the radiative resistivity $1/\lambda_r$ depends on the number of surfaces intersected by a random line traversing the insulation.

Evacuated panels are too expensive for many applications, and most common insulations, such as building insulations, contain gas at atmospheric pressure. It is then an advantage to use fine fibers, fine powders, or foams of fine structure, so that radiation is reduced by numerous interfaces, and the small interstices reduce gas conduction by limiting the molecular mean free path.

In the commonly used glass-fiber building insulations one accepts gas conduction, hoping to reduce the overall conductivity to approach that of air. The fibers serve to eliminate convection in the gas, and to reduce radiation by presenting interfaces and by some absorption. Since radiative resistance depends mainly on the total number of fiber surfaces in the total thickness of the insulation, a limited amount of settling can be tolerated.

Solid foams, which contain the blowing gas in the cells, also make good panel insulations, though they are fragile. It helps if the gas in the cells has a large molecular weight, though there may be environmental concerns. Unfortunately, air tends to leak or diffuse into the cells, and the blowing gas eventually leaks out. This increases conduction, so that foams deteriorate over a time that is too short for the long life required of building insulations. Encapsulation is a possible solution, but this limits the applicability of foams.

Aerogels are an interesting class of materials, developed in recent years. They consist of a skeleton of fine particles with interstices. The particles themselves contain substructures over a range of dimensions, so that the material has intrinsic interest as a fractal structure. The main interest lies in their low density and low thermal conductivity. Aerogels can be produced by supercritical evaporation of many liquid materials; commonly the residue is a form of amorphous silica. After evacuation, the material is lightweight and solid, has low thermal conductivity, and is translucent. For robust insulations some encapsulation or covering film are required. This is currently a field of intense research and development (Fricke, 1986, 1992).

INTRODUCTION AND GENERAL ASPECTS

Acoustic waves or sound waves result from the vibrations of atoms or molecules and, at audible frequencies (lower than about 20 kHz), can be generated in many different ways. Human speech, for example, lies in this range. Sound waves at these frequencies can propagate reasonably well through the atmosphere, as evidenced by the fact that the waves can be heard from afar. But at higher frequencies (about 1 MHz), where sound waves are inaudible, the atmosphere is a poor medium for propagation. Ultrasonic waves are rapidly dissipated in the gases of the air and can be made to travel appreciable distances only in condensed media such as liquids and solids. Acoustic waves vibrating in condensed matter at ultrasonic frequencies are usually generated by radio-frequency excitation of piezoelectric materials such as quartz (see Fig. 1).

In the megahertz region ultrasonic waves have been widely used for the study of underwater objects, internal structural features of materials, and even organs inside the human body. The wavelength of megahertz ultrasonic waves in many solids is typically in the millimeter region, and thus such waves are sensitive to features that are macroscopic in size. Using microwave (Bömmel and Dransfeld, 1960) excitation of piezoelectric thin films or surfaces, one can extend the frequency to the gigahertz (10^9 Hz) regime, and the wavelength can be reduced to the submicrometer region. Since the early 1960s microwave ultrasonics has been widely used for the study of materials (Nowick and Berry, 1972). More recently an ultrasonic apparatus, the acoustic microscope, was developed (Quate, 1979) to generate "acoustic pictures" with a resolution comparable to that of visible light microscopy. Sound waves and light waves are reflected and absorbed differently by the same object and thus can often yield complementary microscopic information about the materials being studied.

Acoustic propagation (see Ilukor and Jacobsen, 1966) with conventional piezoelectric transducers becomes quite difficult at frequencies beyond about 10^{10} Hz. Sound waves with frequencies of hundreds of gigahertz and terahertz (10^{12} Hz) are well into the thermal vibrational spectrum of the solid. At these enormously high frequencies the discrete nature of the thermal vibrational spectrum becomes important, and the quantized lattice vibrations—also referred to as phonons—

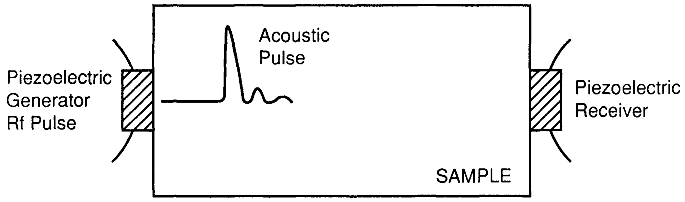

FIG. 1. Schematic of typical acoustic experiment using piezoelectric transducers.

have extremely short wavelengths, in the range 10–100 Å. Because of the short wavelength it becomes extremely difficult to preserve the phase coherence of a piezoelectrically generated wave as it traverses the boundary between the generator and the transmission medium under study. In addition, the propagation of such high-frequency phonons can be severely affected by the presence of defects and by phonon–phonon scattering.

An alternative to piezoelectric excitation of single-frequency lattice vibrational phonon modes would be to use a heat source to generate a broad spectrum of phonons locally on one end of the sample under study and "watch" their propagation with a temperature-sensitive detector at the other end of the sample [Fig. 2(a)]. The time constant and hence the speed with which this can be done is determined by the ratio of the heat capacity and the thermal conductivity of the thin-film transducers. For vacuum-deposited thin (~1000 Å) metal films this time constant is typically about 10^{-8} s, while the travel time across the sample is $\sim 10^{-6}$ s (depending on the phonon velocity and sample thickness). In the case of a normal-metal film such as gold or copper, the resistive heating results in a broad Planck frequency distribution [see Fig. 2(a)] with a peak in frequency that depends on the temperature T_h of the heater. For a value of $T_h \sim 10$ K the peak phonon frequency is ~0.6 THz. Such metal heaters are thus efficient sources of high-frequency phonons, but have a broad distribution similar to tungsten lamps in optics. The heat-generated phonons can be detected at the other end of the sample after a characteristic time of flight by means of a sensitive thin-film bolometer, that is, a device whose resistance is a strong function of temperature. Such heat-pulse experiments in solids were first reported by von Gutfeld (1968).

In order to get a more monochromatic distribution of high-frequency phonons, one has to make use of the detailed quantum-mechanical interaction between electrons and phonons in metals and semiconductors. In the case of superconductors, the existence of the energy gap, 2Δ, leads to the possibility that phonons can excite electrons across the gap, an analogy with the photoelectric effect. The energy gap itself arises because it takes an energy of 2Δ to bind two electrons of opposite momenta into what is known as a Cooper pair. The binding is provided through the mediation of the electron coupling by the strong electron–phonon interaction responsible for superconductivity. A superconducting device that can be used to generate high-frequency phonons is shown on the left-hand side of Fig. 2(b) and is known as a tunnel junction. It consists of a sandwich of extremely thin (~1000 Å) films of two superconductors with an insulator (~20 Å) in between. When a voltage V is applied across the sandwich, the insulator acts as a gate that transmits only electrons of energy $eV > 2\Delta$, where e is the electron charge. Because the electrons can couple to phonons by the electron–phonon interaction, the injected electrons transfer their energy to the lattice in the form of phonons with a spectral distribution that strongly deviates from a thermal Planck distribution. For voltages close to a value such that $eV = 2\Delta$, the recombination radiation (which involves the recombination of electrons of opposite momenta to form a Cooper pair) corresponds to phonons of frequency $\nu = 2\Delta/h$. For higher voltages, "relaxation" phonons of energy $eV - 2\Delta$ can also be emitted. This is because the electron loses its energy in two steps. It first reaches the gap edge by emitting $eV - 2\Delta$ phonons, and then recombines with an electron of opposite momentum to emit a 2Δ phonon. Thus the phonon spectrum depends in a characteristic way on the electron injection energy. The upper frequency limit of the relaxation phonon spectrum is determined by reabsorption processes in the superconducting film, and in favorable cases [see Eisenmenger (1976)] it can exceed the superconducting energy gap. FIG. 2. (a) Schematic of experimental arrangement with thin-metal-film transducers. Emission spectrum for a normal-metal film for a characteristic temperature of 10 K. (b) Spectrum of phonons generated by a superconducting tunnel-junction generator under different conditions of bias. For biases close to the gap edge, only recombination phonons are generated. For higher biases, the electron loses energy in two steps by emitting first a relaxation phonon and then a 2Δ phonon.

the generated recombination and relaxation phonon spectrum is determined in detail by the strength of the electron–lattice coupling and the density of states (i.e., the shape of lattice vibrational spectrum of the superconductor). Table 1 shows the transition temperature T_c and zero-temperature energy gap for a few common superconductors. It is clear that quantum processes in superconductors

Table 1. Transition temperature T_c, energy gap 2Δ, and gap frequency γ for several superconductors.

Superconductor	T_c (K)	2Δ (MeV)	γ (10^{11} Hz)
Al	1.18	0.36	0.9

$Pb_{0.85}Bi_{0.15}$	8.5	3.2	8.02

can be used for the generation and detection of phonons in the range 10^{11}–10^{12} Hz.

In addition to thin metal-film transducers, in the case of semiconductors and insulators one can excite the electronic energy states of donors, acceptors, and other atomic point defects, which, when preferentially excited by optical or electrical means, can lose their energy by phonon processes [see Narayanamurti (1981)]. Laser excitation in general can be a very useful method for studying phonons in solids. Laser beams can be focused to a small spot, scanned across the surface, tuned in frequency to excite specific levels, and pulsed to very short duration. The combination of laser excitation with phonon techniques can thus be very powerful. For example, one can directly excite impurity levels in crystals with far-infrared lasers and then watch the deexcitation through the emission of extremely high-frequency resonant terahertz phonons. In other cases, optical radiation can be absorbed in a thin film in an extremely short (picosecond) time scale, and thereby acoustic phenomena in an entirely new time domain can be observed.

In this article we will provide a survey of the nature of the propagation of both heat and high-frequency quasimonochromatic phonons in solids. We will show that the propagation in appropriate circumstances can be highly directional in nature, a property that can be useful for studying materials. Both the focusing of phonon energy and the use of high-frequency phonons for spectroscopic studies will be described. New applications analogous to photoacoustic spectroscopy will also be briefly presented. Thus the manipulation of phonons with novel transducer materials and the physical studies made possible may be best described as *phonon optics,* a term the author first used in 1979, which will form the major portion of this article.

1. NATURE OF HEAT-PULSE PROPAGATION

Propagation of heat in most materials is generally thought to be a slow diffusive process. This is true if the phonons that carry the heat suffer frequent scattering events. These scattering events are usually the result of the presence of defects and free carriers and of intrinsic phonon–phonon collisions. Phonon–phonon collisions can be minimized by cooling the sample to low temperatures where the population of thermally excited phonons is small. In "perfect" dielectric solids and semiconductors at low temperatures, heat propagation can thus be ballistic; that is, the phonons created by a pulse of heat at one point can travel rectilinearly for distances of the order of centimeters at the velocity of sound [see, for example, von Gutfeld (1968)].

The frequency distribution of the heat pulse, as described earlier, is characterized by a heater "temperature" T_h that can be substantially higher than the ambient temperature of the sample. The problem is like the radiation from the sun. On a clear day, we on Earth see a frequency distribution that is characterized by the temperature of the source (the sun in this case), even though the actual temperature on the Earth is much lower. In a moderate fog our eye detects a diffuse source of scattered photons, but may still observe some ballistic photons that sharply define a dim image of the sun. In a dense fog, only scattered photons can be seen.

As mentioned earlier, the phonons can also scatter along the way between the source and detector. Any perturbation that locally destroys the periodicity of the lattice will act as a scattering center. In an otherwise perfect crystal, even the random distribution of naturally occurring atomic isotopes can act as scattering centers. The isotope scattering is analogous to Rayleigh scattering of light by atoms, and has a strong frequency dependence (ν^4). High-frequency phonons scatter more readily than low-frequency ones. For similar reasons, the sky is blue.

1.1 Ballistic Phonons and Phonon Focusing

Ballistic phonons and their scattering have been observed in numerous solids over the last 20 years. In Fig. 3(a) we show typical heat pulses observed in the ⟨110⟩, ⟨111⟩, and ⟨100⟩ crystallographic directions in nominally pure GaAs for an almost identical propagation length of about 2.3 mm. The separate pulses correspond to ballistic traversal of longitudinal (L) and fast and slow transverse (FT and ST, respectively) phonons, whose velocity depends on the direction of phonon propagation. The longitudinal mode is a compression wave and has the highest velocity. The trans-

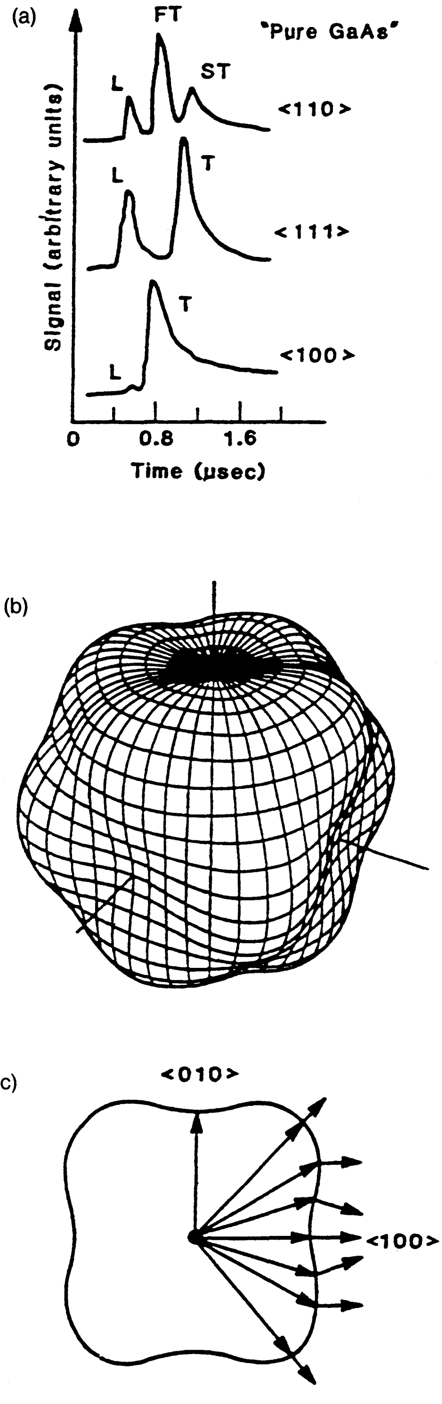

FIG. 3. (a) Ballistic phonons in "pure" GaAs for three different propagation directions; propagation length ~2.3 mm (after Narayanamurti, 1981). (b) Three-dimensional constant-frequency surface in wave-vector space for the slow transverse mode in GaAs. (c) Cross section of the same surface in the [100] plane and showing the focusing of the energy flux. The energy flux is determined by the group velocity $\partial\omega(k)/\partial k$.

verse modes are primarily shear waves and have a lower velocity. The two shear waves in the ⟨111⟩ and ⟨100⟩ directions have the same velocity. It is also clear from Fig. 3(a) that the relative intensity of the T and L pulses changes by more than an order of magnitude depending on the orientation. It is about 2 in the ⟨111⟩ direction and about 20 in the ⟨100⟩ direction. This focusing of the phonon intensity is due to the elastically anisotropic nature of the solid (see, for example, Maris, 1971). In anisotropic crystals the phase velocity $V=\omega(\mathbf{k})/|(\mathbf{k})|$ depends on the direction of the wave vector **k** and can be calculated from the constant-frequency or "slowness" surface $\omega(\mathbf{k})=\text{const}$. This surface is shown for the ST mode in GaAs in Fig. 3(b). The group velocity $V_g=\partial\omega(\mathbf{k})/\partial(\mathbf{k})$, which defines the direction of energy flow for the [100] plane, is shown in Fig. 3(c). In this case the energy flow is strongly enhanced or focused along the [100], [010], and [001] symmetry axes, which explains the high T-mode intensities relative to the L mode observed in the ⟨100⟩ direction in Fig. 3(a).

The focusing of phonon beams can be numerically calculated from a three-dimensional slowness surface such as that shown in Fig. 3(b). Maris (1971) showed that the energy flux enhancement A is determined by the ratio of the solid angles in **k** space and energy flux in ray (**r**) space: $A=d\Omega^k/d\Omega^r$. For a spherical surface $A=1$. For an anisotropic surface A can vary over a wide range, depending on the curvature of the surface.

Another major effect in determining focusing patterns is the effect of phonon dispersion. Figure 4 shows the frequency versus wave-vector relation for the TA mode in the [111] propagation direction of several III-V compound semiconductors. Unlike photons, the curvature of the frequency–wave-vector relation causes a reduction in the group velocity as a function of frequency. Furthermore, the focusing patterns now must depend markedly on frequency.

The effects of dispersion on phonon focusing in III-V semiconductors has been observed by Wolfe and co-workers (see Wolfe, 1989). An x-y laser scanning system is used to excite the heat pulse on one end of the sample under study. A bolometer or a superconducting tunnel junction is used as the detector. Since a tunnel junction has a threshold detection capability, the leading edge of the arriv-

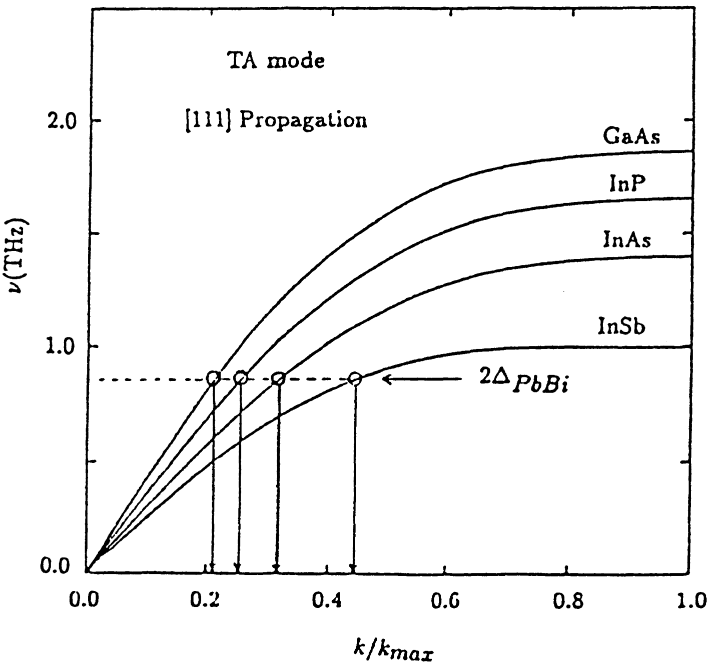

FIG. 4. Dispersion curves for several III-V semiconductors. The onset frequency of a Pb:Bi superconducting tunnel junction is also shown (after Wolfe, 1989).

ing pulse corresponds to the frequency of the energy gap of the superconductor. In the case of Pb:Bi alloys this corresponds to nearly 0.8 THz (see Table 1 and Fig. 4). Figure 5 shows the experimental phonon images for InSb (see Hebboul *et al.*, 1986) with a broadband Al bolometer [Fig. 5(a)] and with a Pb tunnel junction [Fig. 5(b)]. The two images are very different. The images for the tunnel junction require detailed knowledge of the dispersion curve for the solid. This in turn is a strong function of the interatomic forces that determine the lattice dynamics for the solid. By such focusing studies one can differentiate between different atomic force field models for compound semiconductors, as has been shown by Wolfe (1989).

1.2 Second Sound

We now turn to the situation when phonon–phonon scattering becomes important. This becomes true when the temperature is raised, i.e., when the phonon–phonon scattering time (τ) is less than the ballistic propagation time. The most likely phonon–phonon scattering process is a three-phonon process of the type

$$\omega_1+\omega_2\rightleftarrows\omega_3, \qquad (1)$$

$$\mathbf{k}_1+\mathbf{k}_2\rightleftarrows\mathbf{k}_3, \qquad (2)$$

where Eqs. (1) and (2) reflect conservation of energy and momentum. If the frequency of one of the phonons is large, then the final momentum can lie outside the Brillouin zone, and the process results in a directional change of the phonon (momentum nonconserving) with the extra momentum being taken up by the lattice. Such umklapp processes give rise to a decay in the heat flow and to a finite thermal conductivity, even in a perfect dielectric solid. However, if ω_1 and ω_2 are such that the final momentum lies within the Brillouin zone, then the process is referred to as a normal process (momentum conserving) and does not lead to diffusion of heat.

The propagation of a heat pulse (with a temperature T) down a bar of a dielectric solid (see, e.g., Ackerman and Guyer, 1968), can be described by two microscopic equations:

(a) energy conservation,

$$C_v\frac{\partial T}{\partial t}+\nabla\mathbf{Q}=0; \qquad (3)$$

(b) modified heat current equation,

$$\tau\frac{\partial Q}{\partial t}+\mathbf{Q}=-K\nabla T. \qquad (4)$$

Here T is the temperature, which is a function of the propagation direction and the time t, K

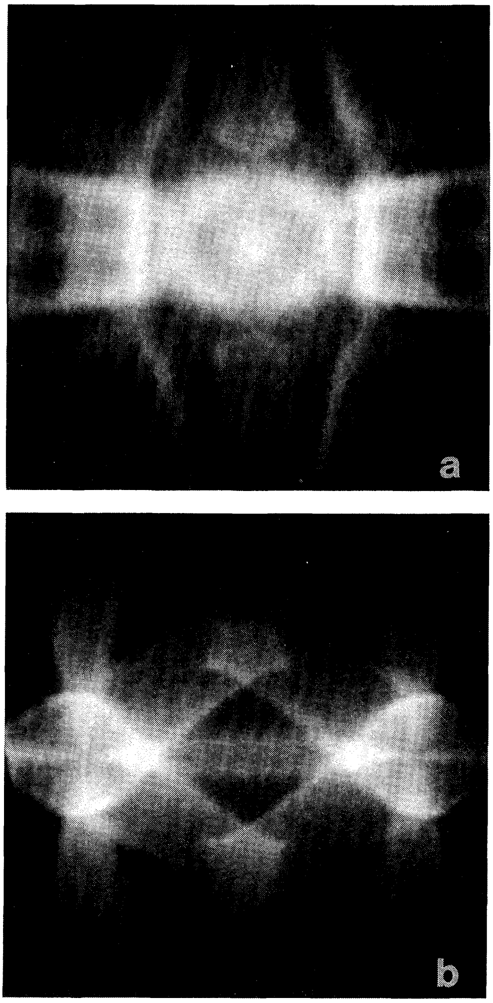

FIG. 5. Experimental phonon images for a 2-mm-thick InSb crystal: (a) for an Al bolometer detector: (b) for a Pb tunnel-junction detector (after Hebboul *et al.*, 1986).

is the thermal conductivity, τ is the relaxation time characterizing the response of the heat current, and C_v is the specific heat at constant volume. In the event $\tau \approx 0$, Eq. (4) describes the well-known Fourier heat law.

Equations (3) and (4) can be combined to lead to

$$\frac{\partial^2 T}{\partial t^2}+\frac{1}{\tau}\frac{\partial T}{\partial t}-\frac{K}{C_v\tau}\nabla^2 T=0. \tag{5}$$

The relaxation time τ consists of two parts: a part τ_N that refers to normal processes, and a term τ_u that refers to umklapp processes. The description of the heat flow when both τ_N and τ_u are finite and comparable to the propagation time is quite complex and is beyond the scope of this article. However, in the limit $\tau_u \to \infty$, Eq. (5) has the simple form

$$\frac{\partial^2 T}{\partial t^2}+\tfrac{1}{3}v_1^2\nabla^2 T=0 \tag{6}$$

for which we have plane-wave solutions for the temperature, $T=T_0+\delta T\exp[i(\mathbf{k}\cdot\mathbf{x}-\omega T)]$, with a dispersion relation $\omega^2=k^2v_1^2/3$; a true temperature wave propagates in the solid with a velocity $v_{\mathrm{II}}=v_1/\sqrt{3}$. Here, we have for simplicity assumed that the phonon velocity v_1 in the solid is isotropic and independent of polarization. Such temperature waves in solids were first predicted by Ward and Wilks in 1951 and experimentally observed in solid helium by Ackerman and Guyer in 1966 (see Ackerman and Guyer, 1968). The wavelike solutions predicted above get quickly damped in ordinary crystals where momentum-destroying defects, including naturally occurring mass defects, cause the heat current to decay with time. Since the velocity of propagation for temperature waves is considerably smaller (by a factor of $\sqrt{3}$) than that for ordinary (first) sound, the arrival time at a receiver is correspondingly delayed. This delay led to the coining of the name "second sound" for temperature waves. Even in pure solids there is only a narrow temperature window (where τ_N is short and τ_u is long) where second sound can be observed. To date second sound has been observed in solid ^{4}He, solid ^{3}He, NaF, and Bi (see, for example, Narayanamurti *et al.*, 1975).

The transition from ballistic phonon flow to second sound occurs in a temperature regime where $\omega\tau_N \ll 1$, i.e., when there are enough momentum-conserving phonon–phonon collisions to describe a true temperature in the gas of phonons. The dispersion relation for finite values of $\omega\tau_N$ can be approximately written as (see, e.g., Narayanamurti *et al.*, 1975):

$$k^2v_{\mathrm{II}}^2=\tfrac{1}{3}k^2v_{\mathrm{I}}^2=\omega^2+\frac{i\omega k^2\tau_N(v_{\mathrm{I}}^2-v_{\mathrm{II}}^2)}{1-i\omega\tau_N}\,. \tag{7}$$

Figure 6 shows the dispersion relation for the heat-pulse velocity from Eq. (7). By measuring the dispersion relation, one can get information on the temperature and/or frequency dependence of the normal-process

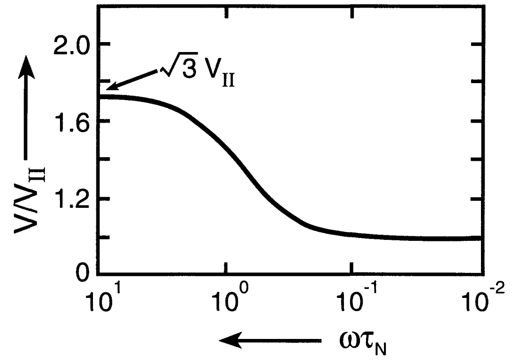

FIG. 6. Dispersion relation for heat-pulse velocity v as a function of $\omega\tau_N$ obtained using Eq. (7). v_{II} is the second-sound velocity and is reached only for very small values of $\omega\tau_N$.

relaxation time τ_N. The limiting second-sound velocity v_{II} is only reached for small values of $\omega\tau_N$ ($<10^{-1}$).

Figure 7 shows a series of traces as a function of temperature for heat-pulse propagation in solid ^{4}He (after Narayanamurti and Dynes, 1975). At very low temperatures one sees a strong transverse ballistic pulse that arrives at the ballistic velocity. As the temperature is raised from 0.07 to about 0.5 K, the pulse broadens and slows down and arrives at later times. By 0.5 K the normal-process collision time is short enough and the second-sound mode is fully developed and has many echoes [Fig. 7(f)]. Figure 8 shows the temperature dependence of the peak velocity. From such measurements detailed information on the temperature dependence of τ_N can be obtained.

2. PHONON SPECTROSCOPY

A great deal of work has been done in which ballistic heat-pulse and tunnel-junction techniques were used to study electronic states of donors, acceptors, and defects in semiconductors and insulators. The phonon coupling to such states depends markedly on the nature of the defect and on frequency, polarization, and propagation direction. Experiments that yield selective attenuation of groups of phonons can serve as a valuable tool for determining energy states and their structural symmetry. This field has been recently reviewed by Wybourne and Wigmore (1988). In the following we will consider a few illustrative examples.

2.1 The Case of Donors and Acceptors in Semiconductors

There are a large number of reported accounts of phonon studies applied to semiconductors. This is in large measure due to the technological importance of semiconductors and the important role defects play in the operation of electronic and optoelectronic devices.

Shallow donor and acceptor states are hydrogenlike and are constructed from the Bloch states of the conduction- or valence-band edge, respectively, multiplied by the approximate envelope function describing the location of the defect. Particularly interesting are donor states. Si and Ge, for example, are indirect

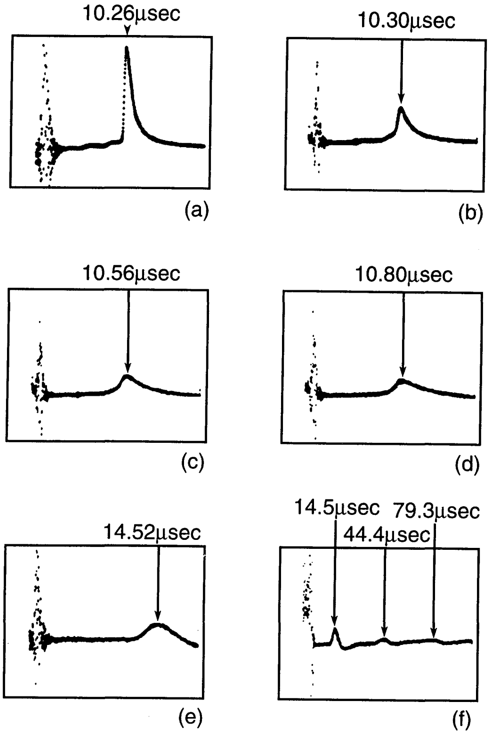

FIG. 7. Temperature dependence of heat-pulse propagation in solid ^{4}He. Molar volume ~21.0 cm^3/mol. (a) T=0.07 K; (b) T=0.18 K; (c) T=0.245 K; (d) T=0.27 K; (e) T=0.495 K; (f) T=0.495 K. The arrows indicate time of arrival of the peak. Time t=0 is determined from the initial electromagnetic ringing. In case (f) the time scale is such that two echoes of the second-sound pulse are readily seen. Propagation length was 2.33 mm (data from Narayanamurti and Dynes, 1975).

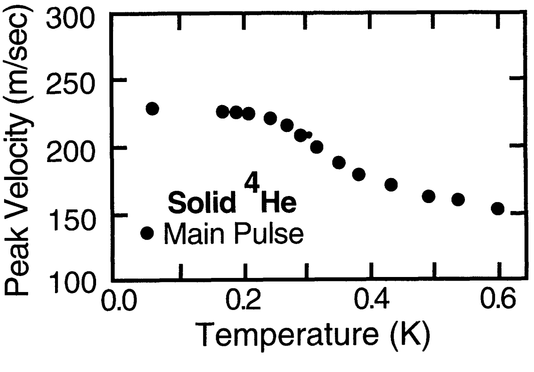

FIG. 8. Temperature dependence of the peak heat-pulse velocity for solid ^{4}He. Molar volume ~21.0 cm^3/mol. The measured second-sound velocity is about 157 m/s.

band-gap semiconductors whose conduction-band minima are sixfold and fourfold degenerate, respectively. The degeneracy of the ground state is lifted by interactions (the so-called valley–orbit interaction). The splitting of the ground and excited states is typically a few meV, which makes these systems ideal for acoustic-phonon resonance studies. Furthermore, the energy levels can be varied by applying pressure on the system.

The first direct phonon resonance absorption experiments in which superconducting tunnel junctions were used as sources and detectors of "quasimonochromatic" phonons were performed by Dynes, Narayanamurti, and Chin (see Narayanamurti, 1981). They used the pressure dependence of the energy levels of the shallow donor antimony in germanium to obtain a resonance absorption of 2Δ phonons generated by a superconducting tin tunnel junction. In Fig. 9 we show a schematic of the experimental arrangement as well as the theoretically predicted variation of the energy levels as a function of uniaxial pressure applied along the ⟨111⟩ direction. The generator was biased at a voltage $eV = 2\Delta = 1.2$ meV so that only recombination radiation was emitted by the junction. At a value of stress corresponding to an energy splitting of 1.2 meV a strong decrease in the phonon transmission was observed. Measurements as a function of phonon polarization and energy yielded the symmetry of the states and the strength of the defect phonon coupling. The observation of the resonance absorption of phonons in this experiment also served as the first direct experimental confirmation of the quantum nature (as distinct from heat) of the recombination process in superconducting junctions.

As a second example we consider the case of deep donor-related states in GaAlAs. In liquid-phase epitaxial growth of this material (see Lang, *et al.*, 1979), donors are believed to form a complex referred to as a *DX* center, where *D* denotes a donor and *X* the unknown second constituent. The *DX* center is believed to be strongly coupled to the lattice, so that when the center captures an electron it lowers its energy substantially. The electronic energy is shown as a function of the lattice configuration *Q*, on the right side of Fig. 10(a). The center can be emptied (ionized) by optical excitation at energy E_{opt}. The combined effect of the electron–lattice coupling and the defect potential produces a bound state when the defect is occupied.

Direct experimental confirmation of the strong defect–lattice coupling and the symmetry of the *DX* centers was observed for the first time by ballistic phonon attenuation tech-

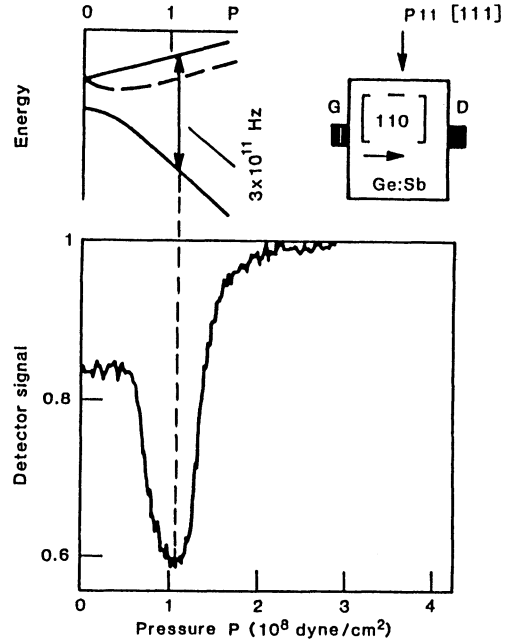

FIG. 9. Transmission of 1.2-meV phonons through a ~4-mm-thick sample of germanium doped with about 2×10^{15} antimony donors as a function of uniaxial pressure (after Narayanamurti, 1981). The top of the figure shows the calculated energy levels of Sb donors as a function of energy. When the energy-level splitting equals the 2Δ phonon energy, a resonance absorption is observed.

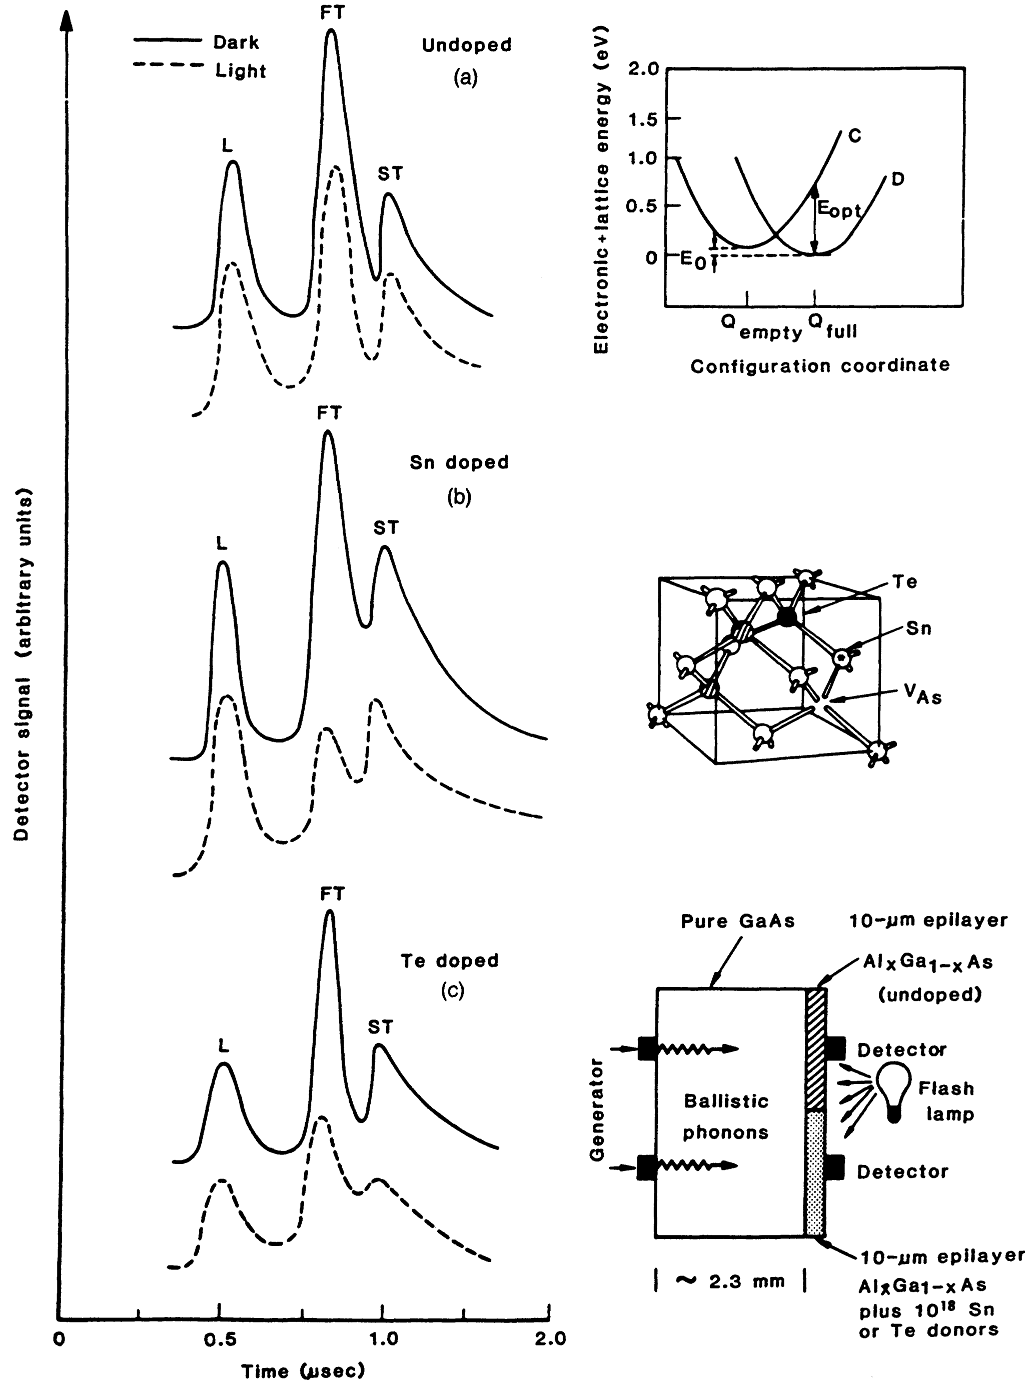

FIG. 10. Ballistic phonon intensities for three different samples of $Al_{0.5}Ga_{0.5}As$: (a) nominally undoped material; (b) with $\sim 10^{18}$ per cm^3 Sn donors; and (c) with $\sim 10^{18}$ per cm^3 Te donors. Solid lines are data taken in the dark; dashed lines are data taken after photoexcitation. The propagation direction is $\langle 110 \rangle$. The intensities of the ballistic phonons reveal selective attenuation of certain groups of transverse modes depending on the symmetry of the donor-related photoconductivity center. A configuration-coordinate model, a crystal model of GaAs, and a schematic of the experimental arrangement are shown on the right-hand sides of (a), (b), and (c). (After Narayanamurti, 1981.)

niques (see Narayanamurti *et al.*, 1979a). The donors used in the experiments were either tellurium (which takes the place of As in the lattice) or tin (which takes the place of gallium). A thick (2.5-mm) sample of GaAs was used as a transmitting medium, on one end of which was grown a $Ga_{0.5}Al_{0.5}As$ epitaxial layer of typical thickness 10 μm. Doped and undoped layers were grown side by side so that the effects of doping could be monitored. Photoexcitation by means of a flash lamp was used to change the occupation of the *DX* centers *in situ* in the epitaxial layers. The propagation direction was ⟨110⟩.

Figure 10 also shows typical ballistic pulses observed in the dark and after photoexcitation. In the case of tin donors strong attenuation of FT modes was observed while attenuation of the ST mode was negligible. In the case of tellurium donors both T modes suffered attenuation. From group-theoretical arguments the selective attenuation was interpreted as arising from trigonal centers in the case of tin doping and orthorhombic centers in the case of tellurium doping. This measurement is particularly useful, as other techniques such as electron spin resonance are difficult to use in this system.

The number of defects that have been studied include the acceptors In, B, Al, and Ga in Si; the donors P, Li, Sb, As, and P in Si; the acceptors Ga and In and Ge; and the different charge states of Cr impurities in GaAs. Detailed references can be found in the review by Wybourne and Wigmore (1988).

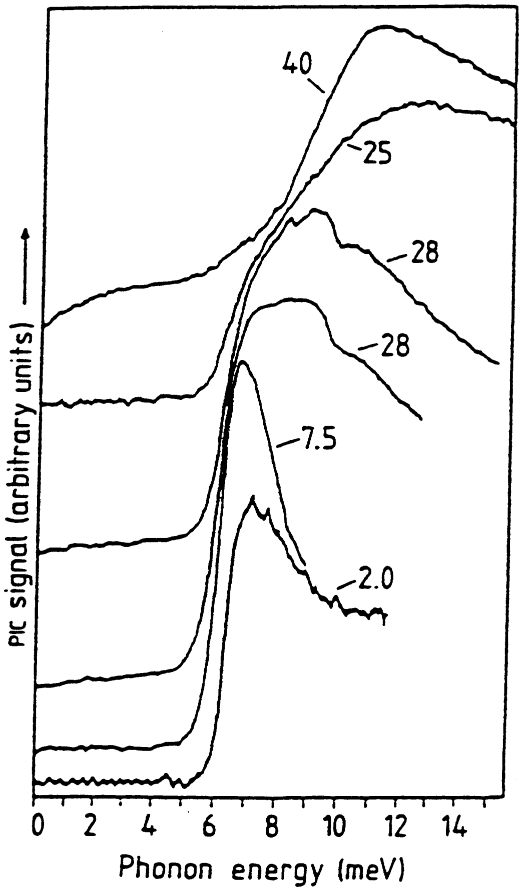

FIG. 11. Phonon-induced conductivity spectra from indium-doped silicon of various concentrations indicated in units of 10^{15} per cm^3. A threshold at the binding energy of 5.9 meV is clearly seen. (After Lassmann and Burger, 1986.)

A particularly interesting variant of the experiments described above involves measurements of the phonon-induced conductivity (PIC) to study the ionization energies of neutral donors and acceptors in Si that have a weakly bound carrier. This has analogy with the photoelectric effect for photons impinging on metals. The excitation of bound states by nonthermal phonons has been well developed as a spectroscopic tool by Lassmann and Burger (1986). The relaxation phonons from a superconducting Al tunnel junction are used to measure the PIC. A typical spectrum is shown in Fig. 11 for various In concentrations in silicon. The threshold in the spectrum at 5.9 MeV ($\sim$ 1.5 THz) corresponds to the binding energy of In in Si. The technique is very sensitive and can be used to detect impurity concentrations in the 10^{12} per cm^3 range and to perform accurate measurements of binding energies of donors and acceptors in Si and Ge.

2.2 Phonon Scattering by Dislocations

So far we have primarily considered scattering and spectroscopy by point impurities. In many crystals, dislocations, which are extended structural defects, are known to influence the thermal transport properties significantly. The static strain fields of the dislocations serve to scatter the phonons. In addition, incident phonons can cause dislocations to vibrate, thereby representing an exchange of energy. The inverse scattering time for slow transverse modes has been theoretically postulated to be

$$1/\tau_{st} \sim N_D \sigma^2 B^2 \gamma,$$

where N_D is the dislocation density per unit area, σ the Grüneisen constant, B the Burgers vector, and γ the phonon frequency (see Kneezel and Granato, 1982). Scattering of other modes is very weak. The preferential scattering of slow transverse phonons and the magnitude of the scattering has been studied in great detail by Northrop *et al.* (1983) for the case of LiF.

A particularly interesting case has been studied by the author. In the case of direct-band-gap semiconductors, such as GaAs, it is known that dislocations can reduce the luminescence efficiency of light-emitting diodes (LEDs) and lasers. This is because electron–hole recombination across the band gap with light emission is interrupted by nonradiative processes where the energy is released in the form of heat instead of light. This drop in efficiency was for many years presumed to be due to nonradiative processes occurring at defects or dislocations. Again phonon techniques provide a very direct way of monitoring such phenomena. Figure 12 shows the phonon emission from GaAs *p-n* junctions (see Narayanamurti *et al.*, 1978). The difference between the "control" and the dislocated junctions is due to enhancement of nonradiative recombination at dislocations. It is clear that the dislocated junction shows enhanced phonon output, particularly for the ST mode.

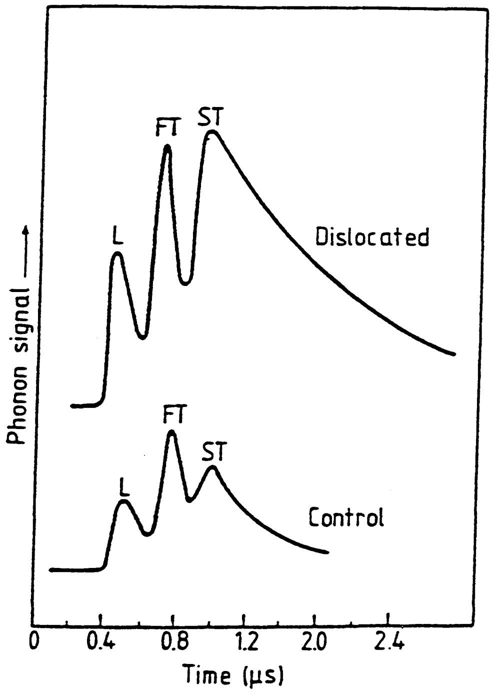

FIG. 12. Phonon emission from GaAs *p-n* junctions. The difference between the "control" and the dislocated junctions is due to enhancement of nonradiative recombination at dislocations. (After Narayanamurti, 1978.)

2.3 Phonon Scattering by Surfaces and Interfaces

The role of surfaces in determining the reflectivity of incident phonons has many analogies to photons. The quality of the surface, i.e., the degree of perfection and smoothness can be expected to have a profound effect. In the case of high-frequency phonons of typical wavelength of a few hundred angstroms, even ordinary "optically" smooth surfaces have been found to cause diffuse scattering and reflection. The damage just beneath the surface introduced during the preparation process has been shown to be very important. The effects of etching and annealing have been shown to be profound (for a review see Wigmore and Wybourne, 1988). For most ordinary surfaces the transmission of high-frequency phonons is found to be much greater than expected, while the reflectivity is much smaller. This anomaly, the so-called Kapitza anomaly, has been the subject of much study for many years.

Trumpp and co-workers (see Trumpp and Eisenmenger, 1977), for example, quantitatively showed that only 10% of the 2Δ phonons generated by a superconducting tin tunnel junction at 280 GHz could traverse the interface with a silicon crystal without degradation into heat. Reflection measurements show a serious degradation of the signal after one reflection. Thus, unlike conventional ultrasonics, it is virtually impossible to observe more than one echo in heat-pulse and/or tunnel-junction experiments.

In the next section we will, however, discuss the case of multiple interfaces that can be prepared to a high degree of perfection using modern crystal-growth techniques, and that obviate the problems mentioned above. This should allow the creation of a new generation of devices of potential use for characterization of materials in analogy with optics.

2.4 Phonons in Superlattices—Mirrors, Filters, and Related Devices

To control the reflectivity and/or transmissivity of photons, multilayer films of precise thickness and refractive index are used. For photons in the optical wavelength, $\lambda \sim 5000$ Å, the films constituting the multilayers are about $\lambda/2$ or 2500 Å thick (see, for example, Brillouin, 1946). In the case of phonons of wavelength 100 Å, the thicknesses are in the 50-Å range. Thus extremely high-quality films are required. Fortunately in the case of compound semiconductors, because of their technological importance, a great deal of effort has been spent in growing superlattices of a controlled period (see, for example, Panish, 1980). This has been made possible through the development of molecular beam epitaxy (MBE), which involves the controlled growth, layer by layer, of the constituent semiconductor material under ultrahigh-vacuum (10^{-10} Torr) conditions. Furthermore, the constituent materials are lattice matched (epitaxially grown) so that interfacial degradation is negligible. This is the case of GaAs/AlGaAs.

I now describe a novel thin-film spectrometer based on the selective transmission of high-frequency phonons through a superlattice of GaAs/$Al_{0.5}Ga_{0.5}As$. The filtering action arises from the selective reflection by the superlattice of phonons of wavelength λ_0 that fulfill the Bragg condition $\lambda_0 = 2d$, where d is the superlattice period (Brillouin, 1954). Quantitatively the magnitude of the selective filtering action depends on the ratios of the acoustic impedances ($Z = \rho v$, where ρ is the density and v the sound velocity) of the constituent materials of the superlattice. The acoustic impedance plays the same role for phonons as the refractive index plays in the case of photons. In view of the close analogy with optical dielectric mirrors, an appropriately designed thin-film superlattice may be called a dielectric phonon mirror. Reflectivity calculations, including the effects of small amounts of disorder, are described in the literature (see Narayanamurti *et al.*, 1979b).

The inset of Fig. 13 shows a schematic of the experimental arrangement used to test some of these ideas. A Sn tunnel junction is used as a source of phonons, which pass through a GaAs/$Al_{0.5}Ga_{0.5}As$ superlattice structure of period 122 Å before detection by an Al tunnel junction. The filter resonance thus corresponds to a wavelength of about 240 Å and a frequency of about 2.2×10^{11} Hz. Figure 13 shows the observed transmission (points) as a function of phonon frequency; also shown are the corresponding phonon wavelengths. The solid line corresponds to the theoretically calculated filter function for an acoustical impedance ratio $Z_1/Z_2 \approx 0.88$ and an overall linewidth of $\sim 0.2 \times 10^{11}$ Hz. Most of the linewidth arises from the width of the superconducting energy gap of the generator and detector used in these experiments. Experiments with superlattices with other periods show the position of the resonance changes as expected with the superlattice period.

The experiments described above involved propagation in the normal direction. For arbitrary propagation directions the Bragg condition becomes $n\lambda = 2d \cos\theta$, where θ is the angle between the phonon propagation direction and the normal direction. Figure 14 shows the differential phonon image for longitudinal phonons of frequency 850 GHz passing through an $In_{0.15}As_{0.85}As$/AlAs superlattice with an individual layer thickness of 20 Å consisting of 40 periods. The dark ring represents the selective reduction of 850-GHz phonons by the superlattice (Hurley *et al.*, 1987).

These results show that phonons of wavelength ~ 100 Å suffer relatively little interface degradation even though they had to pass through 50–100 layers of the multilayer structure. This suggests that interfaces produced by MBE are nearly ideal, and one can think of using superlattice phonon mirrors as phonon spectrometers for the manipulation of phonon diagnostic beams in semiconductors and for the further development of what one might call "phonon optics."

Clearly one can devise many interesting structures consistent with wave propagation in periodic structures. Much work has been done in this area over the last few years. Phonon transmission through quasiperiodic systems and through multisuperlattice structures consisting of two kinds of superlattices has been studied (Tamura, 1989). A particularly interesting example (Mizumo and Tamura, 1991) is the case of bulk material sandwiched between two identical periodic superlattices. This system is analogous to a double-barrier system for electrons where resonant tunneling can occur. Mizumo and Tamura have shown that sharp resonances that involve resonant transmission without

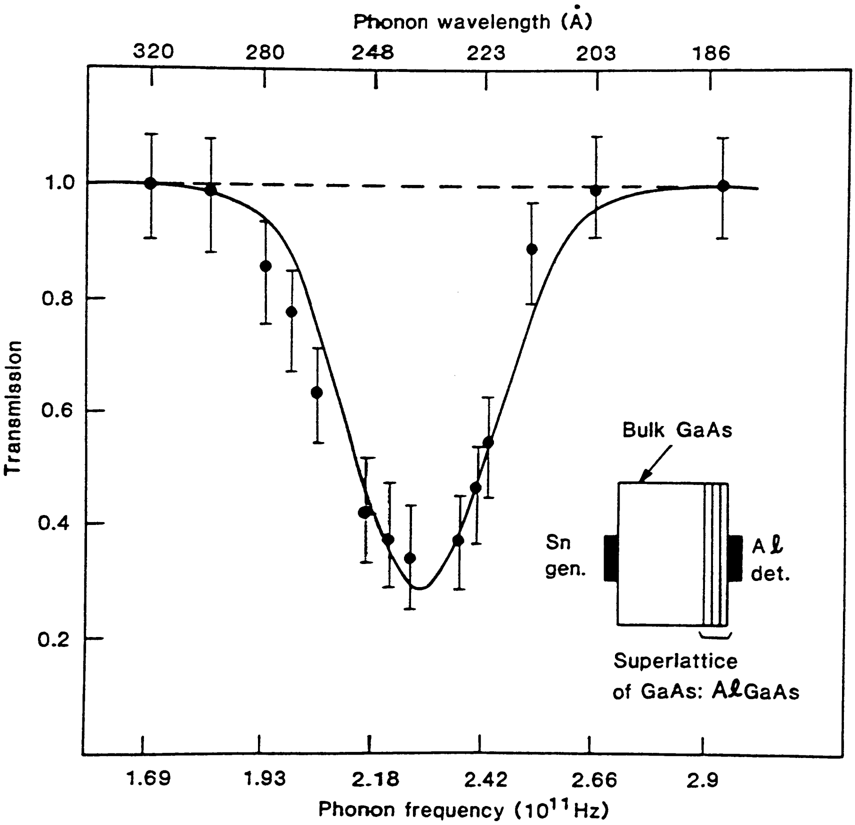

FIG. 13. Phonon transmission through a GaAs/$Al_{0.5}Ga_{0.5}As$ superlattice of period 122 Å and 50 double layers. Dots correspond to experimental points and the solid line corresponds to a theoretical fit for an acoustic impedance ratio $Z_1/Z_2 \sim 0.88$ and an overall linewidth of $\sim 0.24 \times 10^{11}$ Hz. (After Narayanamurti *et al.*, 1979a,b.)

attenuation can occur in the gap. Thus it appears quite plausible that phonon resonators can be designed, and that even a larger variety of phonon optics devices than those originally proposed by the author (see Chin *et al.*, 1982) is possible.

3. OPTICAL TECHNIQUES

We have so far primarily concerned ourselves with heat-pulse (occasionally with laser generation of heat) and quasimonochromatic superconducting tunnel-junction thin-film techniques. These techniques are analogous to ultrasonic techniques albeit in a much higher frequency domain. Optical techniques, on the other hand, generally involve excitation in the bulk of impurity levels (usually transition-metal ions in dielectric crystals), which lose energy after excitation through phonons. The energy level can usually be tuned by a magnetic field and therefore can serve as an *in situ*

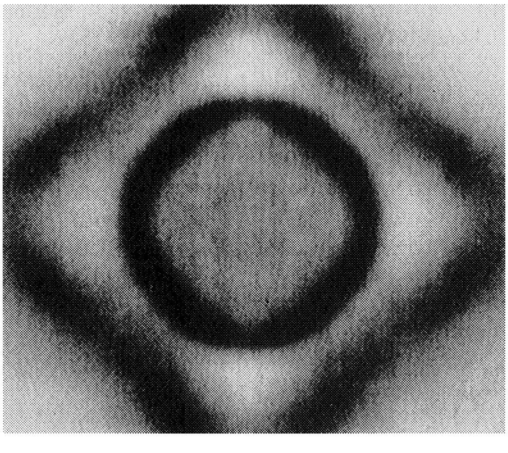

FIG. 14. Differential phonon image for longitudinal phonons of frequency 850 GHz passing through an $In_{0.15}Ga_{0.85}As$/AlAs superlattice. The dark ring represents the selective reduction of 850-GHz phonons by the superlattice. (After Hurley *et al.*, 1987.)

spectrometer. We do not discus these techniques further since they are beyond the scope of this article (see, e.g., the review by Renk, 1985). In the ensuing we will, however, briefly discuss applications primarily deriving from developments in the field of opto-acoustic spectroscopy and generation of phonons using picosecond optical techniques.

3.1 Opto-Acoustic Spectroscopy

We have already had occasion to mention briefly the studies of nonradiative (heat) generation measured by bolometric techniques. The field of opto-acoustic spectroscopy involves the measurement of optical absorption spectra through the detection of acoustical signals generated when the absorbed optical energy decays through nonradiative channels. The use of tunable lasers combined with sensitive acoustic techniques has led to the measurement of extremely weak absorption spectra in condensed matter (see, for example, Patel, 1981).

This technique has been further developed using superconducting tunnel junctions to study the optical absorption of adsorbed molecules, such as tetracene, on a silicon surface (see Dietsche, 1986). The extremely high sensitivity of tunnel-junction detectors has been used to study submonolayer coverages of adsorbed molecules.

3.2 Picosecond Optical Techniques

Conventional heat-pulse techniques are limited to samples that show macroscopic phonon mean free paths (at least fractions of a millimeter) because of the time domain in which such phonons are studied (10^{-7}–10^{-8} s). Such macroscopic mean free paths, as we have seen, are usually achievable only at low temperatures (below 10 K).

To make measurements at high frequencies and high temperatures one has to be prepared to study phonons with very short mean free paths (100–1000 Å). Thus if one wants to do phonon experiments in "real time," time resolution in the 10^{-11}–10^{-12} s range is required. This is not possible with conventional electronics. Maris and co-workers (see Maris, 1986) have used picosecond pulses to excite phonons in thin films at room temperature. Figure 15 shows a schematic of the experimental arrangement to generate and detect phonons in dielectric and semiconducting films. A picosecond optical pump pulse is used to generate a thermal stress (within an absorption distance ~300 Å), which in turn launches a coherent strain wave into the film. Since the optical constants of the material depend on strain, one can envision a change in the reflectivity of the film that depends on the strain. The amplitude of the strain pulse is measured through changes in the reflectivity as a function of time by means of a weak probe pulse also of duration 1 ps. This technique has been used to study phonon mean free paths in several amorphous materials (SiO_2, *a*-As_2Te_3, etc.).

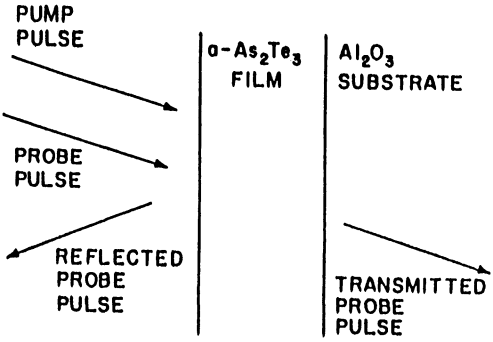

FIG. 15. Schematic diagram of the experiment to generate and detect phonons in the picosecond regime in a semiconducting film (after Maris, 1986).

4. CONCLUSIONS

In this review I have attempted to survey some of the applications of heat-pulse and quasimonochromatic phonon propagation in solids. Clearly the principal applications lie in the area of spectroscopy of both bulk material and of surfaces and interfaces.

The field has advanced sufficiently over the last 15 years that it now possesses many of the traditional aspects of optical spectroscopy experiments: monochromatic generation, rectilinear propagation, polarization dependence, manipulation and steering using superlattice filters, and focusing based on wave propagation in an anisotropic medium. Recent developments in the study of dispersive wave propagation and improved time resolution suggest that virtually the entire range of thermal phonon frequencies can now be studied.

Much work still remains to be done. Study of phonon interactions with lower-dimensional systems, superlattices, and one- and/or zero-dimensional systems clearly would be an exciting arena for study. Preparation of phonon optics devices based on novel double-barrier tunneling systems and their application to nanoscale physics appears feasible. Further developments and evolution in the field should lead to improved understanding of stress-sensitive properties on a truly atomic scale. When combined with molecular beam epitaxy and nanoscale fabrication, phonon microscopy in the 10–100-Å range appears to be a valuable tool for the study of materials.

GLOSSARY

Acceptor: Defect in a semiconductor that releases holes into the valence band.

Donor: Defect in a semiconductor that releases electrons into the conduction band.

Epitaxy: Crystal growth under lattice-matching conditions that permits crystalline growth without defects.

Molecular-Beam Epitaxy: Crystal-growth method that uses controlled deposition of materials in ultrahigh vacuum to grow materials layer by layer.

Phonon: Quantized lattice vibration.

Superconducting Energy Gap: Binding energy for pairing of electrons of opposite spins (Cooper pair), which leads to superconductivity.

Superconducting Tunnel Junction: Sandwich of two superconductors separated by an oxide barrier.

Superlattice: Periodic structure of multilayer films with an artificially introduced periodicity.

Transition Temperature T_c: Temperature below which material is superconducting.

INTRODUCTION

Solid-state compounds containing rare-earth or actinide elements can display a wide variety of unusual behavior, including magnetic order, mixed valence, and heavy-fermion phenomena. These various behaviors reflect the quantum state of the electrons derived from atomic *f* orbitals. The heavy-fermion systems have almost localized electronic states at the Fermi surface that are primarily *f* in character. The electrons in these states interact strongly and give rise to an unusual transformation evident at low temperature. Near room temperature (~300 K), the sublattice of rare-earth or actinide atoms, usually cerium or uranium, has properties resembling those of weakly interacting magnetic moments immersed in a sea of conduction electrons. The electronic transport properties are dominated by incoherent scattering of the conduction electrons by the local moments. As the temperature is lowered, local-moment behavior gives way to electronic properties that are consistent with those of a narrow band of conduction electrons. A crossover temperature, often referred to as the "coherence temperature" T^*, can be inferred from experiments. At sufficiently low temperature, the thermodynamic properties of a system of itinerant electrons may be described in terms of thermal effective masses for the electrons. The electronic effective masses in most metals do not differ much from the mass of a free electron. In contrast, the effective mass deduced from experiments on the heavy-fermion systems is up to 1000 times greater than that of a free electron. Hence these materials were christened with the somewhat whimsical name "heavy-fermion systems."

Heavy-fermion systems display a variety of ground states including antiferromagnetic, superconducting, paramagnetic (at least to the lowest temperatures at which experiments have been performed, ~20 mK), or, as recently observed, semiconducting. Table 1 lists some of the heavy-fermion systems with their ground states and ordering temperatures where appropriate. Note that superconductivity and antiferromagnetism often coexist, with the Néel temperature T_N typically being about an order of magnitude larger than the critical temperature T_c of the superconducting state.

[a] Data from Fisk *et al.* (1988); $CePt_2Sn_2$, Beyermann *et al.* (1991); $YbAgCu_4$, Rossel *et al.* (1987); CeNiSn, Takabatake *et al.* (1990); $Ce_3Bi_4Pt_3$, Hundley *et al.* (1990); and UPd_2Al_3, Amato *et al.* (1992).

Heavy-fermion systems generally appear to be close to an instability, as suggested by the proclivity of many of these systems to display an ordered ground state on the addition of impurities, on the application of a magnetic field, and possibly on the application of pressure.

The low-temperature properties of some heavy-fermion materials display similarities to those of the archetypal Fermi liquid, liquid ^{3}He. In particular, the specific heat of liquid ^{3}He varies linearly with temperature, and the magnetic susceptibility is temperature independent. Both of these quantities are considerably larger than expected for a weakly interacting collection of ^{3}He atoms because of large many-body effects. The low-temperature properties of ^{3}He are well described by the phenomenological Landau Fermi-liquid theory. In the heavy-fermion systems, the specific heat and magnetic susceptibility are also greatly enhanced by many-body effects, and it is generally accepted that the low-temperature properties of these materials can also be described by Landau Fermi-liquid theory. It was hoped that analogies with liquid ^{3}He would help clarify the role of the many-body problem in understanding the physics of the "coherent" heavy-fermion state even though they suffer greatly from oversimplification. Liquid ^{3}He is after all isotropic and translationally invariant, and has only two spin states in contradistinction to the potentially manyfold-degenerate *f* electrons constrained to the symmetry of a crystalline lattice.

In seeking to describe not only the Fermi-liquid state, but also the process whereby a lattice of *f* moments immersed in a sea of conduction electrons becomes a Fermi liquid, microscopic approaches exploit the apparent similarity to the Kondo model. The Kondo model consists of a single impurity atom with a magnetic moment embedded in a metallic host. The heavy-fermion materials may be viewed as a lattice of *f* atoms, each with a magnetic moment, embedded in a metallic matrix; a compelling example is UBe_{13}. At high temperatures the lattice reflects the properties of independent magnetic impurities, and as the temperature is reduced one expects to observe the many-body effects characteristic of the single impurity model. At even lower temperatures, the interactions between impurities become important and the magnetic scattering from the lattice becomes coherent, leading to the formation of Bloch states with narrow bandwidths. A generalization of a system of dense, periodically arranged, single impurities, such as the Anderson lattice model described below, is believed to contain the essential physics of the heavy-fermion phenomenon.

Quite apart from the issue of the formation of the heavy-fermion state itself is the nature of the ordered states. In every case, the ground state listed in Table 1 is unusual as compared to the corresponding ground state encountered in most other materials. The magnetic state is characterized by anomalously small moments associated with the *f*-atom sites. The arrangement of these moments is simple in contrast with the spiral phases often observed in rare-earth magnets. The most studied ordered state is the unusual superconducting state, which is not described by the BCS theory for a conventional superconductor. The analogies between heavy-fermion systems and ^{3}He extend beyond the normal state. Below ~1 mK, the normal state of ^{3}He becomes unstable to the formation of a superfluid state in which the pairing of atoms gives rise to a condensate. A comparison of the properties of the heavy-fermion superconducting state to those of superfluid ^{3}He suggests the possibility of unconventional superconductivity in heavy-fermion systems. The conventional superconducting state is described by an order parameter that is a complex scalar function having the symmetry of the point group of the underlying crystalline lattice. In an unconventional superconductor, as in the unconventional superfluid ^{3}He, one or more of these symmetries may be broken (Rainer, 1988). The order parameter may have more degrees of freedom than its conventional counterpart, and different superconducting phases may be degenerate. The possible consequences of such an order parameter include the existence of domain walls separating different superconducting phases and exotic vortices with complicated core structures; neither of these occurs in a conventional superconductor. The superfluid state of ^{3}He is also unusual because spin fluctuations are believed to provide the attractive effective interaction that results in the pairing of ^{3}He atoms. In an ordinary superconductor where the electron-phonon interaction provides the effective attractive interaction between electrons, spin-fluctuation–mediated interactions are unfavorable to the pairing. The analogy with liquid ^{3}He further suggests that the attractive effective interaction between electrons in the heavy-fermion systems is not provided by the electron-phonon interaction as in ordinary superconductors, but rather is electronic in origin and mediated by spin fluctuations.

While much progress has been made over the past decade, a comprehensive understanding of the heavy-fermion phenomenon is still lacking. It should not be surprising, then, that some of the material presented below, particularly the simple interpretations of various experiments, appears in some cases to be contradictory; this is the nature of the field. Below, we attempt to provide a necessarily incomplete overview of the properties of these materials and of the physical picture that has evolved. One of the most exciting aspects of the heavy-fermion phenomenon is the possibility that they may be unconventional superconductors, which serves as the primary focus of our discussion of the superconducting state. Because of the nature of this article, it is not possible to discuss the many key investigations that have led to the current picture of this phenomenon. It is also not always possible to refer to the original scientific literature, and we direct the reader to the more extensive reviews listed in the Works Cited and under Further Reading.

1. EXPERIMENTS

1.1 Background

Heavy-fermion materials occur in a variety of crystal structures as shown by the examples in Table 2. Many of the heavy-fermion systems have crystal structures of uniaxial symmetry and, as expected, exhibit anisotropic properties. The degree of the anisotropy may be unusually large, as we will see below. A common feature of the crystal structures of heavy-fermion systems is that they all have a center of inversion symmetry, a fact that has important consequences for the classification of possible superconducting states. Ott and Fisk (1987) observe another common feature of the crystal structures of heavy-fermion systems: the nearest neighbors of an *f* atom do not include another *f* atom. The large separation between *f* atoms suggests that the transfer matrix elements directly connecting *f* orbitals on different sites are small.

In spite of the large separation between *f* atoms, these materials are not typical local-moment magnets. Specific-heat experiments played an important role in the discovery of the heavy-fermion phenomenon. While it was known in the 1970s that the properties of $CeAl_3$ below 0.1 K were consistent with those expected for a Fermi liquid characterized by quasiparticles with an anomalously large effective mass (Andres *et al.*, 1975), it was unclear whether this was the correct interpretation of the data. Steglich *et al.* (1979), showed that $CeCu_2Si_2$, a compound with low-temperature properties similar to those of $CeAl_3$, is a superconductor with a specific-heat jump at the transition temperature consistent with superconducting electrons with large effective masses. This was not conclusive at the time because $CeCu_2Si_2$ is difficult to prepare and may contain impurity phases. The large specific-heat jump could be the result of antiferromagnetic ordering (such as in $NpSn_3$), which has a temperature-dependent specific heat similar to that of a BCS superconductor. The "apparent" superconductivity could then be explained by the existence of some impurity phase. The discovery of superconductivity with a similarly large specific-heat jump in UBe_{13} by Ott *et al.* (1983) confirmed the interpretation based on large effective masses, because UBe_{13} lacks the materials problems associated with $CeCu_2Si_2$ but shows similar low-temperature behavior. Other heavy-fermion materials were soon discovered.

Table 2. Crystal structures of some heavy-fermion systems.

Compound	Symmetry	Full-symmetry group
$CeCu_2Si_2$	Tetragonal	$I4/mmm$
UBe_{13}	Cubic	$Fm\bar{3}c$
UPt_3	Hexagonal	$P6_3/mmc$
URu_2Si_2	Tetragonal	$I4/mmm$
UPd_2Al_3	Hexagonal	$P6/mmm$
U_2Zn_{17}	Rhombohedral	$P\bar{6}m2$
UCd_{11}	Cubic	$Pm\bar{3}m$
UCu_5	Cubic	$F\bar{4}3m$
$CeAl_3$	Hexagonal	$P6_3/mmc$
$CeCu_6$	Orthorhombic	$Pnma$
$YbAgCu_4$	Cubic	$F\bar{4}3m$
UAl_2	Cubic	$Fd3m$
CeNiSn	Tetragonal	$I4_1md$
$Ce_3Bi_4Pt_3$	Cubic	$I\bar{4}3d$
$CePt_2Sn_2$	Tetragonal	$P4/nmm$

1.2 Normal-State Properties

1.2.1 Specific Heat. The low-temperature specific heat of the metallic heavy-fermion systems differs dramatically from that of an ordinary metal. For temperatures much smaller than the Fermi energy and the Debye temperature, the specific heat of an ordinary metal consists of an electronic contribution linear in temperature and a contribution from phonons,

$$C(T)=\gamma T+\beta T^3. \qquad (1)$$

The specific heat of an ordinary metal may be understood by comparing γ with that expected for a gas of electrons neglecting interactions, γ_0. At low temperatures, only excitations in the vicinity of the Fermi surface are important. As a result of the interaction of an electron with the periodic potential of the lattice and with other electrons, these excitations are not those of single electrons but rather quasiparticles, which have an effective mass different from the mass of a free electron. Quasiparticle excitations are probed in a low-temperature specific-heat measurement, and the ratio γ/γ_0 provides a rough measure of the effect of interactions. In a metal such as sodium, the energy bands are broad and free-electron-like; the interaction of an electron with lattice excitations is relatively weak; the effective mass of the quasiparticle does not differ much from the free-electron mass; and γ/γ_0 is ~ 1.3. In contrast, enormous γ/γ_0 ratios up to 1000 are inferred for the metallic heavy-fermion systems.

The specific heat of copper is described well by Eq. (1) for temperatures below 10 K with $\gamma \sim 1$ mJ/mol K^2. In many of the heavy-fermion systems, notably UBe_{13}, $CeCu_2Si_2$, $CeAl_3$, and $CeCu_6$, $\gamma(T)\equiv C(T)/T$ shows a strong upturn with decreasing temperature below ~ 10 K, as shown in Fig. 1 for UBe_{13}. With further reduction in temperature $\gamma(T)$ may show a weak maximum, but eventually it tends to a value ~ 1 J/(mol *f*-atom K^2). Table 3 shows extrapolated values of $\gamma(0) = \lim_{T\to 0} C_p(T)/T$ for some heavy-fermion systems. The specific heat of UPt_3 and UAl_2 has been fitted by the expression

$$C(T)=\gamma T+\delta T^3 \ln T+\beta T^3 \qquad (2)$$

for temperatures up to 20 K. This form is suggestive of a strongly interacting Fermi liquid and will be discussed further below.

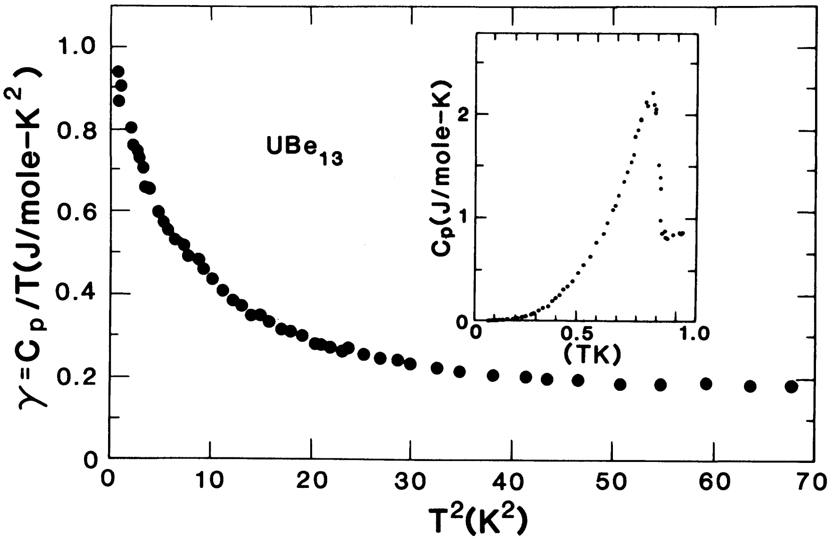

FIG. 1. The specific heat of UBe$_{13}$ divided by temperature, $\gamma(T)$ (Ott *et al.*, 1983), in the normal state. Note the upturn with decreasing temperature and the large extrapolated value of $\gamma(0)$ as compared with 0.07 mJ/mole-K^2 for copper. The inset shows the specific-heat jump at the superconducting transition, indicating that the enormous $\gamma(0)$ should be associated with itinerant electrons.

The antiferromagnets U_2Zn_{17} and UCd_{11} are unusual in that $\gamma(T)$ has already reached a saturation value by 10 K. As discussed in detail by Ott and Fisk (1987), UCu_5 is also unusual in that the characteristic heavy-fermion upturn in $\gamma(T)$ appears below the antiferromagnetic phase transition at 15 K. Thus although a gap associated with magnetic order appears over a major fraction of the Fermi surface, the mechanism that gives rise to the formation of the heavy-fermion state is still operative.

Specific-heat experiments at low temperature also show that the heavy-fermion state is sensitive to impurities and to the application of pressure. For example, substitution of thorium for 3.3% of the uranium atoms in UBe_{13} causes the upturn of $\gamma(T)$ to appear at

lower temperatures and leads to a substantial increase in $\gamma(0)$. A similar replacement of uranium by lutetium causes the opposite effect, resulting in a ~25% decrease in $\gamma(0)$. In $CeAl_3$, UBe_{13}, $CeCu_6$, and $CeCu_2Si_2$ the application of 1 GPa pressure leads to a 30% to 50% decrease in $\gamma(0)$. Evidently some impurity substitutions lead to a contraction of the lattice and have essentially the same effect as the application of pressure.

1.2.2 Magnetic Susceptibility. An interesting crossover between local-moment and narrow-band regimes can be seen in the magnetic susceptibility as a function of temperature for the heavy-fermion systems as shown in Fig. 2 for UBe_{13} and $CeAl_3$. Near room temperature, the susceptibility $\chi(T)$ displays a Curie-Weiss temperature dependence,

$$\chi_{\mathrm{CW}}(T)=\frac{n}{3k_{\mathrm{B}}}\frac{\mu_{\mathrm{eff}}^2}{(T-\Theta_{\mathrm{CW}})}, \tag{3}$$

where μ_{eff} is the size of the local moment, Θ_{CW} is the Curie-Weiss temperature, n is the density of local moments, and k_{B} is Boltzmann's constant. The values of μ_{eff} and Θ_{CW} obtained from fitting $\chi(T)$ by Eq. (3) appear in Table 4 for some heavy-fermion systems. The effective moments deduced from the data are roughly the same as those expected from Hund's rules for free f atoms with integral f occupancy, which are also shown in Table 4 for comparison. The values of Θ_{CW} are always negative and lie between 8 K and room temperature. A detailed discussion of the sensitivity of these fits to the temperature range over which they are performed appears in Ott and Fisk (1987).

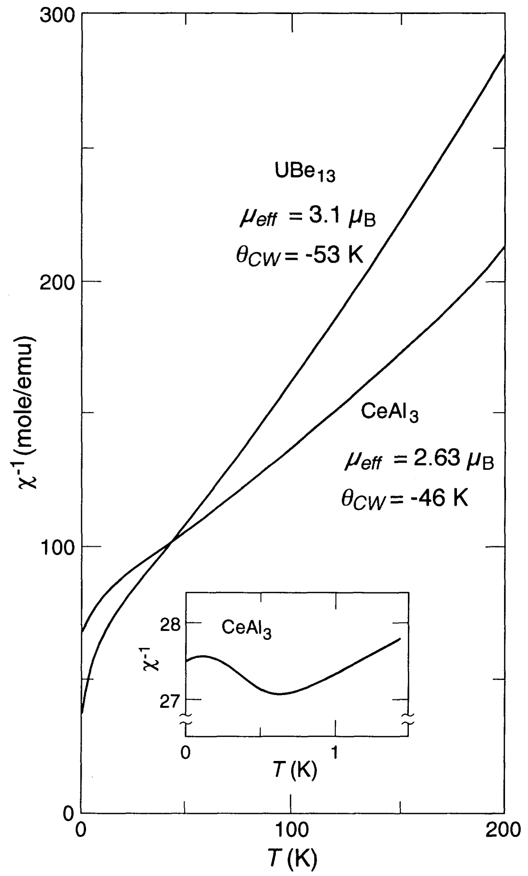

FIG. 2. The magnetic susceptibility $\chi(T)$ of UBe_{13} and $CeAl_3$ plotted as $\chi^{-1}(T)$. The effective moments and Curie-Weiss temperature from a fit by a Curie-Weiss form at high temperatures are also shown. The temperature dependence of $\chi(T)$ weakens with decreasing temperature and becomes Pauli type as shown for $CeAl_3$ in the inset. This is not apparent in UBe_{13}, as a transition to the superconducting state occurs before any behavior consistent with Landau Fermi-liquid theory is observed.

At low temperature, $\chi(T)$ is weakly temperature dependent and resembles a Pauli susceptibility. For a gas of noninteracting electrons, the Pauli susceptibility and linear specific-heat coefficient are related to the density of states at the Fermi energy $N(e_{\mathrm{F}})$ through

$$\chi_{\mathrm{P}}=\mu_{\mathrm{B}}^2N(e_{\mathrm{F}}), \tag{4}$$

$$\gamma=\frac{\pi^2}{3}k_{\mathrm{B}}^2N(e_{\mathrm{F}}), \tag{5}$$

and so a plot of γ vs χ_{P} for various free-electron-like systems lies along the line $\gamma=(\pi^2/3)(k_{\mathrm{B}}/\mu_{\mathrm{B}})^2\chi_{\mathrm{P}}$. The heavy-fermion systems, especially the superconductors, lie quite near this line (Fisk *et al.*, 1985), indicating that the low-temperature magnetic susceptibility and specific heat are enhanced by roughly the same amount. The crossover between these distinct temperature dependences occurs abruptly relative to the upturn in the specific heat, suggesting the existence of a characteristic energy scale.

The magnetic susceptibilities of many of the heavy-fermion compounds are anisotropic. A particularly striking example is that of URu_2Si_2, for which $\chi(T)$ for fields in the basal plane is nearly temperature independent up to room temperature whereas $\chi(T)$ for fields applied along the c axis displays the classic heavy-fermion behavior outlined above. In

the limit of zero temperature, $\chi_c(0)/\chi_a(0) \sim 5$. A less dramatic but still large anisotropy exists for UPt_3. There the basal-plane susceptibility is nearly three times that along the *c* axis and shows a peak at 17 K.

1.2.3 Thermal Expansion. The thermal expansion coefficient of the heavy-fermion systems below room temperature is positive and strongly temperature dependent. A peak in the thermal expansion as a function of temperature is evident for some materials, while others show a thermal expansion that decreases monotonically with temperature. At low temperatures, the thermal expansion is anomalously large by two or more orders of magnitude.

The thermal expansion is often expressed as a Grüneisen parameter,

$$\Gamma=\frac{\alpha_v V_m}{\kappa C}, \qquad (6)$$

where $\alpha_v=(1/V)\partial V/\partial T$ is the coefficient of volume thermal expansion, κ is the (isothermal) compressibility, V_m is the molar volume, and C is the molar specific heat. In an ordinary metal, the low-temperature thermal expansion tracks the specific heat, and Γ is essentially temperature independent. The Grüneisen parameter for a heavy-fermion system increases strongly with decreasing temperature below 10 K. In analogy with the contribution to Γ from the lattice, which is often described by the volume derivative of the Debye temperature, the temperature dependence of Γ is interpreted as the result of a single electronic energy scale, T^*, and an electronic Grüneisen parameter is defined, $\Gamma_e = -\partial \ln T^*/\partial \ln V$. The elastic constants, magnetostriction, and thermal expansion are interrelated by this model as discussed in some detail by Fulde *et al.* (1988).

1.2.4 de Haas–van Alphen Effect. Detailed information on the geometry of the Fermi surface and the cyclotron effective masses can be obtained from the observation of oscillations in the magnetization as a function of the reciprocal magnetic induction. In ascertaining the shape of the Fermi surface, electronic band-structure calculations have traditionally been used as a guide, and for most ordinary metals, calculations and experiment are in good agreement. Generally speaking, the Fermi surface can have many sheets resulting from different bands crossing the Fermi energy. Consider a single sheet. In Fermi-liquid theories, the fundamental frequency of the oscillations gives the area of the extremal cross section of the Fermi surface perpendicular to the applied field. The temperature dependence of the amplitude is related to the cyclotron effective mass, which in turn is related to an average of the Fermi velocity over the perimeter of the extremal cross section. Although the cyclotron effective mass is not rigorously equal to the thermal effective mass, using the Fermi velocities deduced from a de Haas–van Alphen experiment to estimate the specific heat usually gives a result near the measured value.

To observe these oscillations, the mean free path l of a quasiparticle must be larger than a quasiparticle cyclotron radius,

$$l \gg v_F/\omega_H , \tag{7}$$

and the thermal smearing at the Fermi surface must be sufficiently small,

$$T \ll \omega_H . \tag{8}$$

Here v_F is the Fermi velocity, and $\omega_H = eH/m^*c$ is the effective cyclotron frequency of quasiparticles of charge e and effective mass m^* in a field H. For large effective masses and short mean free paths, these constraints suggest that the experiment should be performed at low temperature and high field. It is important to note that the amplitude of oscillation depends exponentially on the effective mass of the quasiparticles. Lighter quasiparticles produce a larger signal and are thus more easily observed.

Experiments have been performed on UPt_3, $CeRu_2Si_2$, and $CeCu_6$ for temperatures ~20–100 mK and fields up to ~14 T. In all cases unusually large effective masses have been observed. For UPt_3, the Fermi surface geometry is in good agreement with that obtained from electronic structure calculations (Taillefer *et al.*, 1987). The effective mass on any given sheet of the Fermi surface, however, is some 10 to 30 times larger than that obtained from band-structure calculations (Wang *et al.*, 1987) suggesting significant many-body effects. The effective masses range from 25 to 200 times the mass of a free electron. The ratio of the effective masses to those predicted by band theory is roughly the same as the ratio of the measured specific heat to that obtained using electronic structure calculations. UPt_3 shows only heavy masses at the Fermi surface, including the largest effective mass ever measured by the de Haas–van Alphen technique. In contrast, lighter electrons are evident in $CeCu_6$ and $CeRu_2Si_2$. Experiments on $CeCu_6$ (Chapman *et al.*, 1990) find effective masses in the range $(6\text{–}80)m_e$ and a Fermi-surface geometry that is neither similar to $LaCu_6$, which has no f electrons, nor to $PrCu_6$, which has f electrons localized in nearly atomic orbitals. Comparisons with specific-heat measurements suggest that unobserved heavier bands exist. Observed electron effective masses for $CeRu_2Si_2$ lie roughly in the range (1–20) m_e.

1.2.5 Transport Properties. At room temperature, the resistivity of a heavy-fermion compound is large, typically of order 100 μΩ/cm as shown in Table 4. In contrast to ordinary metals, where $\partial\rho/\partial T > 0$, $d\rho/dT$ can be of either sign. The qualitative behaviors observed for the resistivity as a function of

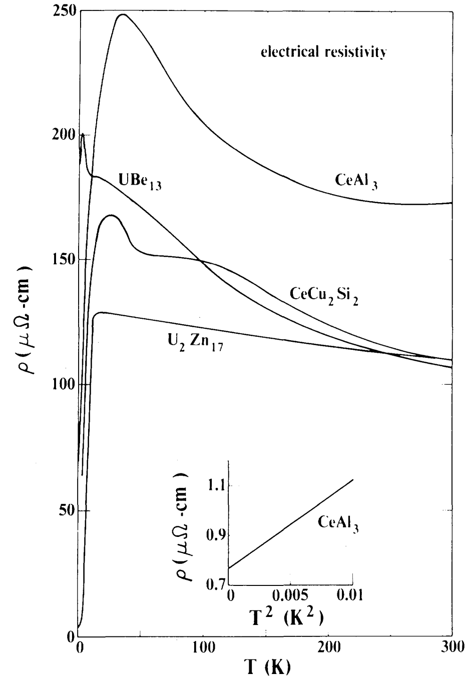

FIG. 3. The electrical resistivity as a function of temperature for the heavy-fermion systems U_2Zn_{17}, $CeAl_3$, $CeCu_2Si_2$, and UBe_{13}.

temperature in the heavy-fermion systems are summarized in Fig. 3. The large value of the resistivity and the often anomalous sign of its derivative are often attributed to the Kondo effect. Below room temperature, those heavy-fermion materials exhibiting the largest effective masses show an anomalous increase in the resistivity with decreasing temperature followed by a rapid decrease, which has been interpreted as the onset of "coherence" leading to the formation of the Fermi-liquid state. The temperature at which this occurs, the "coherence temperature," implies the existence of a characteristic energy scale, presumably the same energy scale inferred from the thermodynamic data. At low temperature, the resistivity of many heavy-fermion materials can be fitted by a form suggestive of strong quasiparticle-quasiparticle scattering,

$$\rho(T)=\rho_0+\rho_{ee}T^2, \qquad (9)$$

where ρ_{ee} is some six to seven orders of magnitude larger than that observed in ordinary metals. The low-temperature resistivity of $CeAl_3$ displays a clear T^2 contribution as shown in the inset to Fig. 3. The resistivities of UPt_3, UAl_2, and YbBiPt do not display a maximum below room temperature but are still described by the Fermi-liquid form of Eq. (9) below a material-dependent temperature less than 10 K.

The resistivity is sensitive to impurities, pressure, and magnetic fields at low temperature, as discussed in detail by Ott and Fisk (1987) and Stewart (1984).

The frequency-dependent resistivity of UPt_3, $CeAl_3$, and $CePd_3$ has been measured in the microwave, infrared, and optical regions of the spectrum. At low frequency, the conductivity can be fitted by a Drude form,

$$\sigma(\omega)=\sigma(0)/(1+\omega^2\tau^2), \qquad (10)$$

where $\sigma(0)$ is the dc conductivity, which is related to a relaxation time τ, a carrier density n, and an effective mass m^* by $\sigma(0)=ne^2\tau/m^*$. A narrow zero-frequency peak is observed at low temperatures; the relaxation time inferred from its width suggests that τ is enhanced compared to that for an ordinary metal by roughly the same factor as the effective mass that is obtained from thermodynamic properties. The narrow peak is not observed at room temperature, indicating that it is a signature of the heavy-fermion state. Complicated structure is observed at higher frequency, possibly due to interband transitions or plasmons.

In an ordinary metal, the Hall coefficient is weakly temperature dependent and provides information on the carrier charge and density. Experiments on the heavy-fermion systems find a strongly temperature-dependent Hall coefficient, as shown in Fig. 4. The Hall coefficient is large and positive at room temperature and increases with decreasing temperature. Usually the Hall coefficient displays a peak at nearly the same temperature as a similar feature in the resistivity. A peak is also observed in UPt_3 and UAl_2, which do not show an associated peak in the resistivity in the

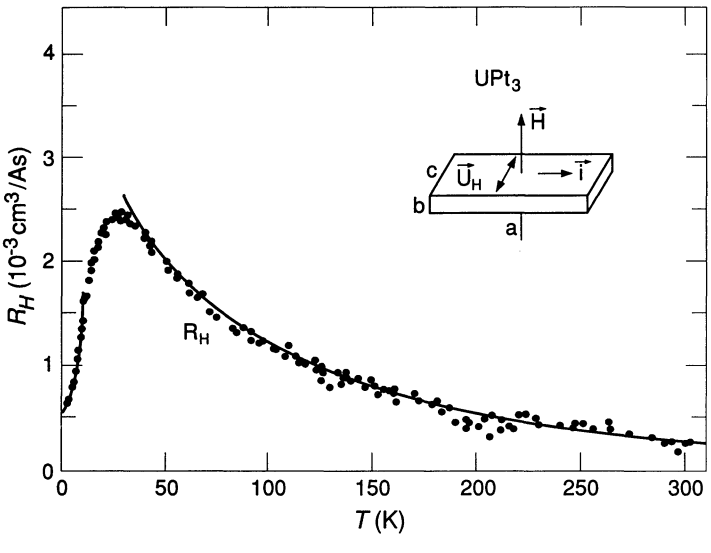

FIG. 4. The Hall coefficient as a function of temperature for UPt_3 measured in a 4-T field (from Schoenes and Franse, 1986). The solid line is a fit by the expression for incoherent magnetic scattering (see text).

corresponding temperature range. For metals containing small concentrations of impurity local moments, the Hall coefficient is often interpreted as the sum of an ordinary Hall coefficient, arising from the Lorentz force, and a generally large extraordinary term representing the incoherent scattering from local moments. At high temperature, this interpretation works well for the heavy-fermion systems (see solid line in Fig. 4) and is an aspect of the single-impurity phenomenology described below. In some heavy-fermion systems, the Hall coefficient changes sign at still lower temperatures. The rapid drop in R_H with temperature just below the peak has been interpreted as a signature of the onset of coherent scattering of the conduction electrons by the local *f*-atom moments.

1.2.6 Ultrasonic Measurements. The appearance of the heavy-electron state is evident in the temperature dependence of the elastic constants. Measurements on $CeAl_3$ (Lüthi, 1985), UPt_3, UBe_{13} (Yoshizawa *et al.*, 1985), and $CeCu_6$ (Weber, 1987) all show structure at low temperature and anomalies at high temperature, which contrast with the generally smooth and featureless elastic constants observed in an ordinary metal. Although some of these features signal structural phase transitions, as in the case of $CeCu_6$ at 220 K, others are interpreted as being due to magnetoelastic coupling to the crystal-field–split *J* multiplets (see Fulde *et al.* 1988). At low temperatures, where the heavy-electron state is developing, the temperature dependence of the elastic constants shows an anomalous change of slope for $CeCu_6$, UPt_3, and UBe_{13}.

The enormous density of states inferred from thermodynamic experiments suggests that the ultrasonic attenuation might be greatly enhanced. In fact, experiment finds that the magnitude of sound attenuation is of the order of that for an ordinary metal. In contrast to the comparatively smooth and featureless ultrasonic attenuation of an ordinary metal, an anomalous peak appears in UPt_3 at 12 K and in $CeCu_6$ at 2.5 K. In the latter case, the peak shifts to higher temperatures and broadens with increasing frequency. At still lower temperature, but above the superconducting transition, UPt_3 displays an attenuation that varies as T^2.

Specific-heat and resistivity data show that the coherent heavy-electron state is well developed at temperatures below ~ 10 K. In this regime, one expects that the phonon contribution to the ultrasonic attenuation should be negligible, and the energy of the sound wave should be dissipated primarily by the heavy-electronic liquid. As noted above, the ultrasonic attenuation is similar in magnitude to that measured for copper, which suggests that the electron-phonon coupling is reduced by an amount similar to the enhancement of the quasiparticle mass. In an ordinary metal, the sound speed v_s is much smaller than the Fermi velocity v_F, the electronic degrees of freedom are able to adjust rapidly to the lattice deformation presented by the sound wave, and the resulting attenuation process is isothermal. Lüthi (1985) pointed out that this is not the case in heavy-electron systems where $v_F \gtrsim v_s$, so that sound attenuation is adiabatic. As a consequence, the leading temperature dependence of the attenuation is due not only to the viscosity of the heavy-electron liquid, but also to the conduction of heat.

1.2.7 Nuclear Magnetic Resonance. At high temperature, the heavy-fermion systems show a nearly temperature-independent spin relaxation time T_1, consistent with the observed Curie-Weiss susceptibility. As the temperature is decreased, there is a regime below $\sim$ 10 K where T_1T is essentially constant (MacLaughlin, 1985), as expected for a Fermi liquid. As shown by Korringa, in a Fermi liquid the relaxation of polarization in the nuclear spin system is due to the coupling of the nuclear spin to the magnetic moment of the quasiparticles, so that $1/T_1T$ is proportional to the density of states at the Fermi surface (see Slichter, 1978). A comparison of T_1T for ^{13}Be in UBe_{13} and in $U_{0.967}Th_{0.033}Be_{13}$ just above T_c shows that $1/T_1T$ tracks the increase in γ observed in specific- heat experiments.

In URu_2Si_2, $T_1(T)$ decreases rapidly as the temperature is decreased through the antiferromagnetic transition at 17 K. It is interesting to note that a Korringa temperature dependence is evident above T_N and below $T \sim 10$ K.

1.2.8 Neutron Scattering. The results of inelastic neutron-scattering experiments on the magnetically ordered heavy-fermion systems U_2Zn_{17} and URu_2Si_2 and on the superconductor UPt_3 (see Aeppli *et al.*, 1988; Kjems and Broholm, 1988) show great similarities to those systems such as $CeCu_6$ and $CeRu_2Si_2$ (see Rossat-Mignod *et al.*, 1988) that remain paramagnetic down to the lowest temperatures. All of these systems have a response function with a large q-independent component that can be fitted by a relaxational form,

$$\chi(q,\omega)=\chi_0\Gamma/(\Gamma-i\omega). \tag{11}$$

The systems also have a smaller q-dependent contribution that peaks at a nonzero q, indicative of antiferromagnetic correlations. As most of the integrated intensity expected from sum rules is tied up in the above response, there is little intensity left to assign to the low-ω and -q peak associated with Pauli paramagnetism. This implies strong spin-orbit coupling between the quasiparticles of a Fermi liquid, and that most of the response is of local origin.

In paramagnetic heavy-fermion systems, the antiferromagnetic correlations only become apparent at low temperatures. The widths of the peaks in $S(q,\omega)$ at fixed ω indicate correlation lengths of the order of 3–10 Å. In the ordered systems, the single-site component of the response function remains comparable to those of the paramagnetic systems, and the phase transitions are considered to be the result of a slight increase in the effective exchange interaction at low temperatures. This interpretation is consistent with the observation that many of the paramagnetic systems can be driven into the ordered phase with the introduction of impurities. It is surprising that of the ordered magnetic systems only URu_2Si_2 shows the existence of sharp spin-wave-like excitations, albeit with a small dispersion. Perhaps the most surprising result of all is found in the elastic scattering peaks: in URu_2Si_2 and UPt_3 the strength of the antiferromagnetic Bragg peak is indicative of an ordered magnetic moment with very small magnitude, $\sim 0.03\mu_B$ and $\sim 0.02\mu_B$, respectively. It should also be pointed out that the Bragg peaks are broadened, indicating finite correlation ranges in the ordered state, probably due to defects.

1.2.9 Photoemission. The photoemission spectrum provides a measure of the occupied portion of the electronic density of states, if surface effects and the interaction between the observed electron and the system can both be neglected. Likewise the inverse photoemission spectrum is related to the unoccupied electronic density of states. Using the phenomenon of resonance, it is possible to extract the f component from the spectra. The resulting spectra show marked distinctions between the normal rare-earth and actinide systems. On one hand, the cerium systems show pronounced features that may be attributable to transitions between localized ionic configurations. The energy separation between these features is taken to be a measure of U_{ff}, the Coulomb interaction energy between the electrons in the $4f$ orbitals on the cerium ions. On the other hand, normal uranium-based systems, such as UIr_3 (Arko *et al.*, 1983), agree quite well with band theory, indicating much smaller values of U_{ff} for uranium. This satisfactory state of affairs does not extend to the heavy-fermion uranium systems. When the $5f$ spectra of UPt_3 and UAl_2 were compared to the density of states obtained from band-structure calculations in the local-density approximation (Allen *et al.*, 1985), it was found that the observed spectra were considerably broader. Similar discrepancies were found for UBe_{13}, U_2Zn_{17}, and URu_2Si_2 (Allen , 1988). It has been shown that these discrepancies in width exhibit a systematic variation (Arko *et al.*, 1988) that is most profound in the heavy-fermion systems and is attributable to the development of satellites in the occupied portion of the spectra. Similar analysis of inverse photoemission experiments on UBe_{13} shows some evidence for the existence of satellites in the unoccupied $5f$ density of states. Thus, in the heavy-fermion systems it appears as though the spectrum may have slight features corresponding to localized states superimposed on top of a $5f$ band that cuts across the Fermi level.

In contrast to the uranium-based heavy-fermion systems, there have been very few high-resolution studies of cerium heavy-fermion systems. The earlier studies seem to indicate that the features seen in the f spectrum are less sharp than those found in the cerium systems with more modestly enhanced electronic masses, perhaps being more akin to the uranium heavy-fermion systems. The interpretation of the photoemission spectra of cerium-based compounds is the subject of considerable controversy (Allen *et al.*, 1986; Liu *et al.*, 1982; Freeman *et al.*, 1987). The spectra show three major peaks: one above, one below, and one cutting across the Fermi level. One school of thought attributes the peaks above and below the Fermi level to transitions from an f^1 initial state to f^2 and f^0 final-state configurations, respectively. The peak near the Fermi level is associated with the Kondo effect whereby a spin polarization is induced in the conduction band at low temperatures, in order to compensate the magnetic moment of the f^1 configuration. The intensity in this peak is expected to scale with T_K, the characteristic energy scale of the Kondo model. A second school of thought attributes the existence of the two peaks at and below the Fermi level to two different mechanisms that are available to screen the charge deficiency associated with the f^0 final state. This school relates these screening channels to the systematic variation of the two peaks found in the photoemission of the praseodymium and neodymium rare-earth compounds, which have electronic mass enhancements of the order of those in ordinary metals.

1.3 Properties of the Superconducting State

Superconductivity in the heavy-fermion systems differs markedly from that in ordinary metals. Here, we briefly summarize some of the unusual properties of the heavy-fermion superconducting state, pointing out the differences between the heavy-fermion and conventional BCS superconducting states that lead to the conjecture that these are unconventional superconductors as defined in the Introduction.

At the transition temperature to the superconducting state T_c, the quasiparticles at the Fermi surface of a conventional superconductor are unstable to the formation of Cooper pairs. In the absence of a current, the Cooper pair consists of two electrons in states of momenta and spin $\mathbf{k},\sigma$ and $-\mathbf{k},-\sigma$ bound in a relative *s*-wave state by an attractive interaction mediated by phonons. Correlations between Cooper pairs generally lead to the formation of a gap in the quasiparticle dispersion relation,* which at sufficiently low temperature results in a thermally activated temperature dependence for specific heat, ultrasonic attenuation, nuclear spin relaxation, and thermal conductivity (see Schrieffer, 1964).

In contrast, the specific heat well below T_c for the heavy-fermion uranium compounds is described by

$$C(T)=\gamma_s T+\delta T^n \tag{12}$$

where γ_s is sample dependent and has often been attributed to conduction electrons that remain in the normal state, and n is 3 and 2 for UBe_{13} and UPt_3, respectively. Power-law temperature dependences have also been observed for ultrasonic attenuation, nuclear spin relaxation rates, thermal conductivity, and penetration depth. Sound attenuation in UPt_3 has been studied particularly thoroughly, and different exponents have been found, depending on the polarization and direction of propagation of the sound wave relative to the crystal axes. The exponents are also sample dependent. The power-law behavior observed in all of these properties strongly suggests that the gap function vanishes for some region on the Fermi surface and thus that, at the very least, the gap function depends strongly on the direction of **k**. The more exciting possibility is that the gap function has a lower symmetry than does the crystal lattice as a result of quasiparticles that pair in a nonzero angular momentum state, possibly in a triplet state as in liquid ^3He.

The many-body wave function of the superconducting state is a phase-coherent superposition of single-particle states, and interference effects can be observed in many experiments. The attenuation of sound waves and the relaxation rate of a nuclear spin show classic signatures of interference effects in a conventional BCS superconductor (Schrieffer, 1964). As the temperature is lowered through the superconducting transition, sound attenuation decreases abruptly and the relaxation rate of a nuclear spin displays a Hebel-Slichter peak as shown for ^{119}In in Fig. 5(a). In the heavy-fermion systems, the Hebel-Slichter peak is not observed, as shown for UBe_{13} in Fig. 5(b); the spin relaxation rate drops abruptly below T_c. The ultrasonic attenuation, on the other hand, does not plummet below T_c but shows a sharp peak for UBe_{13} and for the best samples of UPt_3. A broader peak is evident for URu_2Si_2.

We have already observed that the specific-heat discontinuity is a large fraction of the

---

*This does not occur in so-called gapless superconductors where the gap has been suppressed by impurities. The heavy-fermion superconductors are not intrinsically gapless.

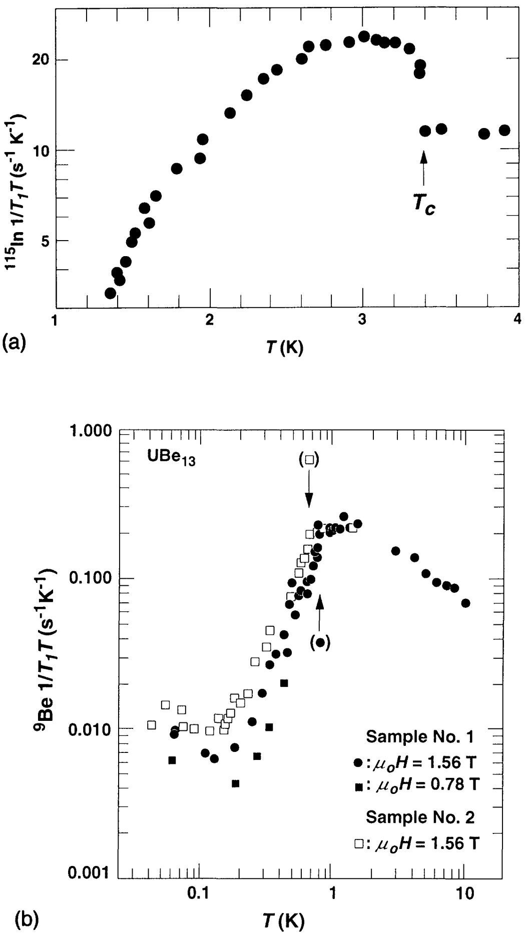

FIG. 5. Nuclear spin relaxation rate for (a) the conventional BCS superconductor ^{115}In and (b) the heavy-fermion system UBe$_{13}$. Note the absence of a Hebel-Slichter peak in UBe$_{13}$.

specific heat at T_c, consistent with the expectation for quasiparticles with a large effective mass condensing into the superconducting state. The normalized specific-heat discontinuities $\Delta C(T_c)/C_N(T_c)$ of several heavy-fermion superconductors are listed in Table 5. For most superconductors, $\Delta C(T_c)/C(T_c)$ lies within 20% of the weak-coupling BCS theory result of 1.43 (Parks, 1969). Larger values may occur as a result of strong coupling to lattice phonons. With the exception of UBe$_{13}$ and CeCu$_2$Si$_2$, the heavy-fermion superconductors show substantially smaller normalized specific-heat discontinuities. Moreover, the transition is often broad, as in UPt$_3$ and URu$_2$Si$_2$. We return to this point below.

The heavy-fermion superconducting state is very sensitive to impurities and defects. The transition temperature can be strongly depressed in UPt$_3$ by grinding the sample. The substitution of a small amount of thorium for uranium in UBe$_{13}$ leads to a rapid decrease of T_c. Further thorium substitution reveals the complicated phase diagram of U$_{1-x}$Th$_x$Be$_{13}$ in Fig. 6 that shows at least two and possibly more superconducting phases. For thorium concentrations lying roughly between 0.017 and 0.05, two phase transitions were observed in specific-heat experiments with discontinuities at the transitions of comparable size. The upper critical field of the higher-temperature phase behaves differently from that for pure UBe$_{13}$ when doped with small amounts of Gd impurities, suggesting that these are two different superconducting phases. Early sound attenuation experiments suggested that the low-temperature phase transition was to a magnetically ordered state. Subsequent neutron-scattering experiments failed to observe a magnetically ordered state. Muon-spin resonance experiments detect a small ordered moment $\leqslant 0.01\mu_B$. The small size of the moment suggests the possibility that the low-temperature transition may separate two unconventional superconducting phases. We discuss this possibility in Sec. 3 below.

The phase diagram of a conventional superconductor is determined by the ratio of the characteristic length scale over which the magnetic field varies, the penetration depth λ,

Table 5. Properties of some heavy-fermion superconductors.

Compound	T_c (K)	$\Delta C(T_c)/C(T_c)$	$-dH_{c2}/dT\|_{T=T_c}$ (T/K)	$H_{c2}(T=0)$ (T)
CeCu$_2$Si$_2$	~0.7	1.3	23	2.0

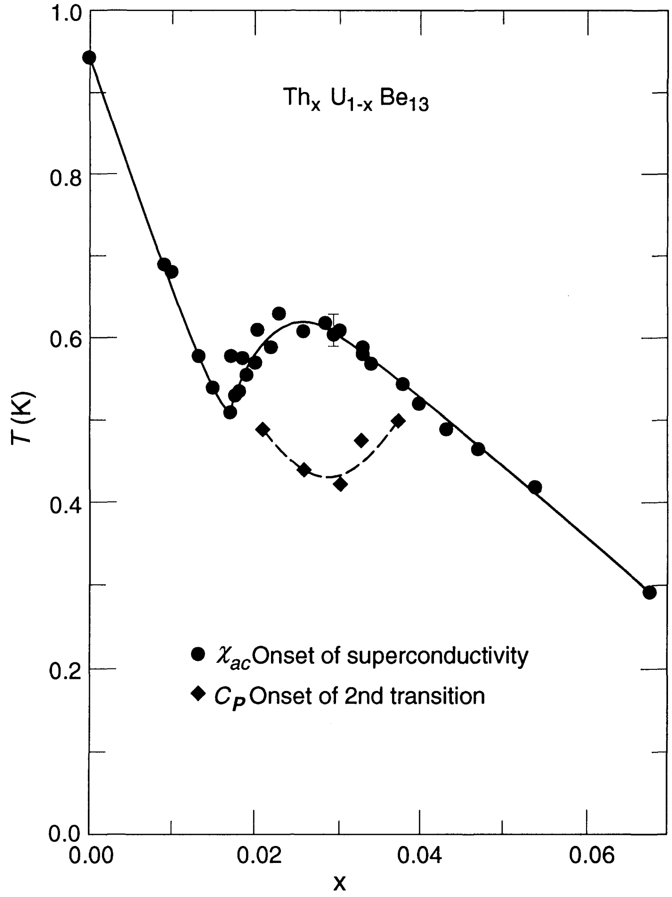

FIG. 6. The temperature–thorium concentration (x) phase diagram of $U_{1-x}Th_xBe_{13}$. Note the striking change in $T_c(x)$ (solid line) as x is increased through $x_c \simeq 0.018$ and the second phase transition at $T_{c2}(x)$ (dashed line).

to that over which the order parameter varies, the coherence length ξ. For a type-II superconductor, $\kappa = \lambda/\xi > \sqrt{2}$, and the H-T phase diagram shows two superconducting phases and one normal phase separated by the lower critical field $H_{c1}(T)$ and the upper critical field $H_{c2}(T)$. In the Meissner phase ($H < H_{c1}$), magnetic fields are excluded from the superconductor. As the field is increased above H_{c1}, magnetic flux penetrates the superconductor in a triangular lattice of flux tubes. Each flux tube is a vortex in the phase of the order parameter. The order parameter vanishes on the vortex axis and heals to its bulk equilibrium magnitude in a distance of the order of ξ. The magnetic field is a maximum at the center of the vortex and decays on the scale of λ. As the field is increased so too is the density of vortices until at H_{c2} the vortex cores begin to overlap and a transition occurs to the normal state.

The heavy-fermion superconductors are type-II superconductors with κ, as inferred from the slopes of H_{c2} and H_{c1} at T_c, as large as ~50 or more. These rank among the largest κ values found in conventional superconductors, for which the large value of κ occurs as a result of scattering from impurities. In contrast, the heavy-fermion substances are pure materials. The temperature dependence of $H_{c2}(T)$ for the heavy-fermion systems is generally unusual. As shown in Table 5, $dH_{c2}(T)/dT|_{T_c}$ for UBe_{13} is unusually large, possibly exceeded only by that for the high-T_c superconductors. In UBe_{13}, $H_{c2}(T)$ is nearly linear over a large range of temperature and shows a change in slope at about 0.5 K. In UPt_3 an anomalous crossover in the anisotropy of $H_{c2}(T)$ occurs with decreasing temperature. For temperatures near T_c, $H_{c2\parallel}/H_{c2\perp} \sim 1.3$ (where $\parallel$ and $\perp$ refer to the field direction with respect to the crystal c axis) and drops to

~0.8 as T approaches 0. The $T=0$ extrapolated value of H_{c2} exceeds simple estimates of the paramagnetic limit at which the spin-polarized normal state is favored over a conventional superconducting state. The upper and lower critical fields in the basal plane of UPt_3, and $H_{c1}(T)$ in $U_{1-x}Th_xBe_{13}$ at the low-temperature transition, show unusual sharp kinks.

The phase diagram of UPt_3 in the H-T plane shows five superconducting phases in contrast to the two observed in an ordinary superconductor. This is strong evidence, as we discuss below, that UPt_3 is an unconventional superconductor. The phase diagram as observed in the sound speed measurements of Adenwalla *et al.* (1990) is shown for field in the basal plane and along the c-axis in Fig. 7 (see also Bruls *et al.*, 1990). The figure shows three phases in the mixed state, but does not show the Meissner phases, which lie close to the temperature axis.

A connection between weak antiferromagnetic order and superconductivity is suggested in Table 1. For some of the heavy-fermion superconductors, a transition to an antiferromagnetic state with an extraordinarily small magnetic moment, of order $\sim 0.01\mu_B$, occurs at a Néel temperature $T_N \sim 10T_c$. A notable example is UPt_3, for which recent specific-heat (Fisher *et al.*, 1989) and sound-velocity experiments observe two superconducting transitions 60 mK apart, which may be a signature of the coupling of an unconventional superconducting-order parameter to a magnetic-order parameter (see Sec. 2.3 and Hayden *et al.*, 1992). It is interesting that prior experiments found only a single broad peak at the superconducting transition in UPt_3 as also observed for URu_2Si_2. This suggests that an aging effect may occur in UPt_3 and that antiferromagnetic order may appear with time (Smith, 1992). A possible mechanism for an aging effect is radiation damage due to uranium decay.

2. THEORY

2.1 Phenomenology

2.1.1 Landau Fermi-Liquid Theory. At low temperature, the linear dependence of the specific heat, the nearly temperature-independent susceptibility, and the large T^2 coefficient of the resistivity suggest that the heavy-fermion systems settle into a strongly renormalized Fermi-liquid state below a (material-dependent) characteristic temperature. Well

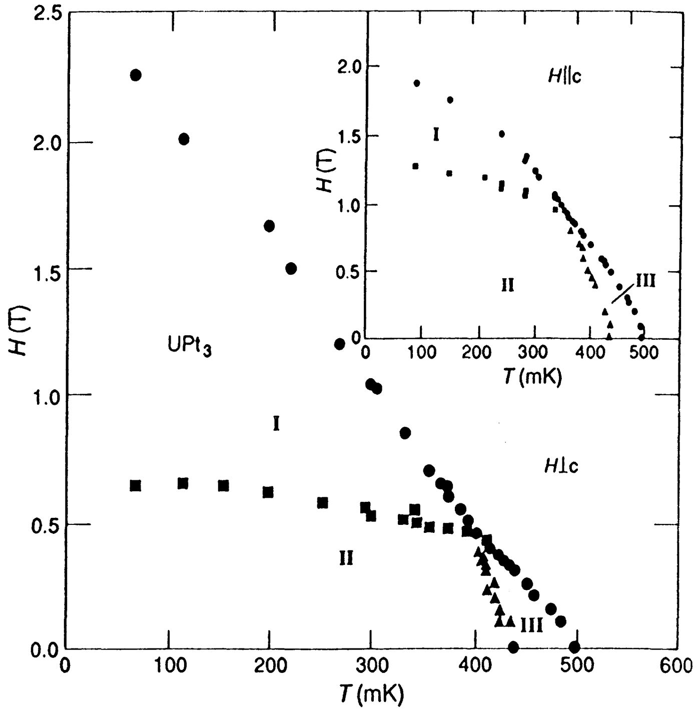

FIG. 7. The field-temperature phase diagram of the superconductor UPt_3 as deduced from sound-velocity measurements for fields in the basal plane (from Adenwalla *et al.*, 1990). The lower critical field separating the mixed phases from the Meissner phases is not shown but lies just above the temperature axis. In all there are five superconducting phases in the H-T plane. Inset: The corresponding phase diagram for fields along the c axis.

below an effective degeneracy temperature, the properties of diverse systems of strongly interacting fermions resemble those of a system of noninteracting fermions and are determined in large part by the low-energy excitations of the interacting system. The phenomenological Fermi-liquid theory of Landau may be used to describe such systems. The central concept of Landau Fermi-liquid theory is the quasiparticle, which is an elementary excitation of the interacting system that can be crudely viewed as a particle surrounded by a cloud of other particles. The lifetime of a quasiparticle near the Fermi energy [varying as $1/(e^2+\pi T^2)$, with e measured from the Fermi energy e_F] is sufficiently long to provide a useful description of the low-lying elementary excitations of the interacting system. The original system of strongly interacting "bare" particles is thought of as a system of interacting quasiparticles. The dynamical properties of these quasiparticles, such as the mass, are renormalized from those of the bare particles by the accompanying motions of the surrounding particle clouds. The Landau theory provides no prescription for calculating the properties of or interactions between quasiparticles; rather, these are to be determined from experiments or microscopic theories. The Landau theory provides relations between physical quantities in terms of the effects of residual screened interactions between the quasiparticles. A proper Landau theory for any metal should incorporate the symmetry of the underlying crystalline lattice as outlined by Fulde *et al.* (1988) for heavy-fermion systems. Such a description is complicated by the occurrence of a large number of parameters describing the quasiparticle interactions. So we describe an overly simplified theory that is similar in construction to the Fermi-liquid theory for liquid ^{3}He, for the purpose of introducing Fermi-liquid theory and also because the results of some calculations based on model Hamiltonians are expressed in terms of the Landau parameters of this model.

The free energy may be expanded about its zero-temperature limit in terms of the interactions between quasiparticles,

$$F(T)=F(0)+\sum_{\mathbf{p}} E^0_{\mathbf{p}}\delta n^\sigma_{\mathbf{p}}+\sum_{\mathbf{p},\mathbf{p}',\sigma,\sigma'} f^{\sigma,\sigma'}_{\mathbf{p},\mathbf{p}'}\delta n^\sigma_{\mathbf{p}}\delta n^{\sigma'}_{\mathbf{p}'} + \text{terms } O((\delta n)^3), \qquad (13)$$

where $\mathbf{p}$ and σ are momentum and spin variables and $\delta n^\sigma_{\mathbf{p}}$ is the deviation of the distribution function from its zero-temperature limit. We have retained only the interaction between two quasiparticles $f^{\sigma,\sigma'}_{\mathbf{p},\mathbf{p}'}$, which is dominant at sufficiently low temperature. Symmetries are used to simplify the form of f and to choose an appropriate set of basis functions; the coefficients appearing in the basis function expansion are the so-called Landau parameters. For example, rotational symmetry in spin space leads to the form $f^{\sigma,\sigma'}_{\mathbf{p},\mathbf{p}'} = \mathbf{1}f^s_{\mathbf{p},\mathbf{p}'} + \boldsymbol{\sigma}\cdot\boldsymbol{\sigma}' f^a_{\mathbf{p},\mathbf{p}'}$. For liquid ^{3}He, the appropriate basis functions are the usual spherical harmonics; $\mathbf{p}$ has the meaning of a quasiparticle momentum and σ the meaning of a quasiparticle spin. Various thermodynamic and transport properties of the system can be expressed in terms of the Landau parameters. In this case one finds for the compressibility

$$\chi_d=\frac{m^*/m}{1+F^s_0}\,\chi^0_d\,, \qquad (14)$$

and for the susceptibility

$$\chi_s=\frac{m^*/m}{1+F^a_0}\,\chi^0_s\,, \qquad (15)$$

where χ^0_d and χ^0_s are the corresponding susceptibilities in the noninteracting system, and the dimensionless Landau parameter $F^\lambda_l = N(e_F)f^\lambda_l$, where $N(e_F)$ is the density of states that appears in the linear coefficient of the specific heat,

$$\gamma=\frac{\pi^2}{3}N(e_F)k_B^2=\frac{m^*}{m}\gamma^0, \qquad (16)$$

m^* is the quasiparticle effective mass, and k_B is Boltzmann's constant.

Carneiro and Pethick (1975) showed that long-wavelength fluctuations of spin and density in a system of interacting fermions will generally contribute a term to the low-temperature specific heat that depends logarithmically on the temperature,

$$C(T)=\gamma T+\zeta T^3\ln T+\beta T^3+\ldots, \qquad (17)$$

where ζ may be expressed in terms of the Landau parameters.

The observation that UPt$_3$ has a specific heat of the form Eq. (17) led to the proposal that quasiparticle spin fluctuations play a similar role in UPt$_3$ as they do in ^{3}He (Stewart, 1984). The electron-phonon interaction can also contribute to the $T^3 \ln T$ term in the specific heat, but the sign of this contribution to ζ is opposite to that produced by the spin and density fluctuations and is also of opposite sign to that observed in UPt_3. A single-band spin-$\frac{1}{2}$ model was developed for UPt_3 and UAl_2, assuming an expression for ζ taken from the Landau theory of ^3He, estimating the effective radius of the Fermi surface, and neglecting scattering processes involving angular momentum channels of $l=2$ and higher (see Pethick and Pines, 1987, for a review). This allowed the analogy of UPt_3 and ^3He to be extended to the superconducting state. In ^3He the superfluidity is believed to occur due to an attractive interaction mediated by spin fluctuations. The analogy yields an attractive effective interaction between two electrons, which produces superconductivity below a critical temperature T_c. They calculated the pressure dependence of T_c and found it to be in agreement with experiment. The mechanism for the formation of Cooper pairs (see Sec. 3) in this model is of purely electronic origin, and the resulting superconducting state is unconventional. A further consequence of this model is that the effective moments of the quasiparticles are renormalized so that $\mu < \mu_B$.

2.1.2 Single-Impurity Model. For temperatures well above the "coherence temperature" T^*, the single-impurity Anderson model provides a useful phenomenological framework for the heavy-fermion systems. This model was originally introduced by Anderson to describe dilute magnetic impurity ions dissolved in a solid. However, the heavy-fermion systems have a relatively high concentration of magnetic (f) ions, and so the use of this single-ion phenomenology in the high-temperature regime implicitly assumes the decoupling of the f orbitals on different lattice sites.

The single-ion Anderson model describes a doubly degenerate localized level, e.g., an f level, that is bathed in a Fermi sea of conduction electrons. The Hamiltonian can be written as

$$H = H_f + H_d + H_{fd}\,, \tag{18}$$

where H_f describes the f-electron system, H_d describes the conduction-electron system, and H_{fd} describes the coupling between these systems. The Hamiltonian H_f is

$$H_f = \sum_{\alpha} E_f n_\alpha + \sum_{\alpha > \beta} U_{ff} n_\alpha n_\beta\,, \tag{19}$$

where n_α represents the number of electrons in the f orbital with spin index α. The first term, proportional to E_f, represents the binding energy of an electron of spin α in the f shell. The second term, proportional to U_{ff}, represents the Coulomb repulsion between pairs of electrons in the f shell. The Pauli exclusion principle makes this term inactive when $\alpha = \beta$. The conduction electrons described by H_d are noninteracting conduction electrons in band states:

$$H_d = \sum_{\mathbf{k}\alpha} e_{\mathbf{k}} n_{\mathbf{k}\alpha}\,, \tag{20}$$

where $n_{\mathbf{k}\alpha}$ is the number of electrons of spin α in the conduction-band state labeled by the Bloch wave vector $\mathbf{k}$ and $e_{\mathbf{k}}$ is the dispersion relation of the conduction-band states. The f- and d-electron systems are coupled by a spin-conserving hybridization interaction H_{fd}, which represents processes whereby individual electrons can tunnel out of the f level into the conduction-band states along with the reverse processes. This hybridization process has matrix elements between localized f states $|f\alpha\rangle$ and itinerant states $|d\mathbf{k},\alpha\rangle$ given by

$$V_{\mathbf{k}} = \langle f\alpha | H_{fd} | d\mathbf{k},\alpha \rangle. \tag{21}$$

Applying Fermi's "golden rule," one obtains an effective f-level width Δ, for the state in which the f electron is occupied by a single electron, given by

$$\Delta = \pi |V|^2 N(e_F), \tag{22}$$

where $N(e_F)$ is the conduction-band density of states, per spin, evaluated at the Fermi energy e_F.

One question of interest is whether the impurity ion can carry a magnetic moment in a metallic matrix. Anderson (1961), working within the Hartree-Fock approximation, showed that a magnetic moment might be formed for sufficiently large U_{ff}/Δ, whereas for smaller values of the ratio the impurity was nonmagnetic. These results can be understood by first considering two extreme limits that can be solved exactly: In the atomic limit, for which $\Delta = 0$, adding an electron of spin β to a localized level already occupied by an electron of spin α costs an energy of $E_f + U_{ff}$, whereas the energy for removing the electron of spin α is E_f. Thus, the one-electron density of states is split into two sharp levels; the β level occurs above the Fermi level, and the α sublevel occurs below the Fermi level. The other extreme limit is the noninteracting limit where $U_{ff} = 0$, in which case the f states admix with the conduction-band states through the hybridization term, giving rise to a resonant peak in the f density of states at E_f with width given by Δ. In this noninteracting case, the f states of spin α and spin β are occupied by equal numbers of electrons (possibly fractionally) and hence possess no net magnetic moment. For the same reason that the f level splits in the atomic limit, the Hartree-Fock solution also shows a splitting of the f density of states for large but finite values of the ratio U_{ff}/Δ. The two subbands are of different spin characters and are separated by an energy of the order of U_{ff}. This split density of states, shown in Fig. 8, can lead to the formation of a local f moment when occupied by electrons in accordance with the Pauli exclusion principle. For systems with a number of f electrons per f ion less than unity, $n_f < 1$, the Hartree-Fock treatment requires that $|E_f - e_F| < \Delta$, which places the lower subband close to the Fermi level and the upper subband above. For almost integer occupation of the f level the lower subband will lie at even lower energies and may have very little weight at the Fermi energy. This

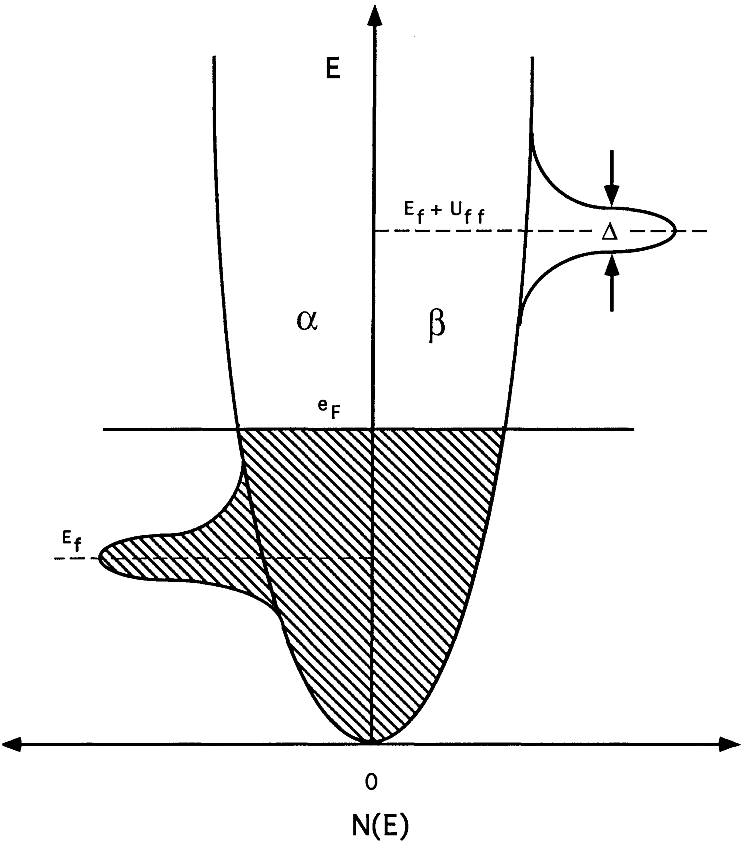

FIG. 8. The density of states from the Hartree-Fock solution to the single-impurity Anderson model showing that the effect of the intra-atomic Coulomb interaction is to split the original f level into two levels according to spin. One level occurs at the position of the original f level, the other at an energy U_{ff} higher and above the Fermi energy. Processes by which an electron can tunnel from an atomic f orbital to the conduction band and the reverse processes called hybridization are responsible for the finite level width $\sim\Delta$.

latter regime is defined as the Kondo regime, in which Hartree-Fock theory would predict well-developed local moments. Schrieffer and Wolff (1966) have shown that these local moments are coupled to the spin polarization of the conduction electrons by an antiferromagnetic exchange interaction of strength $J=V^2/E_f$. This coupling introduces quantum fluctuations in the directions of the local moments that are not included in the Hartree-Fock solution.

The most marked modifications to the Hartree-Fock results are required in the Kondo regime, as is suggested by renormalization-group scaling arguments (Haldane, 1978). What happens is that J produces a bound state that when occupied by an electron produces a compensating spin polarization in the conduction electrons. At low temperatures the resulting complex is a spin singlet, whereas at higher temperatures the bound state is ionized leading to the reappearance of the local moment. This low-energy behavior leads to the appearance of a narrow temperature-dependent resonance in the single-electron spectrum at the Fermi level known as the Kondo peak. Nozières (1974) has shown that the low-temperature properties can be described quite well by a Landau Fermi-liquid theory in which the impurity produces a phase shift for the conduction electrons that reaches $\delta_0(\mathbf{k}_\mathrm{F})=\pi/2$ at the Fermi energy. The picture of a low-energy, low-temperature Fermi liquid can also be obtained by a projection method for minimizing the Coulomb interaction energy, developed by Gutzwiller (1965), which basically renormalizes the hybridization width Δ by a factor of $1-n_f$ corresponding to the elimination of processes in which an electron may hop into an f shell that is already occupied. For cerium, with an f band less than half filled, the maximum intensity in the Kondo peak is above the Fermi energy. The resulting picture of the one-electron spectrum in the Kondo regime is that of a filled subband below the Fermi energy, separated by an energy U_{ff} from an unfilled upper subband, together with a temperature-dependent Kondo resonance located at the Fermi energy. The width of the Kondo resonance is related to the Kondo temperature T_K where $k_\mathrm{B}T_\mathrm{K}\sim\Delta(1-n_f)$ and its peak height is $\sim 1/\pi\Delta$.

Confidence in the above picture has been established by exact Bethe-*Ansatz* solutions (Schlottmann, 1989; Tsvelick and Wiegman, 1983) and by exact numerical renormalization-group studies (Krishnamurthy *et al.*, 1980). One of the most notable features of these solutions is that the thermodynamic properties only depend on a single energy scale given by the Kondo temperature.

For the heavy-electron systems, one imagines a lattice of such impurities (the cerium or uranium atoms). As the temperature is reduced it is possible that the compensating polarization clouds of each impurity lock together in a coherent heavy-fermion state. This possibility has motivated studies of the interactions between two Anderson impurities (Jones *et al.*, 1988). As a result of the occurrence of another energy scale, the exchange interaction J between the impurity moments, two possibilities arise. If $J\ll T_\mathrm{K}$, then the compensation of each local moment occurs independently, whereas if $J\gg T_\mathrm{K}$, the moments order before the screening clouds develop.

Nozières (1985) noted another complication of this picture. The formation of a compensating screening cloud only involves conduction electrons within T_K of the Fermi surface, but the total number of such electrons is much less than that required to screen every local moment in a concentrated compound.

Although much use can be made of the above phenomenologies, it remains unclear to what extent they provide a firm theoretical basis for understanding the properties of a lattice of f ions immersed in a Fermi sea of conduction electrons.

2.1.3 Model Hamiltonians. It is believed that the physics of the single Kondo impurity is related to the physics of the process by which the system of apparently weakly interacting local moments in a sea of conduction electrons is transformed to an itinerant band of heavy quasiparticles. The Anderson lattice model makes this notion more precise and quantitative, by generalizing the Hamiltonian of a single f impurity to a dense lattice of f sites.

The Anderson lattice Hamiltonian may be written as the sum of three terms as in Eq. (18), but with H_f representing a lattice of f ions:

$$H_f=E_f\sum_{i\alpha} n_{f\alpha i}+\sum_{i,\alpha<\beta} U_{ff}n_{f\alpha i}n_{f\beta i}\,, \qquad (23)$$

where i labels the f-lattice sites and α labels an appropriate basis set that reflects the full 14-fold spin- and orbital-degenerate f level. The hybridization terms are generalized by allowing the f level at each site to admix with the conduction-band states. The transformation from the Wannier representation of the f levels to a Bloch representation,

$$|f\mathbf{k},\alpha\rangle=\frac{1}{\sqrt{N_s}}\sum_i e^{i\mathbf{k}\cdot\mathbf{R}_i}|fi,\alpha\rangle, \tag{24}$$

together with conservation of crystal momentum, leads to the simple form for the hybridization matrix element

$$V_{\mathbf{k}}=\langle f\mathbf{k},\alpha|H_{fd}|d\mathbf{k},\alpha\rangle. \tag{25}$$

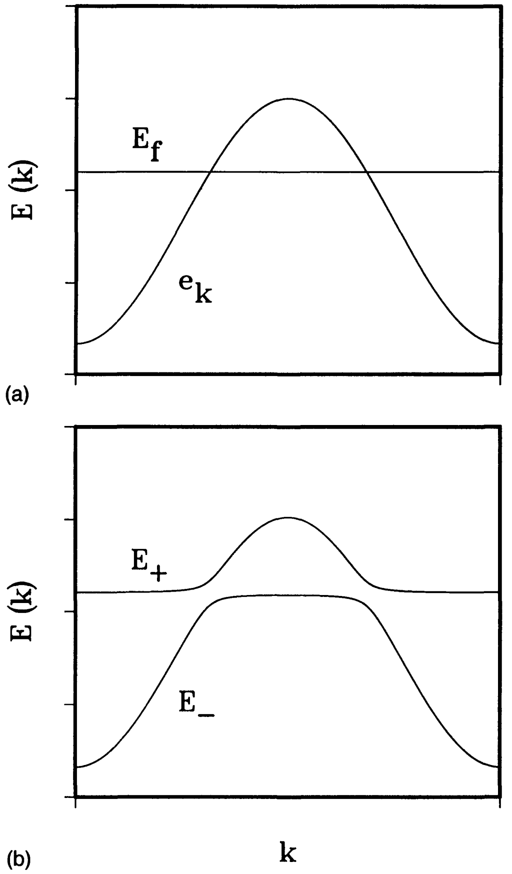

FIG. 9. Flat atomic f level, and a broad conduction band shown as a function of crystal momentum in (a), are admixed by the hybridization matrix element V, to produce the two spin-degenerate bands shown in (b).

In the absence of the intrasite Coulomb interaction, $U_{ff}=0$, the lattice Hamiltonian can be completely diagonalized. This yields two spin-degenerate bands with dispersion relations

$$E_{\pm}(\mathbf{k})=\tfrac{1}{2}\{E_f+e_{\mathbf{k}}\pm[(E_f-e_{\mathbf{k}})^2+|2V_{\mathbf{k}}|^2]^{1/2}\}, \tag{26}$$

which are sketched in Fig. 9. If the hybridization matrix element $V_{\mathbf{k}}$ is non-vanishing over the entire Brillouin zone, then the electronic-spectrum exhibits an indirect gap of magnitude V^2/W where W is the d-band width. The existence of a hybridization gap depends on the validity of many simplifying assumptions such as the neglect of direct f-f hopping, crystalline field effects, spin-orbit coupling, and so on. Nonetheless, the hybridization gap often plays an important role in many-body theories for the heavy-fermion semiconductors.

The introduction of the Coulomb interaction U_{ff} is expected to modify the above simple picture of the electronic states. Unfortunately, no exact solutions for the Anderson lattice model are known, leading researchers to rely on approximate methods.

At high temperature, the Anderson lattice Hamiltonian is expected to behave like an incoherent superposition of single Anderson impurities. As observed above, the properties of the heavy-electron systems at high temperature resemble those of a collection of single Anderson impurities in the Kondo regime. Thus one expects that in order for the Anderson lattice Hamiltonian to describe the heavy-fermion systems, the ratio U_{ff}/Δ should be large and the f level should lie well below the Fermi level. Moreover, the upper single-impurity band, E_f+U_{ff}, lies well above the Fermi level. In this situation, fluctuations of the f-site charge are strongly suppressed and fluctuations of the f-site moments are the important degrees of freedom.

Many different approximations have been developed for the Anderson lattice Hamiltonian, as reviewed by Lee *et al.* (1986) and Fulde *et al.* (1988). Of particular interest for the heavy-fermion systems are strong-coupling approximations that include direct decoupling of the hierarchy of equations of motion for the Green's functions, variational methods (Rice and Ueda, 1985), and expansions in powers of the spin and orbital degeneracy of the f levels, which are generalizations to the lattice of methods used for the single-impurity problem known as $1/N$ expansions. The decoupling schemes and variational methods, depending on initial choices of allowable physical states, are not systematic and have not been the methods of choice for most researchers. For technical reasons, much of the work on the Anderson lattice Hamiltonian (e.g., $1/N$ expansions) has been done for the limit $U_{ff} \rightarrow \infty$ in the hope of describing the essential features of strong correlations.

The expansions in powers of the spin-orbital degeneracy N are made with the assumption that N is a large number and that the expansion is rapidly convergent (Bickers 1987; Newns and Read, 1987). In the limit $N \rightarrow \infty$, a mean-field solution is expected to be exact. This mean-field solution produces a set of bands similar to those shown in Fig. 9(b). However, the position of the f level is renormalized upwards, and the magnitude of the hybridization is reduced in order to minimize the Coulomb interaction energy. Physically, the smaller the number of f electrons, the less the interaction energy. Furthermore, reducing the hybridization matrix element from its noninteracting value makes it less likely for a conduction electron to hop into a localized f orbital and interact with the electrons already present there, which also minimizes the effects of the Coulomb interaction. The above picture is that of renormalized bands, in which the width of the f states is narrowed by the Coulomb interactions. This picture is modified by including terms of higher order in $1/N$. In general, the above states are subject to further changes in their dispersion relations and also acquire a finite lifetime that is both temperature and energy dependent. The energy dependence of the lifetime can cause structure in the electronic density of states that is not directly related to the quasiparticle dispersion relations. For physical values of N, the contribution of the quasiparticle dispersion relations to the density of states is a small peak close to the Fermi energy, and the main structure occurs as a result of the energy dependence of the lifetime.

Many results obtained by the $1/N$ expansion technique can also be obtained by other methods. An example is a variational scheme based on a method of projecting out doubly occupied f states, thereby minimizing the energy of the Coulomb interaction. Rice and Ueda (1985) applied this method to the Anderson lattice model and produced an effective band model similar to that obtained by the $1/N$ expansion techniques. These authors argued that in the Kondo regime the physics should be similar to that of the Hubbard model near localization. The main results are discussed in the Landau Fermi-liquid language introduced above. They find that the divergence of the effective mass, as localization is approached, is balanced by a similar divergence in F_0^s, and thus the charge susceptibility remains unrenormalized. The parameter F_0^a that controls the tendency for magnetic ordering depends strongly on the total degeneracy of the f level. In the direct $1/N$ expansion techniques it has been found that the paramagnetic heavy-fermion state is only stable if the orbital degeneracy is large.

Although the strength of the Coulomb interaction is sufficiently large that series expansions in powers of U_{ff} are not expected to converge rapidly, studies along these lines have been pursued (Czycholl, 1986). The main motivation for applying perturbation theory to the Anderson lattice model is that for the single-impurity Anderson model with particle-hole symmetry ($2E_f + U_{ff} = 2e_{\mathrm{F}}$; see Fig. 8), perturbation expansions for certain quantities are rapidly convergent (Horvatić and Zlatić, 1985). Since the heavy-fermion state itself is apparently a Fermi liquid and the formal underpinnings of Fermi-liquid theory are described in terms of self-consistent perturbation theories that sum infinite classes of diagrams, it is further hoped that such an approach could at least describe the low-temperature limit. Numerical calculations are required to evaluate the expressions of self-consistent perturbation theories beyond Hartree-Fock theory, and it is possible to include the results of band-structure calculations without further approximation. The choice of classes of diagrams to be summed is to some extent arbitrary, although conservation laws provide guidance in selecting sets of terms. Apparently because of the difficulty of the numerical calculations (Schweitzer and Czycholl, 1990), fully self-consistent calculations have not been reported for the Anderson lattice model in three dimensions; the calculations that have been performed have been limited to second-order perturbation theory. The results show that the quasiparticle dispersion relation is strongly renormalized near the Fermi energy and that a temperature-dependent peak appears in the density of states at the Fermi level that bears a qualitative resemblance to the Kondo resonance in the single- impurity model. An unfortunate feature of these calculations is that they have been performed largely for models that include only one spatial dimension; such models may contain well-known pathologies related to low dimensionality.

Both the weak-coupling and strong-coupling schemes do yield results that have some qualitative similarities, namely a narrow temperature-dependent peak in the density of states close to the Fermi energy. However, no quantitative agreement has been reached between the strong- and weak-coupling schemes. This has led various groups to apply numerical techniques, which have given some insight into these problems. Conspicuous among these is the quantum Monte Carlo method, which has allowed the accuracy of some approximate solutions to be assessed. Unfortunately these calculations have been restricted to small systems, high temperatures, and near particle-hole symmetry. Thus, despite its deceptively simple appearance, the exact solution for the low-temperature, low-energy properties of the Anderson lattice Hamiltonian remains elusive.

2.2 Electronic Structure Calculations

The electronic structures of the heavy-fermion systems $CeAl_3$, $CeCu_2Si_2$, $CeCu_6$, UBe_{13}, UPt_3, U_2Zn_{17}, and URu_2Si_2 have all been calculated in the local-density approximation (Fulde *et al.*, 1988). This approach is based on a theorem due to Kohn and Sham (1965) that states that the energy of the fully interacting electronic system is a functional of the electronic density (see ELECTRON STATES IN SOLIDS). Electronic correlations are incorporated by the introduction of an exchange and correlation term in the energy functional, and the result of the calculations should be the exact real-space electronic charge density and the total energy. The exact form of the exchange and correlation functional is unknown, but in the local-density approximation (LDA) it is approximated by the form appropriate for a system with uniform electron density, but evaluated with the local value of the electronic density. As a by-product of the Kohn-Sham formalism a set of eigenfunctions and eigenvalues is generated; the spectrum of eigenvalues often exhibits a close resemblance to the electronic spectrum, as measured by, for example, angle-resolved photoemission. An advantage of these calculations is that crystal-field effects and spin-orbit interactions are automatically included. In the latter case, fully relativistic calculations are required. The results of these calculations share the common feature of a band with primarily f character straddling the Fermi energy. For cerium systems, the occupied $4f$ weight accounts for 1 to 1.3 f electrons, whereas for the uranium systems, the $5f$ count lies between 2 and 3 electrons per uranium atom. The total f bandwidths are of the order of 1 eV as the f character admixes to states in bands that are energetically removed from the Fermi energy. Although this is narrow when compared to the bandwidth of a typical conduction band, it is still too large to account for the order-meV energy scale deduced from the thermodynamic and transport properties of the heavy-fermion materials. Moreover, the calculated total density of states at the Fermi energy is still much smaller than that deduced from the linear temperature coefficient of the specific heat.

A tight-binding parametrization of LDA calculations is essential, if quantitative predictions incorporating many-body correlations are to be made; only a few such parametrizations have been performed. Although the entire parameter sets may vary from one fitting procedure to the next, the individual parameters do indicate the importance of hybridizing the f band with non-f bands.

2.3 Superconductivity

Perhaps the most exciting aspect of the heavy-fermion systems is that some of them might be unconventional superconductors. Various authors have proposed that an anisotropic but still conventional state occurs as a result of the strong coupling of f electrons to the lattice. This point of view is reviewed at length in Fulde *et al.* (1988).

The superconducting state is expected to be unusual at the very least. The standard theory of superconductivity relies in large part on the existence of small parameters. The difference in the thermodynamic potential between the superconducting state and normal state may be expressed as an asymptotic expansion in

T_c/T_F, where T_F is the Fermi energy. The leading term is of order $(T_c/T_F)^2$ and gives the weak-coupling BCS theory of superconductivity, which can allow both conventional and unconventional order parameters. Eliashberg theory, which treats strong electron-phonon coupling, is of order $(T_c/T_F)^2$ and also of leading order in the ratio of the electronic mass to the ionic mass. Strong-coupling corrections due to quasiparticle-quasiparticle scattering appear at the next order in (T_c/T_F). These corrections are known to be important in superfluid ^{3}He where $T_c/T_F \sim 10^{-2}$. Even though T_c is small in the heavy-fermion systems, the effective degeneracy temperature is also small, and $T_c/T_F \sim 10^{-2}$ or larger. Strong-coupling corrections due to quasiparticle-quasiparticle scattering may thus be important in the heavy-fermion superconductors; evidently they are unimportant in an ordinary superconductor where $T_c/T_F \sim 10^{-4}$ or smaller.

In a conventional BCS superconductor, the weak attractive interaction between electrons is mediated by phonons. The ratio T_D/T_F, where T_D is the Debye temperature, is small, allowing one to treat accurately even a strong electron-phonon interaction in second order. In the heavy-fermion systems, this ratio is evidently of order unity, and the validity of this theory is unclear.

The narrow bandwidth of the *f* electrons suggests that the repulsive interaction between quasiparticles due to the Coulomb interaction should be important in these materials. In liquid ^{3}He, strong short-ranged repulsive interactions between ^{3}He quasiparticles discourage Cooper pairing in a relative *s*-wave state, and the quasiparticles form a Cooper pair in a relative *p*-wave state. Analogies with liquid ^{3}He gave rise to the initial speculation that the quasiparticles forming the condensate wave function in the heavy-fermion superconductors are in a relative angular momentum state with $l > 0$. The strong intrasite repulsion between electrons on *f* sites also gives rise to spin fluctuations in the normal state. Analogy to liquid ^{3}He suggests that spin fluctuations, rather than phonons, may provide the attractive interaction between quasiparticles. The mechanism for pairing in the heavy-fermion systems and the microscopic description of the superconducting state are topics of considerable controversy and lie outside the scope of this work. We refer the reader to Lee *et al.* (1986) and Fulde *et al.* (1988) for reviews.

The determination of whether heavy-fermion superconductors are conventional or unconventional rests on the interpretation of experiments that probe the symmetry of the order parameter. The apparent absence of small parameters has prompted an approach that relies primarily on symmetry and on the most fundamental assumptions. Thus a considerable effort has been devoted to exploring the predictions of Ginzburg-Landau (GL) theories of unconventional superconductors. The connection between GL theory and microscopic theory has been studied carefully for superfluid ^{3}He, the archetypal unconventional "superconductor." Superfluid ^{3}He shows two distinct superfluid phases in the temperature-pressure phase diagram. At low pressure the *B* phase is stable, consistent with weak-coupling BCS theory. As a result of strong-coupling corrections, the *A* phase becomes stable at high pressure. The form of the Ginzburg-Landau free energy is dictated by symmetry; the value of the parameters that appear in the free-energy functional may be calculated from microscopic theory or deduced from experiments.

The normal-to-superconducting transformation can be viewed as a second-order phase transition in which quasiparticles form a condensate of Cooper pairs. A natural order parameter describing the superconducting state is the condensate wave function,

$$\langle \psi_\alpha(\mathbf{R}+\mathbf{r})\psi_\beta(\mathbf{R}-\mathbf{r}) \rangle, \tag{27}$$

where **R** and **r** are the center of mass and relative coordinates of the quasiparticles in the Cooper pair, and $\psi_\alpha(\mathbf{r})$ is a field operator that destroys a particle of spin α at **r**. It is a general property of a second-order phase transition that a symmetry of the normal state is broken in the ordered state. In the superconducting state, the gauge symmetry of the normal state is broken by the appearance of the condensate wave function. In an unconventional superconductor, not only is gauge symmetry broken, but a symmetry or symmetries of the crystalline lattice may also be broken because the condensate wave function has a lower symmetry than the crystal lattice. For example, because ^{3}He quasiparticles are paired in a spin-triplet orbital *p*-wave state, parity is broken, and ^{3}He is an unconventional superfluid.

In the heavy-fermion systems, strong spin-orbit coupling breaks full rotational symmetry in spin space, but the crystal structures have a center of inversion symmetry, so that the notions of "singlet" and "triplet" states should be replaced by "even-parity" and "odd-parity" states. The condensate wave function may still be written as above if α and β are interpreted as pseudospin labels.

The general theory of second-order phase transitions allows the possible unconventional superconducting states to be classified according to the symmetry of the condensate wave function, without making assumptions about the nature of the pairing interaction or the extent of strong-coupling corrections to the superconducting state. Here, we give a heuristic explanation of the symmetry classification of the superconducting order parameter, based on weak-coupling BCS theory. A gap matrix related to the condensate wave function is defined by the expression

$$\Delta_{\mathbf{k},\alpha\beta}=\sum_{\mathbf{k}'} V^{\alpha\beta;\gamma\delta}(\mathbf{k},\mathbf{k}')\langle\psi_\gamma(\mathbf{k})\psi_\delta(\mathbf{k}')\rangle, \qquad (28)$$

where $\langle\psi_\gamma(\mathbf{k})\psi_\delta(\mathbf{k}')\rangle$ is the Fourier transform of the condensate wave function and $V^{\alpha\beta;\gamma\delta}(\mathbf{k},\mathbf{k}')$ is the generally spin-dependent pairing interaction. The gap equation separates by symmetry representation, and there is a transition temperature T_c^i for the ith representation. Generally only one representation will occur at the physical T_c, although more than one may be present because of the occurrence of "accidental degeneracies." For order parameters of lower symmetry, the nonlinear gap equation can couple order parameters from different representations so that other representations may be induced below T_c. This has been discussed for ^{3}He by Leggett (1975) and reviewed in more detail along with the symmetry classification by Sigrist and Ueda (1991). A group-theoretical analysis for strong spin-orbit coupling is given by Volovik and Gor'kov (1985) and Blount (1985), and the weak spin-orbit coupling case is discussed by Ozaki *et al.* (1985). A GL theory of the superconducting state can be constructed once the symmetry of the order parameter is known.

As we have noted, at sufficiently low temperatures it is generally accepted that the heavy-fermion systems behave like Landau Fermi liquids. Many authors have used this as justification to proceed with a BCS description of the superconducting state (Sigrist and Ueda, 1991; Lee *et al.*, 1986). The connection between the condensate wave function and the quasiparticle dispersion relation is dependent on the theoretical description of the superconducting state. In BCS theory for a singlet superconductor, the quasiparticle energy is related to the gap function $\Delta(\mathbf{k})$ through

$$E_{\mathbf{k}}=\sqrt{\epsilon_{\mathbf{k}}^2+|\Delta(\mathbf{k})|^2}. \qquad (29)$$

The gap function of an unconventional superconductor may vanish for points or lines on the Fermi surface, which can be determined from the symmetry classification. Such an analysis shows (Blount, 1985) that for strong spin-orbit coupling, odd-parity states have no nodal lines. The thermodynamic and transport data described above suggest that the gap function of the heavy-fermion superconductors vanishes on points or lines, giving rise to power-law (rather than thermally activated) behavior at low temperatures. Detailed calculations of these properties for various unconventional superconducting states show a strong dependence of the "power law" on impurity scattering (see Sigrist and Ueda, 1991), making an unambiguous identification of the superconducting state impossible.

Other experiments have been proposed to probe the symmetry of the order parameter. A GL-theory analysis of upper critical fields by Gor'kov and by Burlachkov (see Gor'kov, 1987) showed that the reduced symmetry of an unconventional order parameter can lead to unusual upper-critical-field anisotropies. For example, the upper critical field in the basal plane of a tetragonal crystal might appear in contour like a four-leaf clover. Similar anisotropies would be apparent in H_{c1}.

The order parameter describing an unconventional superconductor often has more degrees of freedom than its conventional counterpart, and there often exist degenerate superconducting states. Some tests for unconventional superconductivity rest on the consequences of lifting a degeneracy between different superconducting states. Joynt and Rice (1985) showed that the condensation to an unconventional superconducting phase described by an order parameter with lower symmetry than the crystal lattice would be accompanied by a lattice distortion. This effect can be "inverted" by applying a uniaxial stress that induces a splitting of the superconducting transition. The transition to the unconventional superconducting state may break time-reversal symmetry, for example, resulting in a weak magnetic moment, which may explain the small magnetic moment observed below the lower-temperature transition in $U_{1-x}Th_xBe_{13}$. Tokuyasu *et al.* (1990) showed that broken time-reversal symmetry can also result in an unusual anisotropy of H_{c1}. Reversing the direction of the field applied along a high-symmetry direction in an unconventional superconductor with broken time-reversal symmetry creates a vortex state that is inequivalent to that for the original field direction, resulting in a different value for H_{c1}. For this effect to occur, it is crucial that one time-reversal symmetry-breaking state cannot be continuously deformed into the other as is the case in a crystal of uniaxial symmetry. Other tests are reviewed in Gor'kov (1987) and Sigrist and Ueda (1991).

As a superconductor is cooled through the phase transition, different states may nucleate in different areas of the sample and domain walls form. Generally, the presence of domains obscures the simple tests described above. For example, the anisotropy of the upper critical field can be obscured by randomly oriented superconducting domains.

Perhaps the most compelling evidence for unconventional superconductivity is the intriguing *H-T* phase diagram of UPt_3 (see Fig. 7) and the thorium-substitution phase diagram of $U_{1-x}Th_xBe_{13}$ (see Fig. 6). The explanation of these phase diagrams is controversial; however, we will discuss the most developed ideas in the area to illustrate some additional tests for unconventional superconductivity.

A promising model for UPt_3 assumes that the order parameter η has two complex components as allowed by the hexagonal symmetry of the crystal together with the assumption of strong spin-orbit coupling (Tokuyasu *et al.*, 1990). Numerical solutions of the Ginzburg-Landau equations (Tokuyasu *et al.*, 1990; Tokuyasu and Sauls, 1990) for vortices along the *c* axis in the time-reversal symmetry-breaking homogeneous phases $\eta^{\pm} \sim (1, \pm i)$ suggest an explanation for the line separating phases I and II in Fig. 7. For a range of parameters entering the GL free energy, Tokuyasu showed that the low-field solution of the GL equations is a triangular lattice of vortices each axially symmetric, threaded by two quanta of magnetic flux, and having a finite superfluid density in the core. At a higher field ($\sim 0.3 H_{c2}$), this lattice becomes unstable and abruptly transforms into a distorted lattice of single–flux-quantum vortices. A phase line like that shown separating phases II and III in Fig. 7 occurs as a result of the coupling of the order parameter to a symmetry-breaking field that lifts the twofold degeneracy of the pairing interaction (see for example, Hess *et al.*, 1989; Garg, 1992). In zero field, the phase transition is split into two: a transition from the normal state to a superconducting state described by a single complex component, e.g., $\eta \sim (1,0)$, and a lower-temperature transition from the superconducting phase to another superconducting phase that approaches η^+ or η^- with decreasing temperature. A natural candidate for the symmetry-breaking field is the weak antiferromagnetic order in the basal plane that has recently been correlated with the splitting of T_c (Hayden *et al.*, 1992). The additional phase lines in the mixed state may not be true phase lines but may rather mark regions of rapid crossover (Garg, 1992).

Attempts to understand the *x-T* phase diagram of $U_{1-x}Th_xBe_{13}$ assume that superconducting states belonging to two different representations are involved. A simple model with coupled *s*- and *d*-wave order parameters was considered by Kumar and Wölfle (1987). In their picture, pure UBe_{13} is a *d*-wave superconductor in the vicinity of the phase transition. As the temperature is lowered, *s*-wave character mixes in smoothly without introducing a second phase transition. Since a gap of lower symmetry is generally more sensitive to impurities, the effect of doping is to reduce the *d*-wave transition temperature dramatically so that above the critical concentration, the high-temperature transition is to an *s*-wave state. At lower temperatures a transition to a state described by a *d*-wave order parameter occurs. Sigrist and Rice (1989) took into account the cubic symmetry of the crystal and supposed that the pairing interaction leads to order parameters for two or more representations having nearly the same transition temperature. They explored the simple possibilities for various representations and concluded that the most promising phase diagram has an order parameter belonging to the Γ_1 (or Γ_5)

(one- or three-dimensional, respectively) representation for $x<x_c$, while for $x>x_c$ and $T>T_{c2}$ (see Fig. 6) the Γ_5 (or Γ_1) representation appears. For $T<T_{c2}$ the order parameter breaks time-reversal symmetry and belongs to a mixture of the two representations.

3. SUMMARY

The heavy-fermion materials are characterized by *f* electrons that exhibit localized behavior at high temperatures and itinerant behavior at low temperatures. The transformation from one regime to another suggests the existence of a characteristic energy scale. The entropy associated with the high-temperature magnetic moments is retained down to very low temperatures and appears in a specific heat that goes linearly with temperature. The slope of the specific heat at low temperature is anomalously large and suggests a narrow band of electrons characterized by an enormous effective mass. This state appears to be well described by Fermi-liquid theory, but it is unclear how such a state is formed from a lattice of weakly interacting magnetic moments. Taken as a dense lattice of local moments, the single-impurity Anderson model seems to be useful in discussing the high-temperature properties of these materials. Approximate methods applied to a model containing a dense lattice of Anderson impurities appear to yield the essential physics required to understand the heavy-fermion phenomena.

Many of these materials display unusual ordered ground states at low temperatures. Particularly interesting is the superconducting state that can apparently coexist with weak antiferromagnetic order. The unusual nature of the superconductivity suggests an order parameter of lower symmetry than that of the crystal lattice and a pairing interaction of electronic origin. The magnetic state is characterized by small magnetic moments associated with the *f*-atom sites and a simple magnetic structure. Although the magnitude of the magnetic moments is intimately connected with the removal of residual entropy, it is utterly unclear why so little entropy is associated with these transitions.

ACKNOWLEDGMENTS

We would like to thank J. D. Thompson for helpful conversations. We are also indebted to A. Y. Liu for useful suggestions and to J. W. Serene for a critical reading of the manuscript. Work at Los Alamos performed under the auspices of the U.S. Department of Energy.

GLOSSARY

BCS Theory of Superconductivity: Microscopic weak-coupling mean-field theory of superconductivity developed by Bardeen, Cooper, and Schrieffer in which electrons of opposite spin and momenta are paired by a weak attractive interaction.

Effective Mass: A parameter introduced as a renormalization of the electronic mass that takes into account the effect of the crystalline environment on the electronic energy spectrum. It includes the effect of interactions with other electrons and with the periodic potential of the atomic lattice.

Fermi Liquid: A macroscopic system of strongly interacting Fermi particles that can be described for energies and temperatures small compared to the degeneracy temperature as a gas of Fermi excitations (quasiparticles) with an effective mass different from that of a free constituent particle.

Hartree-Fock Approximation: An approximate treatment of the interactions between particles, obtained by replacing the effect of the other particles with a self-consistently chosen potential.

Hybridization: A quantum-mechanical admixture of atomic single-particle states, generally of differing symmetry.

Kondo Problem: The problem of describing a local magnetic impurity in a simple metallic environment.

Local-Density Approximation: An approximation made within the framework of density-functional theory for calculating electronic structure, in which the term representing the effects of electronic interactions is approximated by a quantity that depends only on the local electron density.

Mixed-Valence Materials: Materials containing elements of the lanthanide series, notably cerium, samarium, europium, thulium, and ytterbium, which show properties characteristic of a strong admixture of two or more *f* configurations in the ground state.

Unconventional Superconductivity: A superconducting state with an order parameter that breaks not only gauge symmetry (because the pair wave function is complex), but also some other symmetry of the crystal point group. In a conventional superconductor, only gauge symmetry is broken.

INTRODUCTION

Many technical advances in vacuum technology and several vapor deposition techniques [see CVD (CHEMICAL VAPOR DEPOSITION)] over the past two decades have now made possible the sequential monolayer-by-monolayer deposition of more than one material (elements, alloys, or compounds). Exploitation of this capability for the synthesis of nearly flawless semiconductor superlattices has been highly successful, as discussed in the article HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR.

Early work on artifically layered metals was reported nearly sixty years ago by DuMond and Youtz (1935). Their goal was to mimic the periodic structure of atoms in natural crystals, but with the longer repeat distances necessary to diffract x rays of wavelength λ longer than ≈ 10 Å. This goal of making artificial crystals for soft–x-ray optics has motivated a series of workers up to the present. However, it was discovered very early that interdiffusion greatly degraded most of the multilayered structures produced. This led to a parallel series of studies, whereby many workers used these materials for the study of physics of diffusion.

During the decade starting in the late 1960s tremendous progress was made in the growth of high-quality semiconductor heterostructures, and so by the late 1970s interest in such compositionally modulated materials expanded to include metals. Advances in thin-film deposition technology over the past two decades also motivated renewed interest in attempting to prepare "artificial" multilayered metals that might exhibit different physical properties than found in materials that are naturally occurring. Actually, as in many fields of science, it is not possible to identify a single development that was the "start" of this field. As shown in Fig. 1, "recent" research on metallic multilayers and superlattices dates back to at least the early 1970s. It should be pointed out that the two curves in Fig. 1 included different types of data. For example, the upper curve includes all materials grown by molecular-beam epitaxy (MBE), not just heterostructures and superlattices. However, it is interesting to note how closely the fields have paralleled each other in growth. The exponential growth in research on MBE-

grown semiconductors is in large part due to the practical devices arising from this research. Since various applications of metallic superlattices have started to appear over the past few years, this should stimulate additional research in this field, and should mean a strong future for both basic and applied research on metallic superlattices. A few examples of applications of metallic multilayers discussed in this article are optics for soft x rays, magneto-optic data recording, and magnetoresistive magnetic field sensors.

1. PREPARATION TECHNIQUES

1.1 Introduction

Metallic multilayers and superlattices were first made by evaporation, followed by use of sputtering techniques, and then molecular-beam epitaxy (*q.v.*). Since evaporation and MBE techniques share some features with each other, distinction between them in this article is made depending upon whether pressures are in the 10^{-10} Torr or below range, as well as whether *in situ* analysis techniques are available, such as reflected high- and low-energy electron diffraction (RHEED and LEED), Auger spectroscopy, etc. Simple evaporation is no longer used very much for preparing the types and quality of samples needed for research in the field of metallic superlattices, although such samples can exhibit very useful properties. With appropriate controls, sputtering remains a valuable deposition technique (Falco, 1984).

1.2 Sputtering

A schematic diagram of a sputtering system used for the preparation of metallic superlattices is shown in Fig. 2. The base pressure of most such systems in current use by researchers in this field range from $<1\times10^{-7}$ to $<1\times10^{-9}$ Torr. Such deposition systems are capable of depositing many metals with purity equivalent to the starting target material. Argon is most commonly used as the sputtering gas, with pressures typically $\approx(1–5)\times10^{-3}$ Torr. Sputtering rates are only weakly pressure dependent in this pressure range, so that using gas flow controllers to hold pressure constant to $\pm0.5\%$ is adequate to reduce pressure-induced sputtering-rate variations to a negligible level.

One technique to produce multilayers is to hold a substrate stationary above two or more sputtering guns, and use solenoid-actuated shutters above each gun to expose the substrate alternately to the flux of particles from the guns. Another technique is to attach the substrate to a rotating platform, and use a motor to rotate the substrate alternately above each sputtering gun at controlled angular rotation rates. Variations in layer thickness due to rotation rate or to timing errors can easily be made negligible.

There are two sources of variation in superlattice layer thickness that occur for sputtered samples. The first is the variation during a deposition due to fluctuations or drift in the sputtering rate. Feedback control of the sputtering power supplies is capable of regulating the sputtering rates (typically 20–100 Å/s) to $\pm0.1\%$. This is the dominant source of layer-thickness error in sputtering these materials. The second error is caused by the spatial variation in the sputtering rates at the substrate because of sputtering targets that are not infinite in size. This latter problem also occurs for growth of multilayers in an MBE system. Because of the finite size of any sputtering target, absolute uniformity of layer thicknesses to arbitrary accuracy over the entire substrate is impossible to achieve unless a complex rotating holder is used for moving the substrates during deposition. In practice, variations in layer thickness of less than 1% over substrates several cm in size are easily obtainable.

A significant advantage of sputtering for the growth of metallic superlattices is that most sputtering systems are designed to allow rapid interchanging of targets. Because of this, high-quality sputtered superlattices of a wide variety of materials have been grown. A few of the metallic superlattices fabricated by sputtering and studied in detail are Nb/Cu, Nb/Al, Mo/Ta, Mo/Si, W/Si, Fe/Mo, Fe/W, Fe/Tb, Fe/Pd, Co/Cu, Co/Pd, and Co/Ti.

Although sputtering has many advantages, especially for refractory metals, there remain various limitations of the technique. For example, since *in situ* structural analysis techniques such as RHEED and LEED cannot be used during growth by sputtering, it is difficult to determine the optimum deposition conditions. Also, although the base pressure of a sputtering system can be very good (e.g., $<10^{-8}$ Torr), this is still much too high for studies of surface properties of freshly prepared films to take place before contamination occurs. Another problem is the high thermal conductivity of the Ar sputtering gas, which conducts a substantial amount of heat away from the substrate and therefore makes achieving substrate temperatures higher than a few hundred °C much more difficult than is possible in a high vacuum (where temperatures greater than 1000 °C are routinely obtainable). Such high substrate temperatures are expected to be required for many refractory materials, to give the material sufficient surface mobility to achieve epitaxy. Limitations such as these make it uncertain at present whether the sputtering process intrinsically is incapable of producing metallic superlattices with the highest purity, sharpest interfaces, largest crystalllites, etc.

1.3 Evaporation

Evaporation in vacuum systems with base pressures $>10^{-8}$ Torr using thermally heated ovens or electron-beam guns has been used successfully to prepare a number of metallic multilayers with interesting physical properties. Just as for sputtering, in the evaporation technique the materials are alternately deposited on the substrate by means of shutters, or by rotating the substrates successively over the evaporation sources. In principle, producing metallic multilayer samples with individual layer thicknesses down to the monolayer range is possible. Although base pressures $>10^{-8}$ Torr are used, the concentration of impurities incorporated in the metallic films due to the relatively high pressure, which would be unacceptable for a semiconductor heterostructure, still has allowed a number of interesting phenomena to be observed.

1.4 Molecular-Beam Epitaxy

Because of their high cost, fewer than 20 MBE machines are currently (1992) in use worldwide for the fabrication of metallic superlattices. However, just as for semiconductor heterostructures, MBE is a powerful growth technique, and should find increasing use as further applications of these materials are identified.

Most MBE machines currently in use were designed around the requirements for producing GaAs heterostructures. However, the requirements for a "metals MBE" machine are considerably different than for a GaAs machine. For example, many metals of interest have high melting points, so that reasonable vapor pressures cannot be achieved using standard thermal evaporation sources. Consequently, electron-beam evaporation guns must be incorporated in the growth chamber. Also, the substrate temperature necessary to achieve epitaxy of GaAs is relatively low, so that higher-temperature platforms for the epitaxy of refractory metals are needed. These and other requirements are very similar to those needed for the epitaxy of silicon. Consequently, MBE systems based on Si MBE machines are very appropriate for producing metallic superlattices. A schematic diagram of such a machine is shown in Fig. 3.

The MBE machine shown in Fig. 3 has a number of capabilities specifically for epitaxial growth of refractory materials. For example, the 3-in.-diam substrate is held by a manipulator inside the growth chamber, which operates at temperatures up to 1100 °C (with ±5 °C uniformity) while rotating at 120 rpm (resulting in less than ±0.5% spatial variation of thickness). The substrate may be electrically biased at up to 4 kV if desired.

Whereas vacuums in the 10^{-8}-Torr range are relatively easy to obtain, to reach the $<10^{-10}$ Torr range requires "baking" the entire MBE system at 200 °C for several days after each time it is opened to the room environment. This bakeout is necessary to drive off the water vapor that adsorbs on the vacuum chamber walls. Because of the necessity of this bakeout procedure, it is impractical to open the machine very often to change the materials being deposited. This is a disadvantage compared with sputtering. Consequently, MBE machines typically incorporate a number of deposition sources so that different materials may be grown without having to open the system to change targets. An MBE machine with eight separate deposition sources gives the capability to grow up to 28 different two-at-a-time combinations of materials without having to break vacuum to change sources. Such machines may be opened to the room environment only once or twice each year, to replenish or change materials and to conduct routine maintenance.

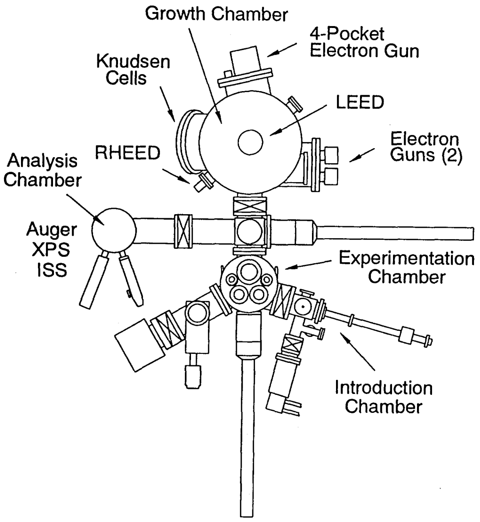

FIG. 3. Schematic diagram of an MBE system for producing metallic superlattices.

The ability to analyze the structural perfection and chemical composition of the multilayers as they are grown, or before they are removed from the ultrahigh-vacuum (UHV) environment, is essential. Because of the UHV environment of MBE machines, a number of *in situ* analytical instruments for studying the multilayers can be attached to the machine. Monitoring the physical structure normally is done during growth by RHEED, and quantitative determination of surface structure is obtained immediately after growth by LEED.

Immediately after growth, information on chemical composition can be obtained by analytical techniques such as ion-mill Auger-electron spectroscopy, x-ray photoelectron spectroscopy (XPS), and ion-scattering spectroscopy (ISS). Increasingly, UHV versions of scanning tunneling microscopes (STM) are being added to MBE machines to study the surface structure of the materials before and after deposition.

2. STRUCTURAL PERFECTION OF METALLIC MULTILAYERS AND SUPERLATTICES

As discussed earlier in this article, layered metallic structures with periodicities close to atomic dimensions have been produced from a variety of metals using sputtering, evaporation, and MBE techniques. Metallic multilayers can be produced with highly regular periodicity along the direction of the layering, but with varying degrees of perfection within the layers and at their interfaces. Multilayers and superlattices made with metallic components have degrees of structural perfection that can be roughly classified in three categories as described below, and as illustrated in Fig. 4. It is important to note that for many studies it is not necessary to have the highly ideal single-crystal epitaxy that can be achieved in certain semiconductor heterostructures. For this reason, preparation and study of metallic materials that have degrees of structural perfection falling into each class of this scheme is worthwhile.

A simple "multilayer" metallic film [Fig. 4(a)] is one that may have sharp interfaces between its two components and with very well controlled average spacing between layers. However, the structure within either or both layers may be polycrystalline or amorphous, rather than crystalline. Because of this, microscopic structural information is not transferred from a given layer to subsequent layers. Even though these "multilayers" have a relatively low degree of structural coherence, they exhibit interesting physical phenomena (e.g., superconductivity) and have properties that make them useful in applications such as x-ray optics and magneto-optic data storage. An example of such a multilayer is Mo/Si, which is of interest for x-ray optics in the wavelength range > 124 Å. Each Mo/Si interface in these multilayers reflects a small amount of incoming x rays. By proper choice and control of the multilayer period, these reflected x rays will coherently add to provide significant total reflectivity for this wavelength region (Haelbich *et al.*, 1979).

"Composition-modulated alloys" (CMAs) [Fig. 4(b)] have a single lattice for the entire sample, but one whose sites are occupied in a periodic manner by alternating elements. Typically, two metals that have the same crystal structure and nearly the same lattice constant are miscible in each other, and thus prone to interdiffusion when in contact. Thus, the boundaries between the two components in a CMA generally are diffuse and, depending upon how thin the layers are, the amplitude of composition modulation in the center of a layer can be in the range from 0 to 100%. Thus, even though a crystalline superlattice exists in these materials, the diffuse interfaces

FIG. 4. Diagram illustrating the degrees of structural coherence obtained in metallic multilayers and superlattices.

obstruct the possibility of observing many phenomena of interest. An example of a CMA is Cu/Ni, which exhibits interesting magnetic behavior.

Ideally, "metallic superlattices" [Fig. 4(c)] have atomically sharp boundaries between the two components as in the case of multilayered films. In addition, however, long-range structural coherence is maintained across many layers of the material, as in the case of a CMA. Thus, one has the roughly natural lattice spacing within the layer modulated by the imposed superlattice layer periodicity. Examples of superlattices include Mo/Ta (grown by sputtering) and Co/Pd (grown by MBE).

3. APPLICATIONS OF METALLIC MULTILAYERS AND SUPERLATTICES

3.1 Introduction

The growth of high-quality crystalline metallic superlattice samples is considerably more difficult than for semiconductors. This is largely due to the absence of the strong directional covalent bonding exhibited by semiconductors. However, in many ways metals are more forgiving of impurities and structural imperfections than are semiconductors. While defect- and impurity-free, highly perfect layering is required for semiconductors in order to exhibit phenomena of interest, metals can tolerate greater levels of structural and chemical imperfections and still have useful properties.

Although the nature of the metal atomic bond makes it more difficult to grow a "perfect" metal crystal than a perfect semiconductor crystal, fortunately it is usually less important. However, there are some physical properties that are sensitive to the fabrication of metallic superlattices. One example is superconductivity in superlattices containing Nb as one of the constituents. Oxygen reduces the superconducting transition temperature of niobium. Since Nb is a strong oxygen getter, ultrahigh vacuum or high deposition rates are required for the oxygen contamination to be negligible in the film. Another example where the physical properties can be affected by the fabrication conditions is in metal/nonmetal samples produced by sputtering, where Ar gas inclusion in the multilayers can be a problem. However, for the remainder of this article, we will assume the metallic multilayers have been fabricated in such a way that contamination or defects have negligible effect on the physical properties being studied.

3.2 Magnetism

An extremely interesting development in the field of magnetism in the past few years is the ability to study, and to some extent to control, the magnetic properties of surfaces and interfaces. Along with the experimental advances described earlier in techniques to prepare magnetic structures reliably by methods such as sputtering and MBE have been equally dramatic theoretical advances in the ability to calculate properties of realistic physical systems. Concurrently, remarkably sophisticated characterization techniques have been developed (e.g., spin-polarized scanning electron microscopy, intense synchrotron sources, pulsed sources for magnetic neutron scattering, scanning tunneling microscopy, etc.), which are now allowing sample characterization at a level not previously possible.

Single-crystal epitaxy of Fe on freshly cleaved NaCl substrates was reported over 50 years ago (Buck, 1936). As mentioned earlier, improvements in vacuum techniques continually broadened the range of materials being successfully studied until by the early 1980s developments in MBE deposition technology for semiconductor research began to be exploited for epitaxial growth of magnetic materials on a variety of substrates. Such work has lead to remarkable advances in this field over the past decade.

Techniques were developed to grow Fe epitaxially on (100)- and (110)-oriented GaAs substrates (Waldrop, 1979; Prinz and Krebs, 1980). More recently, epitaxial Fe films also have been grown on other semiconductor substrates, including ZnSe and lattice-matched $In_{0.2}Ga_{0.8}As$, using techniques based on commerical MBE equipment (Prinz *et al.*, 1986; Farrow *et al.*, 1988; Lottis *et al.*, 1988).

Although research on epitaxial magnetic films has been under way for over 50 years, particularly rapid experimental and theoretical advances have started to appear during the past decade. For example, MBE techniques have been successfully applied to produce magnetic metallic superlattices with high structural quality and very interesting physical properties. Single-crystal, epitaxial superlattices of Gd/Y (Kwo *et al.*, 1985) and Dy/Y (Salamon *et al.*, 1986) have been grown by MBE techniques, and their magnetic properties studied by neutron diffraction. Using these materials it was discovered that the coupling of successive magnetic layers could extend through 150 Å of the Y spacers. For example, epitaxial Dy/Y superlattices maintain the helical magnetic order of the Dy over several bilayers. The chirality of this helical order is conserved while the magnetic coherence length decreases with increasing Y thickness. For Gd/Y, either parallel or antiparallel alignment of the ferromagnetic Gd layers is found depending on the intervening Y-layer thickness. This oscillatory behavior is suggestive of the Ruderman–Kittel–Kasuya–Yoshida (RKKY) interaction. The RKKY model is a long-range indirect exchange interaction, mediated via the conduction electrons, that changes sign from ferromagnetic to antiferromagnetic with increasing radial distance between two interacting spins.

Another example of a discovery made with these materials is the "giant magnetoresistance" first observed in MBE-grown Fe/Cr multilayers (Baibich *et al.*, 1988), and now found in a number of other metallic multilayer systems (Parkin *et al.*, 1990; Mosca *et al.*, 1991). For many of these multilayers, the resistance can decrease by almost a factor of 2 in going from zero field to saturation. This effect has been attributed (Levy *et al.*, 1990) to spin-dependent transmission of the conduction electrons between the magnetic layers through the nonmagnetic layers. These superlattices order antiferromagnetically, so that alternate magnetic layers have opposite magnetization directions in zero field. The resistivity is at a maximum in this ordered state since the electrons interact with magnetic moments of both orientations and therefore have a higher probability of scattering. When a magnetic field of sufficient strength to align the magnetic moments is applied, one spin orientation is eliminated and the probability of scattering of the electrons is therefore reduced, concurrently reducing the resistivity. The large change in resistance observed with a small change in applied magnetic field makes these materials of great interest as possible magnetic field sensors and magnetic recording heads. This effect has attracted considerable attention, both because of the interesting physical properties, and also because of possible technological applications. Subsequent to the discovery of the giant magnetoresistance, it was found that in a wide variety of magnetic/nonmagnetic multilayer systems the exchange coupling between the magnetic layers oscillates between ferromagnetic and antiferromagnetic coupling (Parkin *et al.*, 1990, 1991). These oscillations depend strongly on the structure of the multilayers, and in most materials have an oscillation period of about 10 Å. That is, for each additional ≈10 Å thickness of the intervening nonmagnetic spacer layer, the coupling goes through one complete oscillation from ferromagnetic to antiferromagnetic. This is a fascinating discovery, and explanations of this phenomenon are leading to advances in the fundamental understanding of magnetic coupling (Wang *et al.*, 1990).

An important point to note is that to date there have been no electronic properties observed in metallic multilayers that are a consequence of collective superlattice behavior of the materials. This is to be contrasted to the case of semiconductor superlattices, where such collective effects have been observed for quite some time. As opposed to electronic effects, collective magnetic excitations due to the superlattice structure have been reported and understood theoretically. Thus, future work to study new combinations of metals using both MBE and sputtering may lead to observation of such electronic superlattice effects and additional collective magnetic effects.

3.3 Two-Dimensional Magnetic Behavior

The ability to deposit a perfect atomic monolayer of magnetic material has been a significant goal of surface magnetism research for some time, because of the possibility of testing theoretical predictions of intrinsic two-dimensional behavior in such an ideal film. Such predictions include the disappearance of long-range magnetic order above zero temperature, and substantially reduced values of the magnetization critical exponent as T_c is approached from below. In some ways, multilayers with very thin magnetic layers can be thought of as a collection of individual two-dimensional magnetic films. Thus, studying these predicted effects with multilayers rather than single films becomes possible. In addition, multilayers have several advantages over single, isolated films. The periodic multilayer structure lends itself to characterization by conventional x-ray diffraction techniques, whereas there is far too little material in a single monolayer to be studied with this technique. For the same reason, magnetic measurements on multilayers can be far easier than on single films.

An example of the usefulness of multilayers for the study of lower-dimensional magnetic behavior is the observation of finite-size effects in the spin-glass CuMn layered with Si (Kenning *et al.*, 1987). The Si layers in these multilayers decouple the thin CuMn layers both electrically and magnetically. In this way the spin-glass behavior of each CuMn layer can be amplified to within the sensitivity of conventional measurement techniques.

3.4 Magneto-optics (Perpendicular Magnetization)

The preferred axis of magnetization of a bulk magnetic material is determined by a competition between the anisotropies from the crystal structure, so called magnetocrystalline, and those from its shape, often referred to as magnetostatic demagnetization. The shape anisotropy in a thin film is very strong, and so it normally dominates and tends to constrain the magnetization to be in the plane of the film. However, a few ultrathin magnetic overlayers and superlattices with very thin magnetic layers were discovered that had their magnetization easy axis perpendicular to the plane of the film (Gradmann, 1974; Carcia *et al.*, 1985). Thus, other magnetic anisotropies are present in these materials that are sufficiently strong to overcome the shape and magnetocrystalline anisotropies. Studies of the thickness dependence of this effect have shown that it is the magnetic/nonmagnetic interface in these materials that gives rise to this anisotropy.

Although the precise mechanism is not yet well understood, calculations including the spin-orbit interaction of the magnetic anisotropy for the limiting case of unsupported ferromagnetic monolayers (Gay and Richter, 1986) and for certain overlayer-substrate combinations (Freeman and Wu, 1991) have been made. Magnetizations have been calculated that can be either perpendicular [e.g., Fe (001) on (001) Ag, Au, or Pd] or in-plane (free-standing Ni or Fe). However, it is not yet clear whether additional effects need to be included in the calculations of this effect.

Multilayers with perpendicular anisotropy are of considerable interest because of their potential technological usefulness as high-density data-storage media. It is possible to magnetize the film in domains of diameter $<0.5\ \mu m$ in order to store information, and then to read the stored data using the polar magneto-optical Kerr effect. This readout technique takes advantage of the fact that the plane of polarization of reflected polarized light is rotated by an amount approximately proportional to the perpendicular magnetization of the film. Using a focused laser beam to heat a small region of the film to above its Curie point while in the presence of a magnetic field, up or down magnetic domains can be written or erased. These domains can subsequently be read by a laser operated at a much lower power.

The advantages of magneto-optical data storage include a very high density, erasability, and no physical contact of the optical head with the medium. At present, the density appears to be limited by the spot size of the focused laser. However, fundamental limits on the size of the magnetic domains may exist due to their stability.

Co/Pt multilayers show considerable promise as future recording media due to their strong perpendicular anisotropy, resistance to oxidation and corrosion, and enhanced Kerr rotation at shorter wavelengths than those used in present media. The latter property is necessary for higher density storage, since the wavelength of the recording light ultimately limits the storage density by diffraction effects.

3.5 Superconductivity

Superconducting metallic multilayers are of interest for several reasons: as a route for synthesizing new superconducting materials; as a way to study certain superconducting properties in a controllable way; and for possible relevance for applications.

The characteristic length scale at which layering with a normal metal begins to modify significantly the physical properties of a superconductor is the temperature-dependent coherence length $\xi(T)$. In low-transition-temperature T_c superconducting materials, ≈ 50 Å $< \xi(0) < \approx 5000$ Å. Therefore, if superconductivity were the only physical phenomenon of interest in multilayer materials, layer perfection and interface sharpness on an atomic scale would not be required to observe interesting effects. For simplicity of discussion, we will implicitly assume in this section's discussion that the properties are independent of changes in the microscopic structure of the material, and result solely from the influence of spatial periodicity of the multilayer directly on the superconducting order parameter.

Layering can affect superconductivity in several ways. For this discussion, assume layering of a superconductor of thickness d_{super} with a nonsuperconductor of thickness d_{nonsuper}. For $\Lambda \gg \xi(0)$, where $\Lambda = d_{\text{super}} + d_{\text{nonsuper}}$, the individual layers retain their bulk properties. However, even in this regime of "thick" layers, spatially coherent planar defects are introduced by the layering, which can alter flux pinning by the superconductor. For $\Lambda \cong \xi(0)$ the superconducting order parameter becomes directly affected, and the superconductor will become anisotropic, resulting in the properties being altered significantly from those of the bulk. As a few examples, the critical magnetic fields (Banerjee *et al.*, 1983), critical currents (Raffy and Guyon, 1981), and even dimensionality (Ruggiero *et al.*, 1982) become dramatically different when $\Lambda \cong \xi(0)$. Through the proximity effect the microscopic properties of the superconducting layers also are affected (Banerjee *et al.*, 1982).

For multilayers with $\Lambda < \xi(0)$ superconductivity can be modified at the microscopic level. Control of the quality of the interfaces becomes crucial at this length scale. This is especially true if magnetism, with its much shorter length scale, is involved. Any size-effect modifications in the normal-state properties of the nonsuperconducting layers also may affect the microscopic properties of the superconductor. Examples of such effects are changes in the phonon structure due to interface phonons, density of states, cooperative electronic effects between layers, and epitaxial stress-induced changes. Epitaxial growth or stabilization of crystal phases with altered superconducting properties is also possible.

To date, effects of layering on the superconducting transition temperature, critical fields, and order parameter have received attention. These studies have shown that superconducting multilayer materials exhibit a variety of interesting, and possibly useful, effects.

Changes in the microscopic properties (e.g., Fermi-surface parameters or phonon spectrum) of a superconductor introduced by the multilayer structure also should affect its superconducting properties. Such changes could be caused by strains associated with epitaxial growth or through a high density of localized electron or phonon states at interfaces. However, because of the short Fermi wavelengths typical of metals, work to date has not resulted in materials of sufficient perfection for the additional periodicity to alter the electronic band structure enough to affect superconductivity.

One other possibility should be mentioned: that of stabilization of metastable metallurgical phases through the energy associated with the interfaces in these multilayers. This should lead to new superconducting properties in appropriate materials.

3.6 X-Ray Optics

In recent years there has been accelerating interest in optical elements that operate at soft-x-ray wavelengths ($\lambda_{\text{x ray}} = 10$–$500$ Å). In large part this interest has been driven by improvements in the technology for fabricating these elements, thus making possible several important applications, including soft-x-ray microscopy, astronomy, and microlithography. The development of x-ray microscopes that operate in the water window ($\lambda_{\text{x ray}} = 23$–$44$ Å) would be particularly significant since such microscopes might be able to image living cells in aqueous solutions. Another application, x-ray astronomy, already has provided information about high-energy processes in the universe. Finally, use of x-rays for microlithography should increase resolution over that possible with ultraviolet light, while having a higher throughput than with electron-beam writing techniques.

Conventional optical designs involving lenses and single-surface mirrors operating at near-normal incidence cease to function at soft–x-ray wavelengths. The reasons are twofold: the indexes of refraction of all materials approach unity, and absorption is high. These problems have resulted in solutions that fall into three categories of optics for soft x rays. Optical components are now available based on grazing-incidence reflection, Fresnel zone plates, and reflection from multilayer thin films. Each of these has certain applications for which it is particularly suited, although this article only will be concerned with the last.

There are several properties that make multilayer x-ray mirrors well suited for many applications. First, they are inherently wavelength selective. Also, they can be designed to function at a variety of angles including normal incidence. Finally, they can be made relatively large or small without serious limitations. Since the performance of multilayer mirrors is directly related to their structural perfection, understanding and controlling the structure and interface quality is central to improving their performance.

Just as for the other applications discussed in this article, a multilayer x-ray mirror is produced by alternately depositing layers of two materials. The thicknesses of the layers are designed so that the reflections from each interface add in phase to yield a high overall reflectivity. The best results are obtained by selecting two materials for which there is a large difference in the optical constants of the pair. The properties that make multilayer optics desirable for certain applications, high peak reflectivity and narrow wavelength pass band, result when large numbers of interfaces contribute to the overall reflectance of the mirror. Unfortunately, the nonzero absorption present in all materials at soft–x-ray wavelengths limits the depth of penetration of the x rays, and therefore limits the number of interfaces that contribute significantly to the overall reflectivity. Because of absorption, the reflectivity eventually saturates at some values less than 1, independent of how many total layers are added to the multilayer.

Because of structural imperfections and impurities, in real multilayers the peak reflectivity is always less than for an ideal structure. One type of imperfection is the variation in the layer thicknesses in the direction perpendicular to the layers due to variations in the deposition rates. Other imperfections include interfacial roughness, interdiffusion, and reaction between the materials that make up the multilayer. These imperfections become increasingly important as the layer thicknesses are decreased, because interfacial roughness or interdiffusion that blurs the interface over a thickness greater than $\approx 10\%$ of the wavelength of the light will significantly reduce the performance of the mirror. Since the average layer thickness in a multilayer mirror designed to reflect 40 Å light is no more than ten atomic spacings, it is critical to grow multilayer materials with well-controlled interfaces.

4. DISCUSSION

As illustrated by Fig. 1, there has been considerable work on metallic multilayers over the past several decades. In spite of this, the range of systems that can be successfully grown as metallic multilayers and superlattices is far from completely explored. Also, of those metal/metal systems that have been prepared to date, systematic investigation of the physical properties of many is lacking. Substrate temperature, deposition rate, base vacuum pressure, sputtering pressure, substrate material, etc., all can greatly influence the growth and quality of these materials. Consequently, given this wide range of parameter space, it is not surprising that only a few of the metal/metal systems have been thus far investigated with the required level of detail.

Various multilayers consisting of metal/amorphous semiconductors have been made successfully. Examples include Nb/Ge and W/Si. To date, layered structures of metals and crystalline semiconductors have not yet been produced, at least with the degree of purity required. However, such materials could be of technological importance. In this case, MBE machines specifically designed to incorporate electron-beam evaporation sources and high-temperature substrate platforms are likely to lead to important results.

Much of the work to date on metal/insulator multilayers has been motivated by the interest in efficient optical coatings for soft x rays. Evaporation and sputtering have been used to produce a number of these multilayer materials to date. As mentioned earlier, work has centered on alternating materials that have high electron density with those that have low electron density. Such combinations result in multilayers with the largest differences in optical constants, and hence the highest reflectivity at each interface. Amorphous C, B, and Si are commonly the low-electron-density materials of choice. Use of MBE techniques should result in crystalline Si layers with improved optical properties in certain regions of the soft-x-ray spectrum. An additional benefit of crystalline materials is that they should have the ability to withstand heat loads without recrystallization.

To date, no metallic multilayer or superlattice has been produced that has the same degree of perfection as their semiconductor counterparts. Factors thought to be important in determining structural quality of these materials are the binary phase diagram of the components being layered (including their mutual solubility and whether or not intermetallic compounds can form), interdiffusion rates, the existence of lattice matching and compatible crystalline symmetries, the availability of suitable substrates to promote epitaxial growth, ability to control substrate temperature over a wide range, and precise control over the deposition conditions. Understanding which factors allow the formation of high-quality metallic superlattices is an important research question at the present time.

5. FUTURE OF METALLIC SUPERLATTICES

From some of the applications discussed in this article, the future of metallic superlattices appears to be bright. Highly controllable layered structures in a wide variety of metallic systems have been achieved, and semiconductorlike crystalline properties have been approached in a few special cases. The precise structural nature of the interfaces (lattice matching, epitaxial strains, chemical composition, electronic structure, etc.) in metallic systems has not yet been entirely determined, and is the subject of active work in this field. The use of MBE growth techniques, which is becoming more frequent, with *in situ* determination of interfacial structure and physical properties, should lead to improvements in these materials.

Finally, it is important to emphasize that many of the interesting and important effects possible in metallic multilayers do not necessarily require the high degree of crystal perfection and chemical purity needed by their semiconductor counterparts.

6. SUMMARY

The study of the physical properties of metallic multilayers and superlattices has contributed to a number of significant experimental and theoretical developments over the past decade. Control of these structures at the atomic level recently has become possible, and now offers the opportunity to test a number of physical predictions using extremely well controlled materials.

GLOSSARY

Auger Electron Spectroscopy: Analysis of emitted "Auger" electrons at elemental-specific energies for chemical surface characterization.

Epitaxy: Continuation across the interface into deposited thin films of the underlying substrate crystalline order.

Low-Energy Electron Diffraction (LEED): Surface-sensitive structural probe using normal-incidence electrons with energies on the order of 100 eV.

Molecular-Beam Epitaxy (MBE): Ultrahigh-vacuum evaporation technique using single-crystal substrates and *in situ* surface structure characterization to obtain ordered crystalline thin-film growth.

Reflection High-Energy Electron Diffraction (RHEED): Surface-sensitive structural probe using grazing-incidence electrons with energies on the order of 10 keV.

Scanning Tunneling Microscope (STM): Microscopic surface topographic probe using electron tunneling current collected or emitted by a scanning tip.

Sputtering: Deposition technique that uses bombardment of a target material with an energetic gas plasma to create a vapor flux.

Superlattice: Multilayered structure in which crystalline coherence is maintained across several bilayers.

Ultrahigh Vacuum (UHV): Pressure regime $P \leqslant 10^{-9}$ Torr.

X-Ray Optics: The redirection and focussing of x rays through the interaction with reflecting and /or refracting media.

X-Ray Photoelectron Spectroscopy (XPS): Use of the photoelectric effect to determine the identities, concentrations, and bonding of atoms on a surface. This technique is sometimes called ESCA, for electron spectroscopy for chemical analysis.

INTRODUCTION

In 1970, Esaki and Tsu predicted the emergence of a new field of semiconductor physics if the characteristic length scale of the semiconductor materials could be shrunk below the de Broglie wavelength of the charge carriers (Esaki and Tsu, 1970). Under such circumstances, the wavelike nature of the carriers would fully manifest itself and, for instance, a complete reorganization of the carriers' energy spectra due to the quantum size effects would show up. Even though quantum effects are already present in regular bulk semiconductors, most of the electronic phenomena are accurately described by semiclassical approaches. The implementation of a semiconductor physics based on quantum size effects poses a severe challenge to the fabrication techniques. One has to grow multilayers whose thicknesses can be controlled on the nanometer scale over macroscopic areas. The experimental challenges have been overcome, and one is now able to create artificial semiconductor materials or devices in which the characteristic length scale of the active regions is only a few nanometers. In this article, we briefly discuss some examples of the basic physical phenomena which are brought about by the quantum size effects.

1. FABRICATION TECHNIQUES

Crystalline semiconductors are the basic materials for modern microelectronics and optoelectronics. Conventional epitaxy techniques (e.g., liquid-phase epitaxy or the modified Bridgman method) are growth processes which occur near thermal equilibrium between the solid and liquid phases. They work extremely well for bulk single crystals (e.g., Si, GaAs). To be useful these single crystals have to be processed later on (oxidization, metallization, ...). This generally results in boundaries between the bulk of the active semiconductor component and its surroundings that are atomically ill defined, i.e., that occur on length scales considerably larger than the bulk lattice constant (0.566 nm in GaAs). In the case of heterostructures, i.e., the solids that result from the growth of two or

more semiconductors on top of each other, and that are needed, e.g., for field-effect transistors ($Si+SiO_2$) or double heterostructure lasers (e.g., $GaAs+Ga_{1-x}Al_xAs$), the interface boundaries may extend along the growth axis over several tens of nanometers and are not easily controlled. This may become troublesome when the dimensions of the components are shrunk (e.g., in order to increase their density).

In modern growth techniques such as molecular-beam epitaxy (*q.v.*) or metal-organic chemical vapor deposition [see CVD (CHEMICAL VAPOR DEPOSITION)] the growth rates are very slow (a few μm per hour), and the growth occurs far from thermal equilibrium. Schematically, in MBE the sample is grown atomic plane by atomic plane by sending fluxes of elemental elements (e.g., Ga or As) in a high-vacuum chamber onto a heated substrate ($T \sim 600\,°C$). Because of the slow growth rates the atomic species that have impinged on the surface have time to diffuse on this surface to find their equilibrium positions before the growth of another layer takes place. This layer-by-layer growth allows us (in ideal situations) to make atomically sharp interfaces. For instance, in a GaAs–AlAs multilayer grown along the [001] axis, the boundary between a GaAs and a AlAs layer is an As atomic plane. The nearest-neighbor planes are a Ga plane and an Al plane, respectively. Since, ideally, one can repeat the growth sequence at will, one can obtain with a nearly perfect accuracy any layer (or sequence of layers) of prescribed thicknesses. Thus, depending on the potential use, one can grow single *A*-*B* heterojunctions or double *BAB* heterojunctions, also termed quantum wells, or superlattices that consist of an infinite, periodic, sequence of *A* and *B* layers with thicknesses L_A and L_B, respectively. In the latter case, it is clear that one has superimposed an artificial periodicity d ($d=L_A+L_B$), which is controllable at will, from a few tenths to several tens of a nanometer, on the material hosts' periodicities. Notice that the layer thicknesses can be measured *in situ* (by the so-called reflection high-energy electron-diffraction oscillations technique). Further information on the growth and *in situ* characterization of semiconductor heterostructures can be found in the articles CVD (CHEMICAL VAPOR DEPOSITION) and MOLECULAR-BEAM EPITAXY.

From now on we shall assume that the growths are always ideal, i.e., that the interfaces are perfect. This is not always so, but in the case of lattice-matched host materials, like the pairs $GaAs$–$Ga_{1-x}Al_xAs$ or InP–$Ga_{0.47}In_{0.53}As$, this is a reasonable assumption. Note that the assumption of a perfect bidimensional growth (i.e., atomic plane after atomic plane) implies that in the layer plane the atomic arrangement and therefore the atomic potentials are identical to those found in the bulk, i.e., translational invariance is maintained in the layer plane.

2. BULK BAND STRUCTURE

The electronic structure of each host bulk material is characterized by a band structure, i.e., the set of allowed energy ranges where an electron can propagate in the crystal. These allowed energy bands are separated by forbidden gaps. This alternation of allowed and forbidden bands results from the translational invariance of a crystalline potential along the three basis vectors of the underlying Bravais lattice. The crystal periodicity gives rise to the Bloch theorem: the one-electron eigenstates are plane waves $\exp(i\mathbf{k}\cdot\mathbf{r})$ modulated by functions $u_{n\mathbf{k}}(\mathbf{r})$ that are periodic with the periodicity of the Bravais lattice. The corresponding eigenenergies $\epsilon_{n\mathbf{k}}$ are characterized by a discrete quantum number n, the band index, and a quasicontinuous real wave vector $\mathbf{k}$, which can be restricted to the first Brillouin zone of the reciprocal lattice. All these properties result from the translational invariance, and one should expect their modification when dealing with carrier propagation along the growth axis of the heterostructure where the translational invariance is broken. The new feature is the possible existence of allowed eigenstates in the forbidden gaps of one of the hosts: Having broken the periodicity of the crystalline potential there is no reason to discard the evanescent waves whose energies fall in the forbidden gaps. An evanescent wave is characterized by a wave vector $\mathbf{k}$ that is not purely real. In bulk materials, these evanescent waves have to be rejected as possible solutions (they are not normalizable in an infinite sample), but they have to be taken into account in heterostructures where the layers either have a finite thickness or are at best semi-infinite.

The band structure of many III–V materials in the vicinity of the fundamental band gap [i.e., the one separating the topmost occupied band (termed the valence band) and the lowest lying unoccupied band (termed the conduction band)] is relatively simple. The top of the valence band takes place at $k=0$ (Γ point) and is fourfold degenerate, while the bottom of the conduction band is either the zone center for heavy elements of the third column of the periodic chart (e.g., Ga) or along the [001] axis for the light elements (e.g., Al). Away from the zone center the valence band is split into a heavy-hole and a light-hole band. The Γ band gap shrinks with increasing heaviness of the cation (see, e.g., the sequence AlAs, GaAs, InAs where the Γ band gap decreases from 3.4 to 1.52 eV and then to 0.41 eV).

In a bulk semiconductor the carrier response to a perturbation $V_{\text{ext}}(\mathbf{r})$ that is slowly varying on the scale of the unit cell can be analyzed in a relatively simple way. For energy states that are close to an extremum $\mathbf{k}_0$ of the dispersion relations, $\epsilon_n(\mathbf{k})$ can be approximated by $\epsilon_n(\mathbf{k}_0)+\hbar^2/2\Sigma_{\alpha\beta}(k_\alpha-k_{0\alpha})(1/m_{\alpha\beta})(k_\beta-k_{0\beta})$ where $\alpha,\beta=x,y,z$. $m_{\alpha\beta}$ is the effective mass tensor, which is symmetrical: $m_{\alpha\beta}=m_{\beta\alpha}$. For the Γ conduction band $m_{\alpha\beta}=m_c\delta_{\alpha\beta}$. The carrier wave functions can be approximated by the product of their $\mathbf{k}_0$ Bloch functions modulated by a slowly varying envelope $F_n(\mathbf{r})$. The latter is the solution of a Schrödinger equation where the kinetic energy is $\frac{1}{2}\Sigma p_\alpha(1/m_{\alpha\beta})p_\beta$ instead of the usual $p^2/2m_0$ and where the potential energy consists only of the perturbing term. Thus, the relevant information on the carrier dynamics is embodied in the envelope function, and one may identify the motion of the electron in the perturbed crystal with that of a fictitious particle whose mass is not the bare (scalar) electron mass m_0 but the tensor $m_{\alpha\beta}$ and which moves under the effect of the perturbing potential. The crystalline potential disappears explicitly from the equations of motion, but its existence is manifested in the replacement of m_0 by $m_{\alpha\beta}$. For the filled valence band where $m_{\alpha\beta}<0$, the electronic motion is more easily analyzed if one defines as the fictitious particle the hole, which carries the positive effective mass $-m_{\alpha\beta}$ but a positive charge $+e$. Notice finally that an external disturbance that is attractive for electrons is repulsive for holes.

3. BAND OFFSET

One of the central questions of heterostructure electronic states is the magnitude and sign of the energy difference between the position of the tops of the valence bands of the various host materials. If the interfaces are sharp, we expect that plotting the position dependence of the valence-band edge ϵ_v versus the position z along the growth axis will result in a staircase variation: In the A layer, $\epsilon_v(z)$ coincides with $\epsilon_v^{(A)}$, the value in the bulk A layer, while in the B layer $\epsilon_v(z)$ coincides with $\epsilon_v^{(B)}$, the value in the bulk B layer. This is indeed what has been found for isovalent lattice-matched heterojunctions like GaAs/AlAs, but after considerable computations. The reason is that whatever the interface perfection there is no reason why the chemical bonds in the A and B materials should be exactly identical. This implies the formation of interface dipoles (e.g., at the Ga–As–Al interface the chemical bond Al–As is slightly more polar than the Ga–As one). These interface dipoles modify the electron energy levels and, in particular, shift the band edges. Until recently (van de Walle and Martin, 1987; Bylander and Kleinman, 1987), the unsolved question was to ascertain whether the dipole formation is a fairly localized perturbation around the interface or whether it extends over several lattice planes. For lattice-matched isovalent heterojunctions it appears that the assumption of piecewise constant band edges is nearly true, as shown in Fig. 1, where the valence charge distribution and electrostatic potential energy averaged over a unit cell are plotted versus the position along the [001] axis in a superlattice $(GaAs)_3(AlAs)_3$ (Baroni *et al.*, 1989). On the other hand, plots of the actual charge distributions (i.e., the nonaveraged ones) hardly give evidence of an interface.

Figure 1 helps to visualize a very important concept in heterostructure physics, which is that of wells and barriers. In the GaAs–AlAs superlattice of Fig. 1, the topmost valence electrons experience (in the GaAs layers) a higher cell-averaged electrostatic potential en-

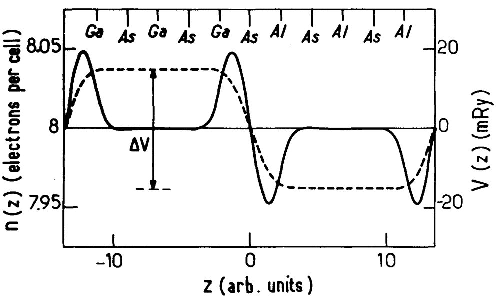

FIG. 1. Calculated cell-averaged charge distribution (solid line) and potential energy (dashed line) of dipolar origin along the [001] axis in a $(GaAs)_3$ $(AlAs)_3$ superlattice (adapted from Baroni *et al.*, 1989).

ergy $V(z)$ of dipolar origin than in the AlAs layers. Also $V(z)$ becomes constant a few tenths of a nanometer away from the interface. The energy difference ΔV of $V(z)$ on the two sides of the interface is not the only electrostatic contribution. One should take into account that GaAs and AlAs are different materials and add a term $\Delta E_v = E_v(\mathrm{GaAs}) - E_v(\mathrm{AlAs})$, which is the energy difference between the two bulk valence-band edges as measured from the (arbitrary) average of the electrostatic potential energy (see Fig. 2 for the general case of an A/B heterojunction). In the GaAs/AlAs pair, ΔV and ΔE_v have the same sign. The sum $\Delta E_v + \Delta V$ is the valence-band offset between GaAs and AlAs. In the GaAs/AlAs pair, it is such that a topmost valence electron with the lowest possible kinetic energy far from the GaAs–AlAs interface has a higher energy in the GaAs layer than in the AlAs one. Equivalently, the lower lying valence holes have a lower energy in the GaAs layer. For the holes, the GaAs layers act as potential wells and the AlAs layers act as potential barriers by analogy with the well known one-dimensional quantum mechanical problems. It is worth noticing that this analogy is facilitated because of our use of cell averages of the actual electrostatic potentials and of our neglect of interface details. We may therefore anticipate that this notion of wells and barriers will be fully operative for layers which are thick compared to the size of hosts' unit cells. In this case and for quantities that vary slowly on that scale, e.g., the cell-averaged carrier density, we shall be justified in neglecting the interface dipole effects. In the GaAs–AlAs case and more generally for lattice-matched isovalent multiple heterojunctions it appears that this is not a very stringent requirement. Indeed, models based on the assumption of flat band edges, i.e., piecewise constant functions $\epsilon_v(z)$ with abrupt changes at (infinitely thin) interfaces equal to $\Delta E_v + \Delta V$, work well, down to layer thicknesses of 1–1.5 nm.

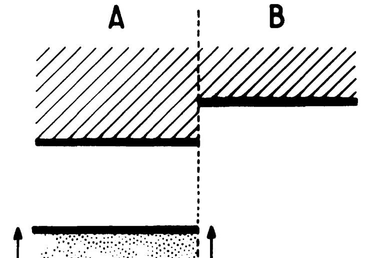

FIG. 2. Relationship between the valence-band offset (VBO), ΔV, and ΔE_v in a A/B heterojunction. In the specific case of the GaAs/AlAs pair, GaAs (AlAs) plays the part of the A (B) material (adapted from Baroni *et al.*, 1989).

3.1 Type I and Type II Structures

Once the valence-band offset is known, any other offset (lower conduction band, satellite conduction bands, and so on) is fixed since the various bulk band gaps are usually known very accurately. In particular, depending on the relative magnitudes of the valence-band offset and band-gap energy difference, one may classify the heterostructures into two main categories (see Fig. 3). In type I structures, e.g., $Ga_{0.47}In_{0.53}As/InP$, one kind of layer ($Ga_{0.47}In_{0.53}As$) confines both the electrons (in the lower conduction band) and the holes (in the upper valence band). In type II structures, e.g., $InP/Al_{0.48}In_{0.52}As$, the electrons and holes are spatially separated: The lowest-lying electron states are found in InP while the lowest-lying hole levels are in the $Al_{0.48}In_{0.52}As$ layers. The type I structures are

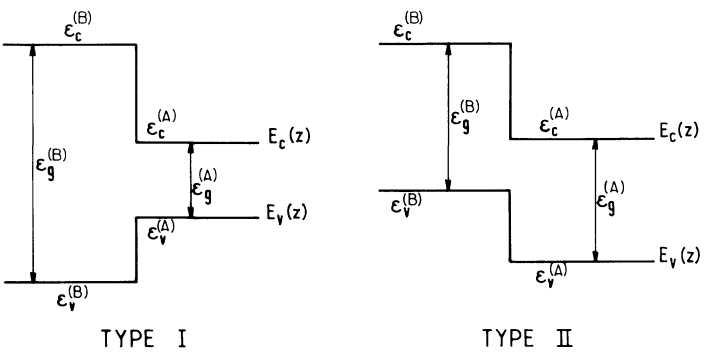

FIG. 3. Conduction- and valence-band edge profiles in type I and type II heterostructures.

by far the more numerous (and up to now the more useful). The pairs GaAs/$Ga_{1-x}Al_xAs$ ($x \leqslant 0.4$), $Ga_{0.47}In_{0.53}As$/InP, $Ga_{0.47}In_{0.52}As$/$Al_{0.48}In_{0.52}As$, and CdTe/$Cd_{1-x}Mn_xTe$ (at zero magnetic field) form type I structures. GaAs/AlAs, InP/$Al_{0.48}In_{0.52}As$, and InAs/GaSb belong to the type II family.

3.2 Length Scales and Envelope Functions

It appears from the previous discussions that different scales of lengths enter into heterostructure physics. The first relevant length is the natural host periodicity (a few tenths of a nanometer). The second is the range of interface dipole effects (also a few tenths of a nanometer in lattice-matched isovalent heterostructures). The third is the layer thicknesses. They can be varied from a few nanometers to hundreds of nanometers. Finally, because of the imperfections, or coupling to the phonons, that necessarily exist in heterostructures, the coherence lengths of the various quantum states come into play. We shall be mainly concerned with the heterostructures where the layer thicknesses are much larger than the natural host periodicity and the range of the interface dipole effects. This will enable us to assume infinitely sharp interfaces separating unperturbed layers (piecewise constant band edges). On the other hand, the layer thicknesses will be assumed smaller than the coherence length to make sure that if, for instance, we look upon the carrier motion in a quantum well, the quantum mechanical effects we expect from the interference of the carrier waves incident and reflected from the boundaries will be observable. Defects, if any, induce transitions between the eigenstates of perfect heterostructures. In particular, they lead to the existence of a finite electrical conductivity (Stern, 1993).

It happens that in many heterostructures the band offsets are a fraction of an eV, i.e., considerably smaller than the bulk conduction and valence bandwidths. This means that in the energy segment separating the same edge (i.e., with the same symmetry), both hosts' dispersion relations are relatively well described by a parabolic expansion. In addition the edge Bloch functions are known to be very similar among the III–V family. Then, for isovalent lattice-matched heterojunctions, it may be shown that the following simple "particle in a box" model works well (Altarelli, 1986). This model amounts to stating that in the heterostructure the complete wave function can be written as the product of the hosts' bulk Bloch function at the extremum by a slowly varying envelope function $F_l(\mathbf{r})$ solution of the effective Schrödinger equation:

$$\left\{-\frac{\hbar^2}{2}\sum_{\alpha\beta}\nabla_\alpha\frac{1}{m_{\alpha\beta}(z)}\nabla_\beta+\epsilon_l(z)+V_{\text{ext}}(\mathbf{r})\right\}F_l(\mathbf{r}) \\ =\epsilon F_l(\mathbf{r}). \qquad (1)$$

Equation (1) was first established by Ben Daniel and Duke (1966). The effective-mass tensor $m_{\alpha\beta}(z)$ is position dependent and actually is piecewise constant: $m_{\alpha\beta}(z)$ equals $m_{\alpha\beta}^{(A)}$ in the A layer and $m_{\alpha\beta}^{(B)}$ in the B layer. $\epsilon_l(z)$ is the position dependence of the energy extremum under consideration. It is also piecewise constant: $\epsilon_l(z)$ equals $\epsilon_l^{(A)}$ in the A layers and $\epsilon_l^{(B)}$ in the B layers. Finally, $V_{\text{ext}}(\mathbf{r})$ is any external perturbing potential, e.g., eFz if there is a constant electric field $\mathbf{F}$ applied along the growth axis of the heterostructure or $V_{\text{imp}}(\mathbf{r}-\mathbf{R}_i)$ if there is an impurity at $\mathbf{R}_i$.

4. APPLICATIONS TO SEMICONDUCTOR QUANTUM WELLS

4.1 Size Quantization and Confinement Energy

In quantum well structures, one realizes a basic quantum phenomenon: size quantization. The simpler quantum well, the rectangular one, corresponds to inserting a slab (thickness L) of an undoped well-acting material (A) between two semi-infinite undoped layers of barrier-acting materials (B). In Eq. (1), such a situation corresponds to $V_{\text{ext}}(\mathbf{r})=0$. Furthermore, let us for simplicity assume that the effective-mass tensor $m_{\alpha\beta}(z)$ is a scalar $m_c\delta_{\alpha\beta}$. The barrier height is the conduction band offset $\epsilon_c^{(B)}-\epsilon_c^{(A)}$.

We immediately notice that the in-plane variables (x,y) decouple from the z variable. Consequently, the envelope function $F(\mathbf{r})$ factorizes into a product of a z-dependent term $\chi(z)$ by an (x,y)-dependent one $\alpha(x,y)$. Since the potential energy is x,y independent, the in-plane motion is free and $\alpha(x,y)$ is the plane wave $S^{-1/2}\exp[i(k_x x+k_y y)]$, where S is the sample area and k_x,k_y the in-plane components of the carrier wave vector. A quasicontinuous parabolic dispersion $\hbar^2(k_x^2+k_y^2)/2m_c$ is associated with the in-plane free motion. This kinetic energy adds to each of the eigenvalues E_n (discrete or continuous) of the z-dependent problem. E_n is termed the edge of the nth two-dimensional sub-band describing the free in-plane motion, which occurs with increasing speed $\hbar k/m_c$ when $k[=(k_x^2+k_y^2)^{1/2}]$ increases.

Let us now discuss the solutions of the z-dependent problem. Analytical solutions exist. We refer the reader to Bastard (1988), where these solutions are given and discussed. For $\epsilon_c^{(A)}\leqslant\epsilon\leqslant\epsilon_c^{(B)}$ a classical particle would be bound in the A material and oscillate back and forth in the well at a constant velocity $[2(\epsilon-\epsilon_c^{(A)})/m_c]^{1/2}$. All energies would be allowed, i.e., one could find a possible classical motion for any ϵ. The quantum mechanical treatment brings two important new features. First, only discrete energies E_n are allowed (size quantization), and the lowest E_n, E_1, is always higher in energy than the bottom $\epsilon_c^{(A)}$ of the quantum well (confinement energy). Second, there is a finite penetration of the particle into the barrier (tunnel effect).

Trapping a quantum mechanical particle in a segment with length L means that the root mean square deviation of its position Δz ($\Delta z=[\langle z^2\rangle-\langle z\rangle^2]^{1/2}$) is of the order of L, where $\langle A\rangle$ denotes the quantum mechanical average of the operator A in a given eigenstate. For quantum particles, Δz and Δp_z cannot be simultaneously decreased to zero. As shown by Heisenberg the inequality $\Delta z\Delta p_z\geqslant\hbar/2$ holds. Knowing that $\Delta z\sim L$, we find $\Delta p_z\geqslant\hbar/2L$. Since in a bound state $\langle p_z\rangle$ vanishes we get $(1/2m_c)\langle p_z^2\rangle\geqslant\hbar^2/8m_cL^2$. Thus the carrier kinetic energy is never zero unless the quantum well is infinitely thick, which implies that the lowest eigenvalue E_1 is larger than $\epsilon_c^{(A)}$, the bottom of the well. This extra kinetic energy is often termed the confinement energy, for it arises from the squeezing of a quantum mechanical particle in a finite segment. We notice that it decreases (roughly) like L^{-2} with increasing L.

All the previous considerations apply as well to the valence band ($m_{\alpha\beta}=-m_v\delta_{\alpha\beta}$). In particular, the topmost valence eigenvalue is not $\epsilon_v^{(A)}$, the valence-band edge of the well-acting material, but is at lower energy ($-H_1+\epsilon_v^{(A)}\sim-\hbar^2/2m_vL^2$). Like the electrons, the holes display a confinement energy. Besides, the fourfold degeneracy of the bulk valence band edge is lifted. For a given L, the light holes have a larger confinement energy than the heavy holes. Therefore, the lowest-lying bound hole state is the heavy-hole state H_1 (in unstrained materials).

The confinement energy is very important with regard to the light-absorption (or -emission) edge of quantum wells versus the corresponding bulk ones. The absorption (emission) edge of a bulk semiconductor A is the lowest possible photon energy $\hbar\omega_g$ that can be absorbed (emitted) by the semiconductor. For a perfect material, at $T=0$ K, assuming that the band-to-band transition is optically allowed and neglecting the electron–hole interaction, one finds $\hbar\omega_g=\epsilon_c^{(A)}-\epsilon_v^{(A)}$. A quantum well of the same material clad between suitable barriers will display an absorption (emission) edge that is blue-shifted with respect to the bulk-A situation. This blue shift is equal to the sum of the confinement energies of the electron (E_1) and the hole (H_1). Therefore, it scales roughly like L^{-2} with the quantum well thickness. Thus it will be larger for the thinner well. In addition, by carefully selecting the thickness L, which is possible if the sample growth is well controlled, one may tailor the absorption or emission edges of the quantum well to a prescribed wavelength, a very desirable feature with regard to optoelectronics applications. We illustrate in Fig. 4 the effect of quantum well confinement energies in the case of $Ga_{0.47}In_{0.53}As$ where we show the L dependence of the shift E_1+H_1 of the absorption (emission) edge in the type I systems $Ga_{0.47}In_{0.53}As/InP$ and $Ga_{0.47}In_{0.53}As/Al_{0.48}In_{0.52}As$. In both cases $Ga_{0.47}In_{0.53}As$ is the well-acting material.

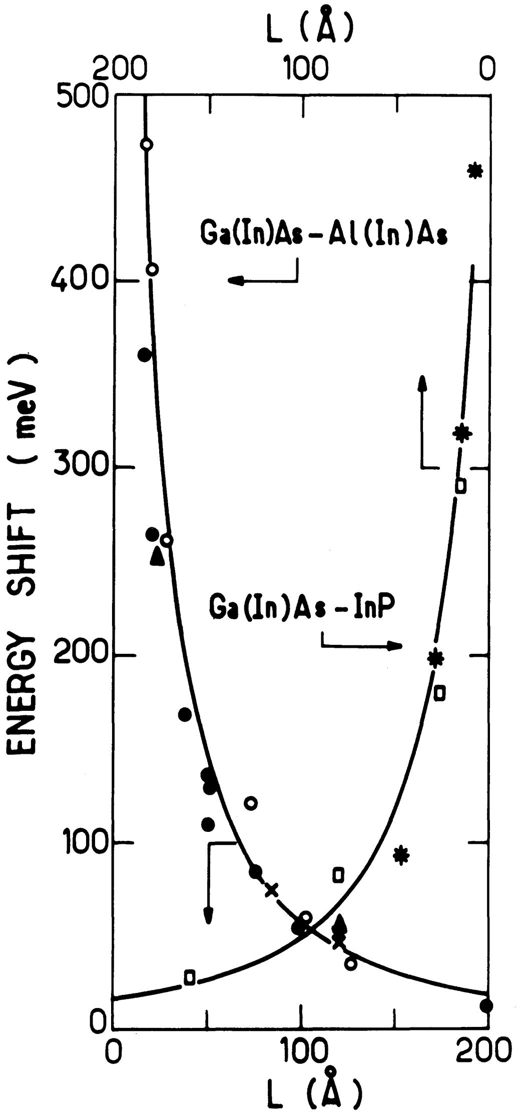

FIG. 4. The shifts of the absorption edge in $Ga_{0.47}In_{0.53}As/InP$ (right and upper scales) and $Ga_{0.47}In_{0.53}As/Al_{0.48}In_{0.52}As$ (left and lower scales) quantum wells, plotted versus the $Ga_{0.47}In_{0.53}As$ layer thickness. Solid lines: theory neglecting excitonic effects. Symbols: experimental data. From Bastard *et al.* (1991).

Why are the quantum mechanical allowed energies discrete for the bound states? This arises from the requirements of continuity that the solutions of a second-order differential equation must fulfill. In the effective Schrödinger equation for the z motion the potential-energy term and effective-mass tensor are piecewise constant functions. The integration of that equation around any point z leads to the continuity of $\chi(z)$ and $m_c^{-1}(z)\chi'(z)$. Notice that in the case of a constant $m_c(z)$, we recover the more familiar $\chi(z)$ and $\chi'(z)$ continuities. For a given energy ϵ, the solutions of Eq. (1) in each of the three layers can be written as a linear superposition of the free bulk solutions since in each layer both $m(z)$ and potential energy are constant. These solutions are evanescent waves in barriers, $\exp\{\pm z[2m_B/\hbar^2(\epsilon_c^{(B)}-\epsilon)]^{1/2}\}$, since $\epsilon \leqslant \epsilon_c^{(B)}$, and propagating waves in the well, $\exp\{\pm iz[2m_A/\hbar^2(\epsilon-\epsilon_c^{(A)})]^{1/2}\}$. We have therefore six unknown multiplicative coefficients. Two should be set equal to zero, for they multiply the exponentially growing solutions when $z\rightarrow\infty$ or $z\rightarrow-\infty$, which are not normalizable. We are therefore left with four multiplicative unknowns. Since four constraints have to be fulfilled (two per interface), we end up with a homogeneous system which can be satisfied only for discrete energies E_n.

It is easy to prove algebraically that a rectangular well admits at least one bound state and that in the large-L limit $E_n-\epsilon_c^{(A)}$ equals $\hbar^2n^2\pi^2/2m_cL^2$. The number of bound states that a rectangular well may accommodate is $1+\mathrm{Int}\{2m_cL^2(\epsilon_c^{(B)}-\epsilon_c^{(A)})/\hbar^2\pi^2\}^{1/2}$, where $\mathrm{Int}(x)$ denotes the integer part of x, i.e., this number is proportional to L in the large-L limit.

For eigenstates above the top of the well $(\epsilon>\epsilon_c^{(B)})$ the bulk solutions are propagating waves in the three layers. Thus no solution has to be discarded for normalizability reasons. Thus, we end up with four constraints versus six unknowns and each energy ϵ is allowed. The allowed spectrum is therefore continuous for energies above the top of the well. Each energy eigenvalue is twice degenerate corresponding to an electron either coming from $-\infty$, being partially reflected and transmitted

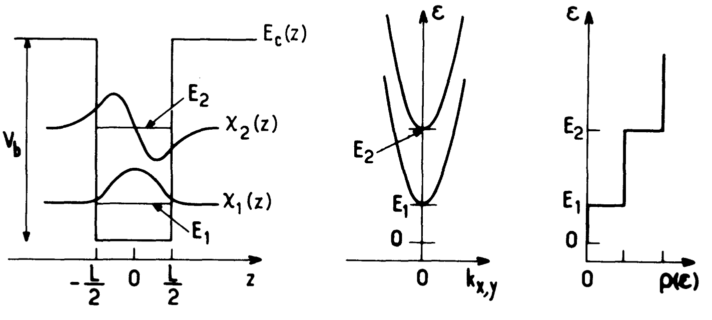

FIG. 5. A summary of quantum well electronic properties. Left panel: band-edge profile, and envelope functions $\chi_1(z)$, $\chi_2(z)$ of the first (E_1) and second (E_2) lowest lying bound states in the well. Middle panel: in-plane dispersion relations of the E_1 and E_2 sub-bands. Right panel: density of states. Adapted from Bastard (1988).

at the interfaces, and finally escaping to $+\infty$, or undergoing the reverse motion (Bohm, 1951).

The classical particle could never enter the barrier region if $\epsilon<\epsilon_c^{(B)}$, otherwise its kinetic energy would have to be negative, which is meaningless in classical mechanics. The quantum states do show a finite penetration of the carrier envelope functions in the barriers on account of the wavelike nature of the quantum particle. In this barrier, the waves are evanescent, i.e., they decay exponentially far away from the interfaces, but they are not zero. This is the well-known quantum mechanical tunnel effect. A summary of the quantum well properties is shown in Fig. 5.

An important quantity for evaluating a number of statistical properties is the density of states $\rho(\epsilon)$. By definition $\rho(\epsilon)d\epsilon$ is the number of allowed quantum states between ϵ and $\epsilon+d\epsilon$. One may easily work out that for a given sub-band n, $\rho_n(\epsilon)$ is a constant if $\epsilon>E_n$. Thus, for the sub-bands attached to the N bound states of the well one has

$$\rho(\epsilon)=\sum_{n=1}^{N}\rho_n(\epsilon)=\frac{m_cS}{\pi\hbar^2}\sum_{n}Y(\epsilon-E_n), \qquad (2)$$

where $Y(x)$ is the Heaviside (step) function and where a twofold spin degeneracy has been accounted for. The staircase aspect is noticeable and means that compared to a bulk situation where $\rho_{\text{bulk}}(\epsilon)\sim(\epsilon-\epsilon_c^{(A)})^{1/2}$ one expects sharper physical features when a sub-band becomes populated.

If we investigate the spatial localization of the ground bound state versus L, as, e.g., measured by the quantity Δz, we find that Δz first decreases with decreasing L (roughly like L) to reach a minimum value. Then, on further shrinking of the well, Δz increases again (see Fig. 6). The thickness L_{min} where Δz is minimum decreases with increasing barrier height, and for quantum wells clad between infinitely high barriers Δz is exactly proportional to L. The reason why Δz reaches a minimum versus L before increasing (to infinity) when L goes to zero is a consequence of the finite penetration in the barrier. We have seen that the confinement energy $E_1-\epsilon_c^{(A)}$ increases with decreasing L, roughly like L^{-2}. We expect on physical grounds that the ground state of a quantum well with vanishing thickness will coincide with the conduction-band edge of the barrier-acting material since in the

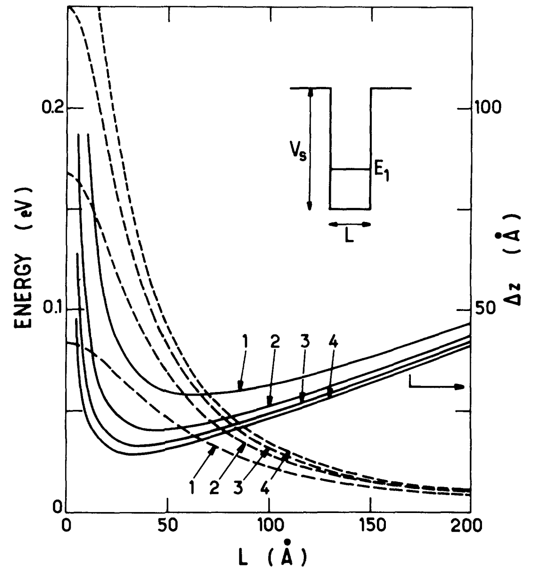

FIG. 6. Calculated confinement energy (left scale, dashed lines) of the E_1 state and root mean square deviation Δz (right scale, solid lines) of the electron position in the E_1 state versus the well thickness L. The curves labeled 1,2,3,4 respectively correspond to well depths V_b of 83.5, 167.1, 250.6, and 334.2 meV. The carrier effective mass is 0.07 m_0. From Bastard *et al.* (1991).

limit $L \to 0$ we deal with a bulk-like barrier. One can in fact show algebraically that $E_1(L)$ is a monotonically decreasing function of L from $\epsilon_c^{(B)}$ at $L=0$ to $\epsilon_c^{(A)}$ at infinite L. When L is large the barrier penetration is negligible and Δz, the uncertainty in the carrier position, is of the order of the quantum well thickness L (in fact $\Delta z \sim L$ at large L). In the narrow-well limit, instead, the spreading of the wave function takes place mostly in the barrier; with decreasing L [i.e., increasing $E_1(L)$] the evanescent wave vector in the barrier, which varies like $(\epsilon_c^{(B)} - E_1)^{1/2}$, decreases and the carrier wave function samples the barrier more and more, i.e., the particle becomes delocalized again.

4.2 Exciton Effects in Quantum Well Absorption Spectra

We have seen that the absorption or emission edge of a quantum well is blue shifted with respect to the corresponding bulk quantity. We neglected the electron–hole interaction in establishing this feature. Actually, the line shape of a quantum-well absorption edge does not display the predicted staircase behavior. Rather, it shows strong peaks at lower energies than the predicted plateaus, which persist even at room temperature (Fig. 7). Peaks are also seen in bulk materials at cryogenic temperatures. They arise from excitonic effects. The exciton is in fact a manifestation of many-body effects in solids (see COLLECTIVE PHENOMENA IN SOLIDS; EXCITONS). Let us for simplicity use the approximate picture of an exciton as the bound state formed between an electron and a hole. In a bulk semiconductor like GaAs the binding energy of such a pair is considerably smaller than one Rydberg (13.6 eV), which is the ionization energy of the ground (1*S*) state of atomic hydrogen in vacuum. This decrease comes from the lighter electron-hole reduced mass ($\sim 0.07 m_0$ in GaAs) compared with the bare-electron mass m_0 and from the weakening of the Coulombic electron–hole attraction which takes place not in the vacuum but in a dielectric medium of high permittivity ϵ_r (~ 12.4). The exciton binding energy is only ~ 5 meV in bulk GaAs, and the corresponding effective Bohr radius a^* is ~ 10 nm instead of 0.053 nm for hydrogen in vacuum. Thus the weakly bound excitons are easily dissociated, either by imperfections or random electric fields or by thermal excitation (kT is ~ 25 meV at room temperature).

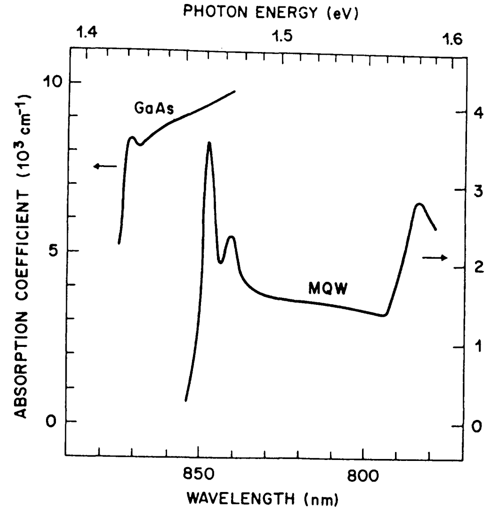

FIG. 7. Energy dependence of the room-temperature absorption coefficient in bulk GaAs and of a GaAs–Ga(Al)As multiple quantum well. From Chemla (1985).

Let us consider such an exciton in a quantum well. In the (ideal) purely bidimensional case, where the electron and hole would be constrained to move in the same plane, the exciton would be four times more bound than in three dimensions. The two-dimensional Bohr radius would be $\frac{1}{2}a^*$. This ideal situation is never achieved but we may anticipate that decreasing the well thickness will make the exciton quasibidimensional leading to an increase of its binding energy, if not by a factor of 4. The three-dimensional Coulombic potential $-e^2/4\pi\epsilon_0\epsilon_r r_{eh}$ mixes the free electron-hole pair eigenstates. The latter are labeled by a two-dimensional wave vector k of the reduced motion and by the sub-band indices n_e and n_h for the electron and hole, respectively (the in-plane wave vector K for the exciton center of mass is unaffected by the Coulombic term, which depends only on the relative electron-hole distance). We saw that by decreasing L we increase the sub-band separation. Thus by decreasing L the mixing between the ground sub-bands and the excited ones weakens, and if the sub-band spacing becomes larger than the bulk Rydberg this mixing becomes very weak. In this limit of strong quasibidimensionality the z motions of the electron and the hole become forced by the quantum-well potential, and what remains to be bound is the in-plane reduced motion of electron–hole pair.

This binding occurs not via the bulk Coulombic potential but by its average over the ground electron and hole probability densities along the growth axis. It is easy to show that this averaged Coulombic potential varies like ρ_{eh}^{-1} at large ρ_{eh}, the electron–hole distance in the layer plane. However, at small ρ_{eh} it varies more slowly than ρ_{eh}^{-1}, and more so when the sub-band separation decreases. Therefore, one does get an increase of the exciton binding energy when the quantum well thickness decreases, but it is less than that predicted by the purely bidimensional limit, as expected. Typical figures for the exciton binding energy and Bohr radius in GaAs quantum wells are 11 meV and 7 nm, respectively. This is apparently enough to produce very strong excitonic features in the absorption spectra of quantum wells, even at room temperature. Notice that the presence of strong absorption peaks with large oscillator strengths concentrated in a narrow energy range ($\leqslant$10 meV at room temperature) make the quantum well structures very attractive for optical nonlinear responses (Chemla, 1985).

4.3 Stark Effect in Quantum Wells

We saw that some tunability of the quantum-well band gap may be achieved through the well-thickness dependence of the electron and hole confinement energies. However, for a given quantum well, it is likely desirable (in view of optical applications) to control and tune its band gap by means of an external parameter. A convenient one is an electric field **F** is applied parallel to the growth axis. To produce such a field, either one evaporates a Schottky gate on the sample surface and biases it with respect to the doped substrate or one inserts (during the growth sequence) the quantum well in the intrinsic part of a *p-i-n* junction, which is reverse biased to achieved a large (several times 10^6 V/m) and homogeneous field.

The potential energy V_{ext} to be inserted in Eq. (1) is eFz_e $(-eFz_h)$, $e>0$, for an electron (a hole). Such potentials can be arbitrarily large and negative at large and negative z_e (positive z_h). This implies that the Schrödinger equation for the z motion admits no bound state. However, one feels that if the field is small enough, there should exist states that look more like quantum well bound states than do the other states of the continuum of allowed solutions. This feeling may be more quantitatively formulated if one uses the properties of the virtual (or metastable) bound states of the quantum well, i.e., states that, instead of being stationary, decay in time with a characteristic time constant τ_{ex}. The escape frequency τ_{ex}^{-1} is proportional to the transmission of the triangular barriers through which the electron or hole has to tunnel to escape to infinity (see Fig. 8). A long-lived virtual bound state is obtained if the barrier is very opaque. For the ground state E_1 of the electron in the tilted well (barrier height V_e) the criterion for low transparency is $eF \ll (V_e - E_1)^{3/2}(2m_c/\hbar^2)^{1/2}$. A similar criterion holds for holes with V_h, H_1, m_v replacing V_e, E_1, and m_c, respectively. Under usual circumstances

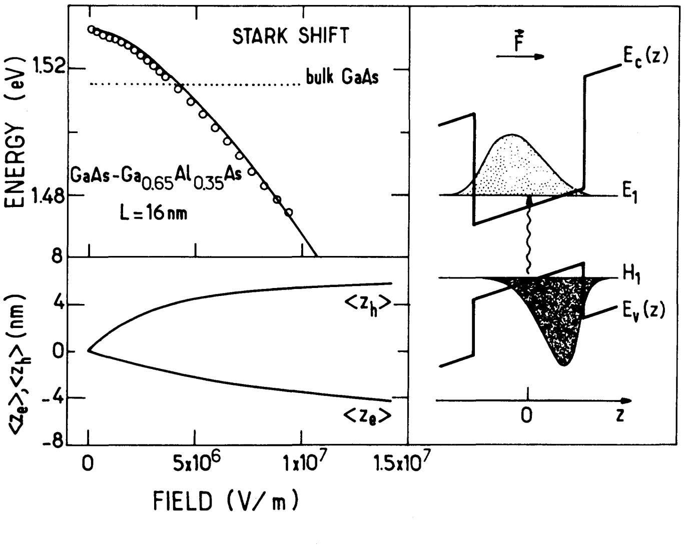

FIG. 8. Stark effect in quantum wells. Right panel: band-edge profile, and electron and hole envelope functions of the lowest lying quasistationary states (E_1 and H_1). Left panel, upper part: field dependence of the experimental (circles) and theoretical (solid line) lowest lying interband optical transition in a GaAs–Ga$_{0.65}$Al$_{0.35}$As quantum well (L $=16$ nm). Adapted from Vina *et al.* (1987). Left panel, lower part: calculated field dependence of the average positions of the electron ($\langle z_e \rangle$) and hole ($\langle z_h \rangle$) in the lowest lying electron (E_1) and hole (HH_1) state for the same well as in the upper panel.

($L\sim 15$ nm, $V_{e,h}\sim 0.2$ eV, $F\leqslant 6\times 10^6$ V/m) the criterion is very well fulfilled and the lifetime τ_{ex} is very long. For optical absorption experiments the finite lifetime effects, due to the field-induced ionization of the quantum well, are usually negligible.

The electric field not only induces the levels' metastability, it also shifts them, and this Stark effect is the useful feature for applications. At zero field the center of gravity of the electron and hole envelope probability densities is at the center of the quantum well by symmetry. If $F\neq 0$ the electron (hole) cloud will be shifted toward the left-hand side (right-hand side) interface of the well. In other words, the electric field induces for both particles an electric dipole, which, to the lowest order in F, is proportional to F. The induced dipole interacts with the field to give rise to energy shifts of either the electron or hole states that are quadratic in F (see Fig. 8). For the ground states, the induced dipoles are parallel to the field, and therefore, for both the electrons and holes, these quadratic Stark shifts are red shifts. In other words, the quantum-well band gap decreases with F. Using perturbation calculus, it is easy to show that the band-gap variation with F roughly scales like $F^2L^4(m_c+m_v)$ (Bastard *et al.*, 1983). This means that the quantum well thickness should not be too small, so as to allow sizable shifts. Representative figures are $L=16$ nm, $F=4\times 10^6$ V/m, leading to a Stark red shift of 16.2 meV in GaAs–$\text{Ga}_{0.7}\text{Al}_{0.3}\text{As}$.

The dipole formation has the disadvantage that it separates the electron and hole clouds, thereby weakening the exciton binding energy as well as the oscillator strength of optical transitions. Notice, however, that in the absence of quantum wells the electron and hole would be infinitely separated by the field. In quantum wells, instead, the exciton dissociation is inhibited by the presence of the quantum well barriers where the carriers accumulate in strong fields (but not so strong as to shorten significantly the carriers' lifetimes). Since L, roughly the maximum electron–hole separation, is comparable to the exciton Bohr radius, there remains enough of the exciton binding energy to ensure visible excitonic features in the room-temperature electroabsorption spectra of semiconductor quantum wells (Chemla, 1985). Since one can tune the excitonic absorption peak of a given quantum well with the field to make it match a prescribed wavelength, it has been possible to implement efficient electro-optical devices based on such a basic effect as the electric-field–induced Stark shifts of the quantum-well eigenstates (Miller *et al.*, 1985).

4.4 Modulation Doping of Semiconductor Heterostructures

When substitutional elements are introduced in a bulk semiconductor, the crystalline potential is no longer periodic. This gives rise most often to impurity states in the forbidden gaps of the pure material. For donor (acceptor) impurities that have one more (less) valence electron than the unit cell atom they replace, the impurity levels are energetically located below the conduction-band edge (above the valence band edge) of the pure material. In a simple hydrogenic model the binding energy ϵ_d of an electron bound to a donor is $13.6\text{ eV}\times[m_c/m_0\epsilon_r^2]$ in the $1S$ ground state. In GaAs, this corresponds to $\epsilon_d\sim 5$ meV for the bound electron ($\epsilon_a\sim 34$ meV for a bound hole). These impurities can be thermally ionized to supply the semiconductor conduction (valence) band with free electrons (holes), which ensure the electrical current flow. Since the impurities are located at random they scatter the free carriers (very effectively).

The characteristic feature of the shallow impurity states in bulk materials is that their binding energy or the scattering cross section of carriers by one such impurity does not depend on which unit cell hosts the impurity. This feature clearly arises from the translational invariance of the pure semiconductor. In heterostructures, this invariance remains as far as the in-plane location of the impurity is concerned. On the other hand, introducing impurities in the barrier-acting or in the well-acting material does lead to major differences both in the impurity binding energies and in the scattering cross section. Consider a single AB heterojunction and assume that only the barrier (B) is doped with donors. In the bulk B material such a donor would create shallow impurity levels below the conduction-band minimum. At $T=0$ K, the electron would be frozen on the lowest available state: the $1S$ bound state. There would be no electrical current because of a complete depopulation of the conduction band with free carriers. In the AB heterostructure, instead, the $1S$ barrier impurity state is no longer the ground electron state if the conduction-band offset exceeds the donor binding energy. There exists a whole electron continuum that corresponds to eigenfunctions mostly localized in the well-acting material. To ensure thermal equilibrium, the electrons have to be transferred to the well, leaving the ionized donors in the barrier. There is thus a spatial separation between the parent donors and the electrons. It gives rise to a band bending: The electrons are squeezed in a quasitriangular potential well formed on one side by the conduction-band offset and on the other side by the electrostatic potential energy (Ando, 1982). Bound states are formed in this well, and the electron motion becomes quasibidimensional. The scattering of charge carriers by the purposely set back impurities is much weakened compared to the bulk case (Dingle *et al.*, 1978). The low-temperature mobilities of such modulation-doped GaAs channels have reached unprecedented records: At liquid He temperature there is an improvement by more than two decades over the bulk GaAs figures. Notice, however, that at room temperature there is not much improvement obtained by using modulation-doped structures. This is because the dominant scattering mechanism at $T=300$ K is the scattering by the polar optical phonons in GaAs.

5. COUPLING EFFECTS BETWEEN QUANTUM WELLS

5.1 Double Quantum Wells in an Electric Field

Two identical rectangular quantum wells separated by a finite barrier are the simplest example of the quantum mechanical resonance effect. When isolated, each of the wells supports bound (at least one) and extended states. When brought into interaction—simply by the fact that the right-hand-side (rhs) well has a finite left-hand-side (lhs) barrier and vice versa, i.e., that the isolated well eigenstates are no longer eigenstates of the whole structure—the eigenstates delocalize over the two wells. That is to say, an electron in a stationary eigenstate of the double-well structure has an equal probability of being found in either well. If the two wells are different (e.g., because their thicknesses are not the same or because the bottoms of the two wells are not at the same energy) this perfect delocalization is broken. Some survives, however, if the difference remains small compared to the coupling.

To quantify these statements let us examine a simple one-level tight-binding analysis of the two wells. We mean that the two ground states of each well are well separated from their respective excited states, which allows us to approximate the ground state of the two-well system by a linear combination of the ground states $|\phi_l\rangle$, $|\phi_r\rangle$ of the lhs and rhs wells respectively:

$$|\psi\rangle=a_r|\phi_r\rangle+a_l\rangle|\phi_l\rangle, \tag{3}$$

$$(T+V_{l,r})|\phi_{l,r}\rangle=\epsilon_{l,r}|\phi_{l,r}\rangle. \tag{4}$$

The full Hamiltonian $T+V_r+V_l$ is left operating on $|\psi\rangle$. After projections on $\langle\phi_r|$ and $\langle\phi_l|$ one finds that Eq. (3) is an eigenstate of the double well with the eigenenergies

$$\epsilon_{\pm}=A\pm\sqrt{\delta^2+\lambda_{lr}\lambda_{rl}}\,, \tag{5}$$

where we have assumed $\langle\phi_l|\phi_r\rangle=\delta_{lr}$ for simplicity and

$$E_{l,r}=\epsilon_{l,r}+\langle\phi_{l,r}|V_{r,l}|\phi_{l,r}\rangle;$$

$$\lambda_{lr}=\langle\phi_l|V_l|\phi_r\rangle;$$

$$\lambda_{rl}=\langle\phi_r|V_r|\phi_l\rangle; \tag{6}$$

$$A=\tfrac{1}{2}(E_l+E_r);\quad \delta=\tfrac{1}{2}(E_r-E_l). \tag{7}$$

$E_{l,r}$ is the energy level of the isolated well corrected by a (downward) shift due to the presence of the other well. Also, A is the average of these two values and 2δ is their difference. Finally, λ_{lr} and λ_{rl} are transfer integrals (in the tight-binding terminology) that express the electron hoppings from one well to the other. Indeed, for identical wells ($\lambda_{lr}=\lambda_{rl}=\lambda$), if at $t=0$ the electron wave function is $|\phi_l\rangle$, the probability of finding it in the state $|\phi_r\rangle$ at time t is equal to $\sin^2(\lambda t/\hbar)$. Thus, $\pi\hbar/2|\lambda|$ is the jump time from one well to the other.

It is clear from Eq. (5) that the key dimensionless parameter of the problem is $(\lambda_{rl}\lambda_{lr})^{1/2}/\delta$. If this parameter is large the eigenstates are extended (over the double-well structure), while if it is small they are essentially localized in a given well. To use a chemistry analogy, the double-well bond is covalent or polar in these two limits.

Let us first discuss the case of symmetrical double wells where $\delta=0$, $\epsilon_l=\epsilon_r$, and $\lambda_{lr}=\lambda_{rl}=\lambda$. One finds immediately that $a_l^{\pm}=\pm a_r^{\pm}=2^{-1/2}$: The probability of finding the carrier in one well is evenly distributed between the two wells for both the ground (ϵ_-) and excited (ϵ_+) states. The twofold degeneracy of the infinitely separated wells is lifted by a quantity that is equal to twice the coupling term, i.e., the transfer integral. Like in the H_2^+ molecular ion, the ground state in the double-well problem corresponds to the symmetric combination of the isolated wells' eigenstates. This ensures the maximal gain of potential energy. The excited-state wave function instead has a node in the middle of the intermediate barrier.

It is remarkable that the electron delocalization persists even if the intermediate barrier is very thick, i.e., the coupling λ is very small (λ decreases exponentially with the barrier thickness). This shows that the coupling cannot be treated perturbatively in the $|\phi_l\rangle$, $|\phi_r\rangle$ basis. This is due to the energy degeneracy of the two interacting levels, a feature characteristic of resonances (cf. again the chemistry analogy with the π bonds in the benzenic ring).

In reality, it is seldom possible to achieve a strictly symmetrical double quantum well because of the imperfect control of layer thicknesses and barrier heights (many host materials are ternary random alloys). Thus one should investigate the effect of a nonzero δ on the carrier delocalization over the two wells. Besides, even if the wells are identical, it is always possible to create a controllable asymmetry by biasing the double well. This is actually realized by inserting the double well in the intrinsic part of a reverse-biased *p-i-n* junction. In this case 2δ is equal to $eF(L_w+L_b)$, where F is the magnitude of the constant electric field (**F** is parallel to the growth axis) and L_w (L_b) is the well (intermediate barrier) thickness.

One readily finds that an increase in δ leads to a convergence of ϵ_+, ϵ_- toward E_r and E_l respectively $[E_1\pm eF(L_w+L_b)/2]$ in the biased symmetrical double well. Concomitantly, the wave functions become more and more polarized on a given well: $a_l^+\to 0$, $a_r^+\to 1$ while $a_l^-\to 1$, $a_r^-\to 0$ in the large-δ limit. In the polar situation, the energy mismatch 2δ exceeds by far the coupling $(\lambda_{lr}\lambda_{rl})^{1/2}$ and the interwell coupling can be treated by perturbation calculus. This is because the unperturbed levels are nondegenerate ($\epsilon_r\neq\epsilon_l$) or off resonance.

We notice that an electric field induces a tunable transition from a resonant ($\delta=0$) to a nonresonant ($\delta\neq 0$) situation. Equivalently, one may state that the electric field transforms extended eigenstates ($\delta=0$) into localized ones ($\delta\neq 0$), a feature that is at first sight unusual and that leads to spectacular effects in superlattices (see below). Instead of misaligning degenerate levels one can start on the contrary with different ϵ_l and ϵ_r (i.e., an asymmetrical double well) and line them up with an appropriate bias. The field thereby induces a delocalization of the eigenstates over the two wells while, under flat-band conditions, they were heavily localized in one well or the other. The study of biased double wells has recently received considerable attention because they are the simplest fully quantum semiconductor structures where one can study the carriers (electron, hole) or exciton transfer from one well to the other (vertical transport).

5.2 Semiconductor Superlattices in an Electric Field

A superlattice is a periodic stacking of well-acting (thickness L_w) and barrier-acting (thickness L_b) identical layers (Esaki and Tsu, 1970). The band-edge profile in Eq. (1) becomes periodic with a tailorable periodicity d ($d=L_w+L_b$). This new periodicity implies the Bloch theorem for the envelope functions in Eq. (1):

$$F_l(x,y,z+nd)=e^{iqnd}F_l(x,y,z), \tag{8}$$

where q is the superlattice wave vector, which can be restricted to the first superlattice Brillouin zone $[-\pi/d,+\pi/d]$. It can be shown that the dispersion relations of the allowed energy bands in a one-dimensional superlattice are necessarily of the form

$$\cos qd=f(\epsilon), \tag{9}$$

where $f(\epsilon)$ is a function that depends on the band-edge profile inside a superlattice unit cell. For piecewise constant band edges (undoped layers, no external fields) one finds $f(\epsilon)$ explicitly:

$$f(\epsilon)=\cos k_w L_w \cos k_b L_b-\frac{1}{2}\left(\frac{k_w}{m_w}\frac{m_b}{k_b}+\frac{k_b}{m_b}\frac{m_w}{k_w}\right)\sin k_w L_w \sin k_b L_b\,, \qquad (10)$$

where m_w (m_b) is the electron effective mass in the well (barrier) and k_w, k_b are the corresponding carrier wave vectors at the energy ϵ.

In the absence of coupling between the wells ($L_b \to \infty$) each quantum well level E_1 is $(2N+1)$-fold degenerate where $(2N+1)d$ is the macroscopic superlattice thickness. This degeneracy is lifted at finite L_b (exactly like in the double-well situation), and one finds a miniband extending on each side of E_1 [the term miniband arises from the smallness of the superlattice bandwidths (~ 50 meV) and size of the Brillouin zone compared to those of bulk materials (a few eV)]. The one-level tight-binding analysis leads to the following dispersion relation and z-dependent envelope functions:

$$\epsilon(q)=E_1-2|\lambda|\cos qd, \qquad (11)$$

$$\chi_q(z)=(2N+1)^{-1/2}\sum_{-N}^{+N} e^{iqnd}\phi_1(z-nd), \qquad (12)$$

where E_1 is the isolated well eigenenergy corrected by the shift due to the other potential wells. $\phi_1(z-nd)$ is the associated envelope function for the well centered on the nth superlattice period and λ is the nearest-neighbor transfer integral. It is worth noticing that the lowest allowed eigenenergy ($q=0$) is red shifted by $2|\lambda|$ (i.e., half of the bandwidth) from the isolated well level E_1. This maximal gain of potential energy is realized with an envelope function $\chi_{q=0}$ that is nodeless, in close analogy with our findings in the double-well situation. The superlattice eigenstates are extended since the probability of finding the carrier in any of the $2N+1$ periods is $1/(2N+1)$, whatever q.

We restate that the delocalization occurs because we are considering the (resonant) coupling between exactly degenerate single-well levels. One may thus expect a partial or complete localization of the eigenstates if by any means the levels of consecutive wells become misaligned. This can occur in a number of ways. The most noticeable ones are the following:

1. A random fluctuation ΔE_1 of the isolated well levels that is too large in magnitude ($\Delta E_1 \geqslant 4|\lambda|$) leads to a complete localization of the carrier eigenstates (Anderson localization). Optical evidence of such a localization has been obtained by Chomette *et al.* (1986).
2. A constant energy shift eFd of one superlattice period with respect to the neighboring one, as achieved by biasing the superlattice, may lead if $eFd \geqslant 4|\lambda|$ to a complete localization. It is associated with a discrete (in fact evenly spaced) energy spectrum: the Wannier–Stark ladder.

These two situations are currently much investigated by means of electrical transport and optical experiments. The optical studies (absorption) are simpler since they probe directly the electronic density of states without any recourse to relaxation effects. The latter are of paramount importance in transport experiments. Let us restrict ourselves to a brief analysis of the consequence of the Wannier–Stark quantization in semiconductor superlattices for their optical properties.

In the presence of a longitudinal electric field and in the one-level tight-binding scheme outlined previously, one finds that the quasi-continuous band spectrum defined in Eq. (11) is destroyed and replaced by a set of evenly spaced levels:

$$\epsilon_\nu=E_1+\nu eFd, \quad \nu=0,\pm 1,\pm 2,\ldots, \qquad (13)$$

while in the envelope-function expansion of Eq. (12) the plane-wave term $(2N+1)^{-1/2} \times e^{iqnd}$ has to be changed into $J_{\nu-n}(-2|\lambda|/eFd)$, where $J_p(x)$ is the Bessel function of integer order p. These results were first established by Wannier in the late fifties (Wannier, 1959) and were much disputed on theoretical grounds. There were not clear cut experimental observations of these ladders in bulk solids essentially because $2|\lambda|/eFd \sim 10^2-10^3$ in bulk materials, which means that as far as localization effects are concerned, the bulk materials are always in the weak electric field regime. In the νth Wannier–Stark state the average position $\langle z\rangle$ of the carrier is equal to νd. The νth eigenstate extends over $\sim 2|\lambda|/eFd$ periods on each side of the nth period. Thus, with reasonable figures for bulk materials ($2|\lambda| \sim 1$ eV, $d \sim 0.5$ nm, $F \leqslant 10^7$ V/m) there is little hope to get a significant localization. In semiconductor superlattices instead

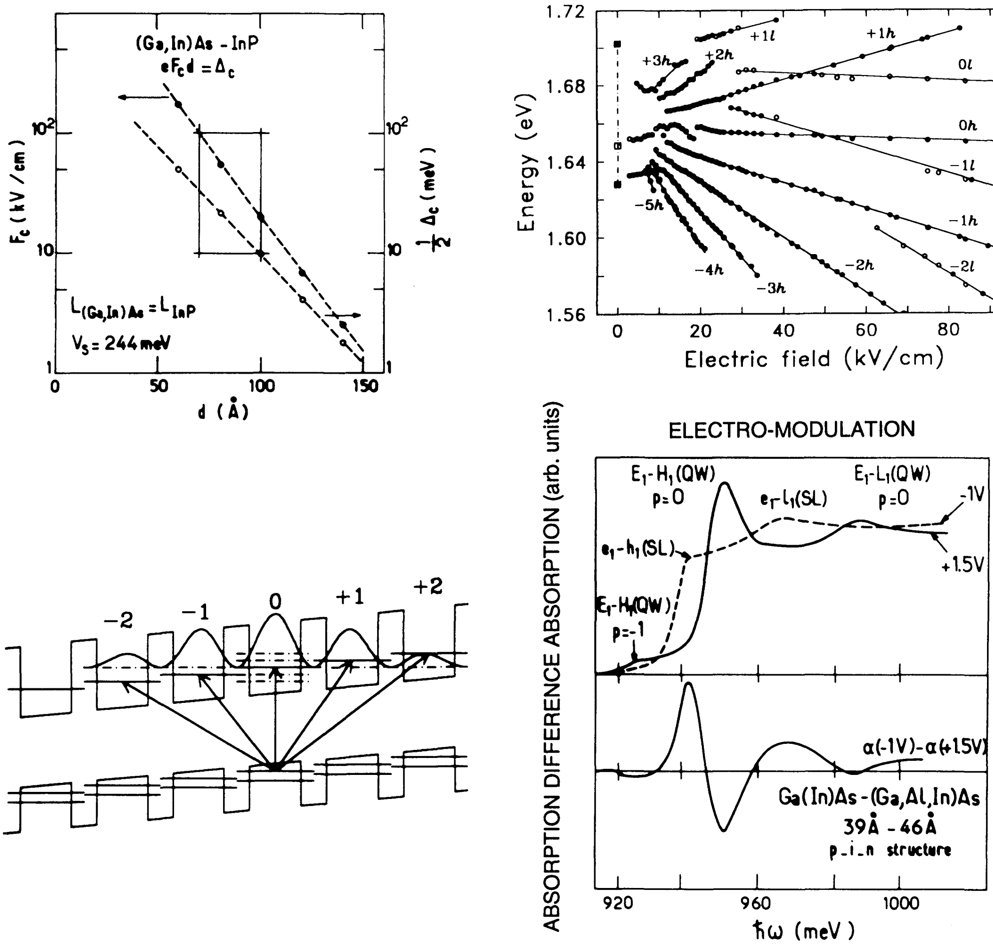

FIG. 9. Wannier–Stark quantization in superlattices. Right upper panel: fan chart of the observed interband optical transitions in a biased GaAs–$Ga_{0.65}Al_{0.35}As$ superlattice. $T=5$ K. The labels h and l correspond to heavy-hole–electron and light-hole–electron transitions, respectively (from Mendez and Agullo-Rueda, 1989). Right lower panel: absorption coefficient of a $Ga_{0.47}In_{0.35}As$–(Ga,Al,In)As superlattice for two different biases (adapted from Bleuse *et al.*, 1988b). The labels e_1h_1... identify superlattice transitions (zero electric field). The labels E_1-H_1, $p=0,-1$ correspond to vertical ($p=0$) and oblique ($p=-1$) transitions in (or between) nearly isolated quantum wells ($F\sim4\times10^6$ V/m). Left upper panel: half of the conduction sub-band width ($\frac{1}{2}\Delta_c$) and field strength (F_c) required to achieve a complete localization ($eF_cc=\delta_c$) plotted versus the superlattice period d in $Ga_{0.47}In_{0.53}As$/InP superlattices with equal layer thickness. Inside the rectangle a significant blue shift ($\frac{1}{2}\Delta_c>10$ meV) is achievable at a reasonable field ($F<10^7$ V/m). Left lower panel: band-edge profiles of a biased superlattice. A conduction envelope function centered at the 0th period is also shown. Several conduction Wannier–Stark states are displayed as well as vertical and oblique optical transitions from a Wannier–Stark valence state which is almost entirely localized in the 0th period ($\lambda_v \ll |\lambda_c|$).

$2|\lambda|\sim20$ meV, $d\sim5$ nm, and there is no difficulty to reach significant localization of the νth eigenstate around the νth period. A complete localization is achieved when the potential energy drop over a period eFd is equal to the zero-field bandwidth $4|\lambda|$.

At zero electric field, the oscillator strength of the optical transitions across the bandgap of the superlattice is nonzero only if the transition takes place vertically in the reciprocal space. This is due to the negligible wave vector carried by the photons. In addition the oscillator strength is proportional to the modulus squared of the overlap integral between the valence and conduction envelope functions. Let the absorbance $\alpha(\omega)$ be such that the transmitted (I_t) and incident light (I_0) intensities are linked together by the Lambert–Beer law: $I_t=I_0e^{-\alpha(\omega)}$, reflection losses being neglected. In the previous tight-binding scheme, one finds the frequency dependence of the superlattice absorbance $\alpha(\omega)$:

$$\alpha(\omega,F=0) = [(2N+1)/\pi]\alpha^{\mathrm{QW}}\arccos\{(-\hbar\omega + \epsilon_g^{\mathrm{QW}})/ 2(|\lambda_c|+\lambda_v)\}, \qquad (14)$$

where α^{QW} is the isolated well absorbance due to E_1-H_1 transitions ($\alpha^{\mathrm{QW}}\sim 0.3\%$ in usual III–V or II–VI materials). ϵ_g^{QW} is the band gap of the isolated quantum well (i.e., $\epsilon_g+E_1+H_1$ where ϵ_g is the band gap of the bulk well-acting material and E_1,H_1 the respective electron and hole confinement energies). $\alpha(\omega,F=0)$ merely reflects the joint density of states between the H_1 sub-band (width: $4\lambda_v$) and the E_1 sub-band (width: $4|\lambda_c|$). The absorption edge in the superlattice is $\epsilon_g^{\mathrm{QW}}-2(|\lambda_c|+\lambda_v)$, i.e., is red shifted by half the sum of the bandwidths with respect to the isolated quantum well edge. For $\hbar\omega>\epsilon_g^{\mathrm{QW}}+2(|\lambda_c+\lambda_v|)$ the absorbance is constant $[=(2N+1)\alpha^{\mathrm{QW}}]$. At nonzero F, one finds similarly

$$\alpha(\omega,F)=(2N+1)\alpha^{\mathrm{QW}} \times \sum_{\nu=-\infty}^{+\infty} J_\nu^2\left(\frac{2(|\lambda_c|+\lambda_v)}{eFd}\right) \times Y[\hbar\omega-\epsilon_g^{\mathrm{QW}}-\nu\, eFd]. \qquad (15)$$

From Eq. (15), it is clear that formally there is no more absorption edge in the biased superlattice. This is clearly due to the breakdown of the translational invariance of the superlattice potential imposed by the nonvanishing field. A staircase-shaped edge, linearly varying with F, is associated with any spatially oblique transitions ($\nu=\pm 1,\pm 2,\ldots$) where electron–hole pairs with a mean electron–hole separation *nd* are photogenerated (see Fig. 9). Since excitonic effects, not included in Eq. (15), sharpen these quasibidimensional edges, one expects to observe a series of evenly spaced peaks in electroabsorption experiments performed at fixed F. Conversely, oscillations periodic in F^{-1} should show up in experiments done at fixed ω and varying F. All these predictions were clearly confirmed in the last few years (Mendez *et al.*, 1988; Voisin *et al.*, 1988; Agullo-Rueda *et al.*, 1989).

A striking feature takes place in the strong-field regime where electron and hole envelope functions become electroshrunk in a single superlattice period. In that limit all the oblique transitions fade away [$J_\nu^2(x)\sim(x/2)^{2\nu}$ when $x\rightarrow 0$] to the benefit of the vertical transition [$\nu=0$ in Eq. (15)], and in effect the biased superlattice behaves like a collection of $2N+1$ isolated quantum wells. This effect is further strengthened by excitonic effects that are weak in superlattices at $F=0$ (three-dimensional materials) but are strong in isolated quantum wells (quasibidimensional materials). Once all the oblique transitions have collapsed, the absorption edge of the biased superlattice is effectively ϵ_g^{QW}, i.e., it is blue shifted with respect to the $F=0$ edge (Fig. 9). This blue shift can rightfully be termed a macroscopic quantum effect in that it arises from a purely quantum mechanical effect: the destruction by the electric field of the tunnel coupling between resonant (i.e., energy aligned) quantum levels. This spectacular effect has also been observed (Bleuse *et al.*, 1988b) and is currently used in the design of low-power electro-optical switches operating at room temperature (Bigan *et al.*, 1990).

6. CONCLUSION

This short article has, it is hoped, introduced the reader to a domain of semiconductor research, the heterostructures, that is explosively growing. The guiding line of the physics in these new materials is the preeminent part played by quantum mechanical effects (size quantization, tunnel effect, field-induced localization, etc.). It is expected that many more experimental breakthroughs and device implementations will result from semiconductor heterolayers.

GLOSSARY

Quantum Well: A double heterostructure that consists of a slab of a well-acting material inserted between two semi-infinite slabs of barrier-acting materials. Note that the notion of well and barrier is relative to a given band edge.

Resonance: A situation widely encountered in many branches of physics. It corresponds to the (fortuitous or induced) lining up of two characteristic frequencies of the system under consideration.

Stark Effect: The perturbation of electron states by an electric field.

Superlattice: An infinite, periodic sequence of slabs of two (or more) materials. Doping superlattices (i.e., alternate and periodic *n* and *p* doping of a given semiconductor) have also been studied.

Tunnel Effect: A quantum mechanical (wavelike) phenomenon that takes place when the carrier eigenenergy is locally smaller than the potential energy. The carrier wave function in these regions of space is exponentially varying with distance.

Tunnel Coupling (between Wells): The modification of the eigenenergy of a carrier moving in a multiple quantum-well structure over the one found in the isolated wells. It is due to the tunnel effect in the barriers separating the wells.

Valence-Band Offset: The energy difference between the topmost valence electron states that are localized on each side of (and far enough from) an interface between two semiconductors.

INTRODUCTION

This article presents techniques applicable to the study of a wide range of physical phenomena at pressures greater than 0.1 GPa (see Glossary for pressure unit conversions). It is characteristic of the field that many of the investigations involve small-scale studies in which details have been ingeniously worked out by individual investigators to make possible measurements over appropriate ranges not only of pressure, but of temperature, magnetic field, and other variables in a wide variety of materials. It is currently possible throughout the 1-GPa range to apply most of the techniques for investigation of condensed matter used at ambient pressure—for example, electrical resistivity, optical absorption and reflectivity, and Raman scattering. Techniques examined in this article shall not emphasize a lower limit to the term high pressure because some investigations at relatively low pressures require interesting methods and generate interesting results.

The boundaries keep shifting. Capability and sophistication are growing within all ranges, and the maximum attainable pressures have increased remarkably in recent years, as has the ability to carry out sophisticated experiments at those pressures. We shall describe some of the generally applicable high-pressure techniques, including pressure generation and measurement, and communication of the relevant dependent variables—e.g., electrical resistance—from samples within high-pressure cells.

High-pressure phenomena *per se* are not simply laboratory phenomena. Most of the condensed matter in the universe is at substantially elevated pressures. The observation

digital Encyclopedia of Applied Physics

that the gravitationally generated pressures at the center of Earth and of Jupiter are about 364 GPa and 10^4 GPa, respectively, should be convincing evidence that the study of high-pressure phenomena is driven in part by the fields of geophysics and planetary physics.

There is a problem of determining what *is* "high" pressure in its interaction with disparate objects such as biological systems, atoms, and neutron stars. It is made easier by recognizing the identity of force per unit area and energy per unit volume (see Glossary). Thus it is possible to use dimensional analysis to make very crude, but sometimes illuminating, order-of-magnitude estimates of pressures required to produce various results by identifying characteristic energies and volume changes. For instance, pressures required to cause significant changes in chemical binding might be expected to be (chemical binding energies) ÷ (changes in volume in chemical reaction). These would be

$$\frac{\text{kilojoules/mole}}{\text{cm}^3\text{/mole}} \sim 1 \text{ GPa}. \qquad (1)$$

Or, the pressure at which pressure disruption of electronic "shell" structure of atoms into white dwarf stars would begin could be expected to be of the order of some characteristic electronic energy, e.g., 1 Ry, divided by the volume of an atom, e.g., $(4\pi/3)\times(\text{Bohr radius})^3$, i.e.,

$$P^* \simeq \frac{1 \text{ Ry}}{(4\pi/3)a_0^3} = 3511 \text{ GPa}. \qquad (2)$$

Going even further, the pressure to break down nuclei into neutron stars, i.e., ~(nuclear binding energies) ÷ (nuclear volumes), could be

$$\sim \frac{\text{millions of electron volts}}{(3 \text{ fermi})^3} \sim 10^{22} \text{ GPa}. \qquad (3)$$

These estimates are of course crude, but they do indicate the severe limitation of contemporary experimental maximum pressure techniques when examined on the scale of astrophysical phenomena, even though recent work has resulted in a reported static pressure of 416 GPa, greater than that at the center of the Earth (Ruoff *et al.*, 1990). Present (1992) upper limits of dynamic high-pressure experiments are even higher, at ~700 GPa for light gas guns (Holmes *et al.*, 1989) and pressures near 10 TPa using laser-driven shock waves (Cottet *et al.*, 1986). At the other end of the high-pressure scale, significant effects on living cells occur at pressures below 0.2 GPa (Zimmerman, 1970).

High-pressure techniques also form an important part of industrial technology. Very large-scale operations are applied to the manufacture of polyethylene, while one of the outstandingly successful examples of transformation of laboratory techniques to a major manufacturing activity is found in the synthesis of diamond. The former work involves large volumes and low pressures of a few tenths of a GPa, while the latter is carried out at about 5.5 GPa (simultaneously with temperatures near 1600 K). Polyethylene is one of the most important common plastics requiring production of an enormous yearly tonnage. See SOLIDS, HIGH-PRESSURE EFFECTS IN and DIAMOND AND DIAMONDLIKE CARBON for more detailed discussion of man-made diamonds.

Finally, the matter of safety of high-pressure systems, particularly large pressure vessels containing compressed gases, is an important and extensively studied subject (Dawson, 1977). Even small-scale laboratory apparatus using significant volumes of gas or liquids at high pressures must be treated with respect, using appropriate guards and shields, as well as common sense, to minimize chances of an injurious accident. Fortunately, small-scale "dry" systems such as the widely used diamond-anvil cells may be made safe by following relatively simple procedures, especially to protect eyes from chips that could spall from stressed brittle materials.

1. STUDIES USING STATIC TECHNIQUES

1.1 Principles

"Pressure" is given by normal force per unit area. The simplest means of applying pressure might be found in an apparatus in which a sample is squeezed between faces of two cylinders by a force F yielding $P=F/A$. If the length of the cylinders was about equal to the diameter, a definition of compressive strength σ_c of the cylinder material suggests that the maximum pressure on the sample would be about equal to σ_c. Although such a simple device could in fact be useful, pressure cells are usually more complex structures and can reach pressures higher than the simple compressive strength.

1.1.1 Strength of Pressure Chambers. In Fig. 1, we note that the splitting force generated by the internal pressure $F=Pdl$ in a simple cylinder must be successfully opposed by the tensile stresses in the wall of the cell. The wall stresses are not uniform: the tangential stress is largest near the interior wall and diminishes at larger radial distances. A cell made of a reasonably ductile material, as is usually the case, typically fails by a crack parallel to the axis that propagates outward from the inner cell wall. Quantitative treatments of the state of stress within simple pressure-vessel forms may be found in numerous places (Spain and Paauwe, 1977) but must always be used with caution as predictors of failure pressure. One must particularly note that the so-called thin-wall formula given by (average tensile stress) = (pressure) $\times d/(D-d)$ overestimates the bursting pressure of a thick-walled vessel if the average tensile stress is taken to be the tensile strength of the material of which the vessel is constructed. Not surprisingly, as interest has grown in reaching even higher pressures, stronger and stronger materials have been used in constructing high-pressure components, ultimately including diamond, which is the hardest material known at this time. Also, "geometrical" and statistical advantages have been applied. Of these, the so-called principle of massive support and Auerbach's law (Seal, 1984) are sufficiently evident in contemporary apparatus to demand description. The principle of massive support states that higher contact pressures may be obtained without failure when the contact area is supported by adjacent relatively unstressed regions, as in Fig. 2 showing a so-called Bridgman anvil. Auerbach's law will be described in Sec. 1.5 in relation to diamond-anvil cells. Calculating the stresses in a system such as a diamond-anvil cell is a complex problem, but a number of "finite-element" calculations have been carried out (Moss and Goettel, 1987) both to gain insight into maximizing performance of the cells and to improve confidence in values of indirectly measured pressures.

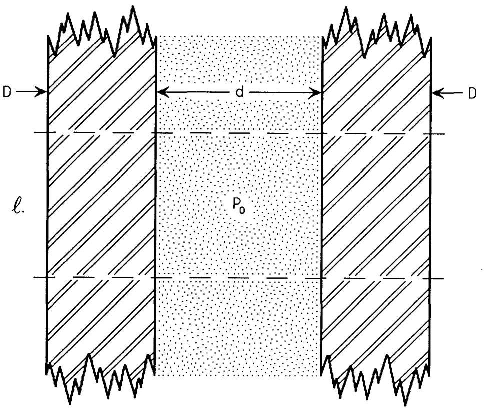

FIG. 1. Cross section of a long, hollow cylinder filled with fluid at a pressure P_0. d and D represent internal and external diameters, respectively. The splitting force P_0dl must be opposed by the tensile stresses in the cylinder walls.

1.2 Materials of Construction

Construction materials are quite varied, depending not only on the mechanical strength required but, in particular cases, on the need to resist corrosion, on performance at high temperature, on optical access, etc.

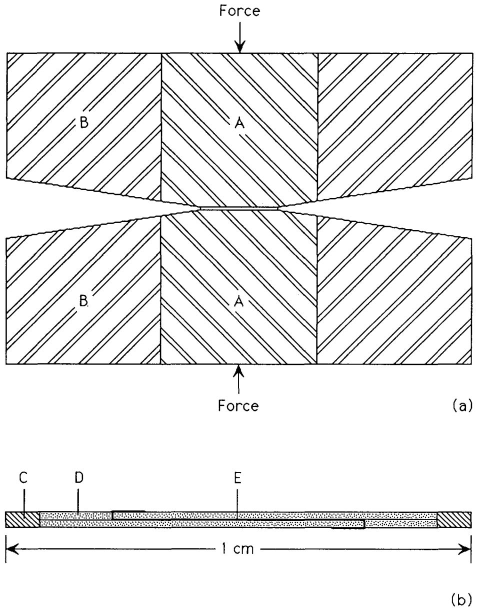

FIG. 2. (a) "Bridgman-anvil" apparatus: A, cemented tungsten carbide anvils; B, support rings of alloy steel. (b) Sample detail: C, compressible gasket; D, silver chloride or other "soft" material; E, electrical resistor wire sample. The diameter ϕ of the compressed region is typically about 1 cm.

Traditionally, for nonaggressive pressure media, alloy steels combining high strength and reasonable ductility such as SAE 4340 have been used. Alloys such as this requiring quenching from high temperatures show substantial deformation in the hardening process so that final machining often must be done after heat treatment. A more recently available class of alloys, the so-called nickel maraging steels, combine tensile strengths greater than 2 GPa with reasonable ductility, do not require quenching, and hold their dimensions well during the aging process by which they are hardened. Experience has shown, however, that the material frequently contains flaws, and pieces intended for critical construction should be sonically tested before a substantial investment is made in machining them. Various stainless steels are frequently used for components, most commonly type 316, which has good corrosion resistance properties. Pre-heat-treated type 416 stainless steel is a higher strength, less corrosion-resistant variant, which is useful as a general material for moderately stressed parts. It is sometimes forgotten that although the *strengths* of different steel alloys may be quite different, the elastic moduli that determine their *elastic* deformations under stress are practically the same, regardless of composition or condition of hardness. Thus it is often not necessary to use expensive superalloys for support purposes in which rigidity is required rather than extreme strength. Some pressure media affect pressure cells chemically or physically. Hydrogen in particular may severely attack steel alloys. Hydrogen embrittlement may be avoided by use of beryllium copper (BeCu) alloys or hydrogen-resistant steels such as A-286, which are, however, neither as strong nor as ductile as the maraging steels when both are heat treated to nearly maximum strength. Oxygen has been known to ignite a pressure vessel from within, with disastrous results. [It is often possible to use alloys resistant to attack such as BeCu as material for the core of a composite vessel, along with a material such as type 416 pre-heat-treated stainless steel as an external support—designed such that the latter is not exposed to the high-pressure fluid.] Various grades of cemented tungsten carbide are used where great compressive strength is needed but significant ductility is not required. These are commonly found in piston-cylinder and "anvil" applications, which will be discussed later. The ultimate high-strength material at present is diamond. This is extensively used in so-called diamond-anvil cells discussed in Sec. 1.5 of this article. Specialized, very simple cells are also being constructed using commercial sapphire spheres as anvils (Takano and Wakatsuki, 1991; Daniels *et al.*, 1991). Other materials used for particular purposes, such as electrically insulated lead-ins, optical windows, and neutron transmission will be discussed as they appear under those techniques.

1.3 Systems Using Pumped Fluids as the Pressure Medium

In spite of the relatively low pressure range, apparatus using pumped fluids demand the most complex equipment. Practically speaking, pumped-fluid apparatus are limited to about 3 GPa maximum pressures, but are more commonly used to only slightly above 1 GPa. The chief advantages of these systems are that the pressures can be truly hydrostatic (hence will not induce shear stresses even in soft single crystals) and accurately measured, and that they are very versatile. A wide variety of electrical, optical, magnetic, and other measurements may be made on compressed materials using these systems. Figure 3 illustrates the components of a typical system intended to compress a sample using helium as pressure medium to pressures near 1 GPa. It consists of a gas supply, a prepressurizing system, intensifiers, a pressure-measuring device, and a sample cell containing the material under study. The components are connected by high-pressure tubing. The sample cell is designed to accommodate appropriate electrical leads, optical windows, etc., relevant to the phenomena under study. The cell shown would be appropriate for Raman scattering. Many of the components, especially for the lower parts of the 1-GPa range, may be obtained commercially.

1.3.1 Seals. Prevention of leakage at pistons, closures, and connections is a fundamental problem in working with fluids at high pressures. The so-called Bridgman unsupported-area principle (Bridgman, 1952) is widely applied to provide leak-free closures. Figure 3(b) illustrates an application to a compression piston seal. The principle is based on the observation that fluid will not leak past

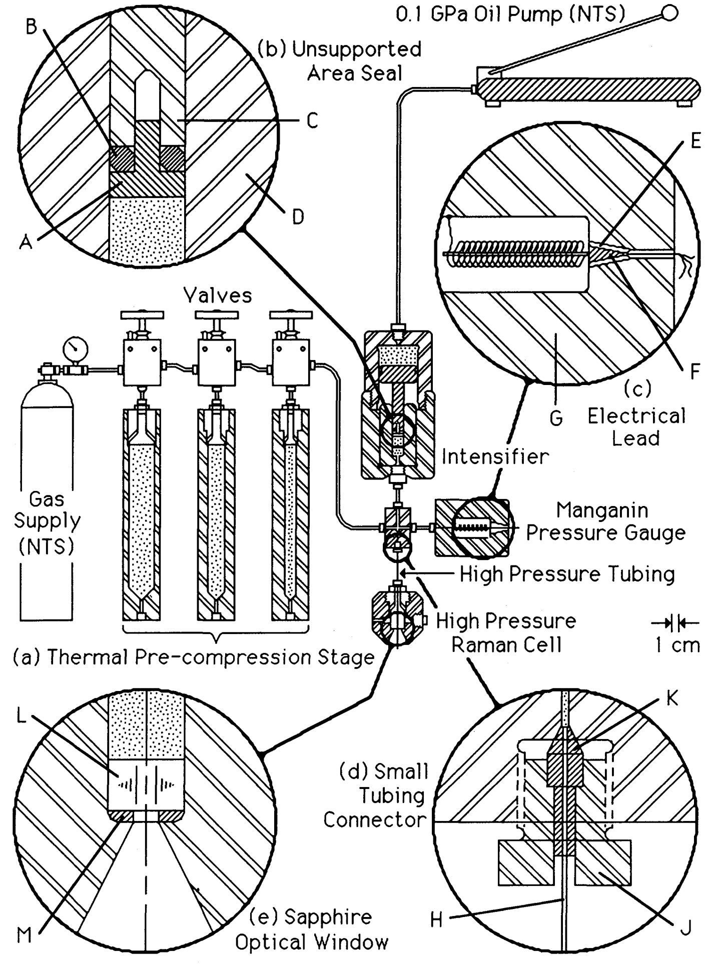

FIG. 3. System for generation of high pressure using helium as pressure fluid. The gas is supplied by a commercial high-pressure cylinder. The pressure cell shown is used for Raman scattering. In the details, *A* is the so-called mushroom of the unsupported area seal; *B* is the soft packing, guarded by antiextrusion rings; *C* is the high-pressure piston of the intensifier; *D* is the intensifier cylinder; *E* is the thin insulating core; *F* is the matching conical electrode; *G* is the pressure-gauge cell wall; *H* is the pressure tubing; *J* is the gland; *K* is the plug, with tubing hard-soldered into it; *L* is the single-crystal sapphire window, oriented with the crystallographic *c* axis along the cylinder axis; and *M* is the window seat. (NTS = not to scale.)

a soft solid packing in which the pressure is higher than the pressure in the fluid, together with a geometry for maintaining that condition. Ignoring frictional forces and nonhydrostatic stresses, the mushroom-shaped piece *A* is in equilibrium under the force applied by the pressure medium $F = P \times$ (area of the mushroom heads), and the force $F' = P'$ in the packing multiplied by the area of the annulus S' formed by the packing: thus $P'_{\text{packing}} = P_{\text{system}} \times S/S'$. Geometrically, $S' < S$ and so $P' > P$. That is, the packing pressure is automatically maintained higher than the fluid pressure and leakage will not occur. In practice, small scratches and irregularities can provide pathways for leakage, especially with light gases such as helium and hydrogen at cryogenic temperatures where sealing materials lose their plasticity. Careful construction and polished surfaces are beneficial. Packings are typically inert, soft, low-friction materials such as Teflon^{TM} or soft metals such as lead or indium (although the latter seems to embrittle some steels and beryllium-copper alloys). Antiextrusion rings, usually of phosphor bronze or brass, must be used to prevent the soft packing from extruding either out to the atmospheric pressure region or even into the pressure chamber (since $P' > P$!).

1.3.2 Tubing. Tubing suitable for high pressures is available from several suppliers. The reader is referred to commercial catalogs for details of its use, which typically involves threading a collar onto the tubing and forcing a conical end of the tubing into a mating cavity. Very small tubing [e.g., type 316 stainless steel tubing as small as 0.8 mm diam (0.32 in.) having a bore 0.15 mm (0.006 in.)] is convenient in coupling to sample cells, which are to be kept at very low temperatures, because of the mechanical flexibility and the small heat conduction by such tubes. Connections for this small tubing are shown in Fig. 3(d). The soldering operation must be done carefully to avoid overheating and annealing the tubing, which is usually more sensitive to temperature than the plug, which may be made of maraging steel. Maraging steel fittings, type 316 stainless steel tubing, and a silver solder have been used comfortably with inert pressure fluids (e.g., helium) to greater than 1 GPa. Beryllium copper fittings and tubing together with high-strength solder have been used satisfactorily, but never comfortably, with an aggressive material, hydrogen, to about 0.7 GPa.

1.3.3 Precompression. If the pressure fluid is a relatively incompressible material such as oil, precompression may take the form of a commercial oil pump that can fill the system with oil and drive the intensifier piston to an appropriate initial position. On the other hand, if the medium to be compressed is a gas, e.g., helium, it is often desirable to precompress it so that the desired high pressure may be reached in one stroke of the high-pressure intensifier. There exist 0.2-GPa diaphragm pumps for this purpose. An inexpensive alternative, satisfactory for light gases such as He or H_2, uses thermal compression. If one has convenient access to liquid nitrogen, the method may be a useful one. Commonly three cylinders, having decreasing volumes and increasing maximum pressure capability, are connected by tubing and valves as shown in Fig. 3(a). In operation, all three cells are initially immersed in liquid nitrogen and filled from a standard commercial helium or hydrogen high-pressure gas cylinder while connected to the system. After pressure and temperature have equilibrated, the valve between the supply tank and the first cylinder is closed, and that cylinder is warmed gently to room temperature or even higher, driving gas to subsequent cylinders and to the system. Then the valve between the first and second cylinders is closed and the second cylinder is warmed, etc. Three stages ($V_1=300$ cm^3, $V_2=100$ cm^3, $V_3=30$ cm^3) used with hydrogen generate about 0.2 to 0.3 GPa starting pressure in a system having a volume about 10 cm^3 with the intensifier initialized. Advantages of thermal compression are simplicity and absence of moving parts, which might introduce contaminants. A disadvantage is the relatively large volume of gas held at high pressure. *Safety shielding must be provided.*

1.3.4 Intensifiers. The intensifier is an elementary pressure multiplier having gas (system) pressure at one end and oil (pump) pressure at the other end. If the pressures and piston areas are P_1, A_1, and P_2, A_2 and the piston is in mechanical equilibrium, $P_1 A_1 = P_2 A_2$ ignoring friction. (Maximum oil pressure$\approx$0.1 GPa.) Ratios are commonly chosen so that a commercial oil pump can provide the low pressure needed. The high-pressure piston seal is usually a Bridgman seal, and the low-pressure side may use an O-ring or other packing together with an antiextrusion ring. Principally for safety, an external supporting sleeve of ductile material is usually pressed onto the high-pressure end of the intensifier. An appropriate valve arrangement may be used so the system can be multiply stroked to accommodate larger-volume sample cells.

1.3.5 Valves. Valves may be purchased or constructed in a variety of configurations. Commercial valves are available for pressures to about 1 GPa. Usually commercial valves require adaptation for use with very small-diameter pressure tubing.

1.3.6 Pressure Measurement. The fundamental measurement of pressure as a force per unit area is the concept embodied in the free piston gauge (Newhall *et al.*, 1963), sometimes also called a pressure balance or deadweight tester. The principle is simple—balancing of the force generated by pressure on a piston having a known area, against the gravitational force on weights placed on top of the piston—but the practice is complex. Sophisticated schemes to reduce friction by rotating the piston, application of controlled clearance seals, and calculations of corrections due to area changes and hydrodynamic stresses lie beyond the scope of this article (Newhall *et al.*, 1963). More practical secondary gauges include Bourdon-tube gauges and gauges based on pressure dependence of electrical resistance R of a coil of wire within a pressure cell. The Bourdon-tube gauges are available in various ranges, up to about 0.7 GPa with accuracy claimed to be as high as 0.1% of full scale. Electrical resistance gauges usually use Manganin wire, an alloy of copper, manganese, and nickel, because of its availability and its relatively small sensitivity to temperature change. Typical values of the pressure coefficient $d \ln R/dP$ are near 2.3 $\times 10^{-2}$ GPa^{-1}.

In the search for a calibration reference more widely accessible than the free-piston gauge, the melting pressure of pure mercury has been accurately determined as a function of temperature with free-piston gauges (Lloyd *et al.*, 1969). Using a reasonably high-quality resistance bridge and a temperature-controlled cell containing elemental mercury, together with a means for determining coexistence of the fluid and solid phases, any laboratory can calibrate its gauges to within better than 0.5% over a range to ~1 GPa. An alternative to the Manganin cell—useful for material such as hydrogen (which attacks Manganin)—is a small vessel with conventional strain gauges mounted on its *exterior* surface to sense expansion generated by the internal pressure.

1.3.7 Dependent-Variable Techniques in Fluid Systems. These techniques deal with communicating values of various physical quantities from within pressure cells. For example, electrical resistivity measurements require electrical leads into the system, optical absorption studies require transparent windows in appropriate regions of the spectrum, etc. The following are some of the most generally used techniques.

1.3.7.1 Electrical Leads. These are required for measurements involving electrical resistance or dielectric constants. The technique requires use of stressed electrically insulating material. A difficulty has been that insulating materials are usually not as strong as metals. The most widely used electrical lead is due to Bridgman (1952). It has the form of a 16° conical aperture open toward the high-pressure side of a closure, insulated by a thin (~0.2 mm) hollow cone of insulating material as shown in Fig. 3(c). Originally, mineral material such as pipestone or pyrophyllite were used as insulators; contemporarily a strong plastic such as nylon, Delrin^{TM}, or Lexan^{TM} is used. The unsupported-area principle is involved with this, i.e., the pressure in the insulator is higher than in the system, but attention to quality of the conical surfaces is required, especially when used with light gases as a pressure medium.

1.3.7.2 Optical Windows. These permit absorption and reflectivity measurements within their spectral transmission regions, and scattering experiments such as Raman and Brillouin scattering. Fortunately, single crystals of sapphire combine high mechanical strength and broad spectral transmission—in principle from about 6 μm in the infrared to about 150 nm in the ultraviolet, but impurities reduce the range significantly in typical commercially available crystals. Recently, however, nonlinear optics methods have been applied to high-pressure spectroscopy in order to extend the spectrum to excitations deeper in the ultraviolet (Lipp and Daniels, 1991). In these multiphoton methods, resonances at excited-state energies that are sums and differences of the probing photon energies become accessible. Thus, these processes can use photons that are transmitted by the windows to probe states at energies inaccessible to one-photon processes because of window absorption at those energies. The technique may be more important in anvil-type apparatus. The form of window most commonly used takes the form of a short cylinder, having the crystal *c* axis parallel to the cylinder axis, about 6 mm diam. by 4.8 mm thick covering an aperture about 3 mm diam. (or similar proportions) on the interior of a pressure cell or closure plug as shown in Fig. 3(e). Both the window and the seating surface must be very flat and highly polished. Sometimes an aluminum foil gasket is used between the window and its seat to improve sealing. The arrangement of the windows can be made to optimize the requirements of a particular technique. For example, for laser-excited Raman scattering, a window for collecting the weak scattered light may be at 90° to the exciting laser-beam window axis, and the laser windows may be much smaller in size than the collection window.

1.3.7.3 X-Ray Diffraction. This very useful technique is only rarely applied to pumped fluid systems—largely because of the large absorption of x rays by common high-strength materials and because diamond-anvil cells excel in this respect. On the other hand, a few investigations have been done below a few tenths of a GPa using very small beryllium cells on account of the low absorption of x rays by that material (So *et al.*, 1992).

1.3.7.4 Neutron Diffraction. In contrast with x rays, neutrons interact weakly with most materials; hence pressure cells relatively transparent to neutrons may be made. Unfortunately, as a corollary to this, samples must be relatively large to be studied successfully by neutron scattering, typically ~0.25 cm^3, requiring cells capable of accommodating them. Several designs have appeared to accomplish this, based on either aluminum alloys (Schmidt *et al.*, 1984) or high-strength alumina (Block *et al.*, 1976).

1.3.7.5 Pumped Systems at Cryogenic Temperatures. Use of low temperature is often a consideration in study of solid-state physics phenomena. A technique that has been used in a substantial number of combined high-pressure, low-temperature experiments requires solidifying helium around the sample under study, at high pressure, then cooling the combined sample+solid helium to the temperature of observation. After the helium freezes, such a process follows approximately an isochore (constant-volume trace) of the solid helium, yielding a final pressure dependent on the final temperature in an accurately predictable way (Schirber, 1970). In spite of the fact that the pressures are applied by *solid* helium, the stresses have been observed to be very hydrostatic and homogeneous.

1.4 Dry Systems—in Which Solids are Generally Used as Pressure-Transmitting Media

These fall into two categories, piston-cylinder devices and compressible-gasket systems. Both have the advantages of great simplicity and typically can be used at much higher pressures (12 GPa) than fluid systems. Readers are referred to a recent review covering these (Bundy, 1988). Some of the dry systems allow simultaneously high temperature together with high pressure. Consequently they often form the basis of geophysical investigations and are used in the commercially important process of diamond synthesis. The advantages are obtained at the expense of a system of stresses on the sample that is often nonhydrostatic and inhomogeneous as well as generating some difficulty in accurately defining and measuring the pressures applied. The article by Hall (1958) is still a useful reference for anyone contemplating work at high pressures and temperatures (although both the maximum pressures and temperatures suggested as possible are on an obsolete scale, values reported in early work being too high).

1.4.1 Piston-Cylinder Devices. As the name suggests, these consist of a pair of pistons loaded by an external press compressing a sample within a hollow cylinder filled with a solid or semisolid material. The latter may be the sample itself, as in the case of direct compression for equation-of-state measurements, or a material such as pyrophyllite, a hydrous aluminum silicate, or Teflon^{TM}, surrounding the sample under study. Pyrophyllite may easily be machined to accommodate specific samples, heaters, etc., and is a relatively good thermal insulator. The cylinders used for the highest pressure work may use cemented tungsten carbide cores, surrounded by one or more pressed-on steel support rings. The pressure limit of these devices, about 5 GPa, is usually set by compressive failure of the cemented tungsten carbide pistons. Pressure may be inferred from the force exerted on the pistons by the external press, calibrated in a independent experiment involving a known pressure dependence such as the bismuth I-II phase transitions at 2.55 GPa. The change of phase of the bismuth is signaled by large change in electrical resistance. The press load versus pressure on the sample in the piston-cylinder device usually has a large hysteresis upon cycling up and down in pressure. Solid lubricants such as molybdenum sulfide or powdered Teflon^{TM} are sometimes used to minimize the hysteresis.

Pyrophyllite is a good electrical and thermal insulator, making it possible to use internal electrical resistance heaters surrounding a sample region to generate temperatures ~1500 °C while keeping the stressed cylinder walls at an acceptably low temperature. Sample temperatures may be measured using thermocouples led into the solid matrix from the outside or by detecting melting points of materials in the cell. A modification of the piston-cylinder devices has been used extensively at low temperatures for superconductivity and magnetism studies. In it, a mechanical arrangement is made to clamp the piston in place after pressurizing the system at room temperature in a press, retaining the sample in its compressed state (Chester and Jones, 1953). The clamped piston-cylinder device is then removed from the press, placed in a cryostat, and cooled to the measurement temperature as a free-standing object.

1.4.2 Anvil Systems. Historically, in the hands of P. W. Bridgman, these generated a major step upward in the limits of attainable pressures. They introduce the principle that fractionally small surface areas on objects may be much more highly stressed than the usually defined compressive strength limit of a material. This is referred to as the principle of massive support (cf. Fig. 2). Further, since the stresses in the externally supported anvils are almost entirely compressive, it is possible to use in their construction hard but brittle materials such as cemented tungsten carbide, supported on their external cylindrical surfaces by pressed-on alloy steel rings (Hall, 1958).

1.4.2.1 Compressible-Gasket Anvils. In the most primitive form, the stressed areas may be small truncations on a pair of shallow conical "anvils" with the sample occupying a wafer-shaped space between the opposing faces. Mean pressure may be inferred approximately from the quotient of applied force and the area of the face. Addition of a compressible gasket of pyrophyllite as shown in Fig. 2 defines the sample better, and with use of a soft medium such as silver chloride or Teflon^{TM} surrounding the sample, a more homogeneous distribution of pressure is obtained, making it possible to measure semiquantitatively even structure-sensitive properties such as electrical resistance. Significant increases in pressure range and addition of optical access is provided by Drickamer cells (Drickamer and Balchan, 1962) in which the conical surfaces of the anvils are partially supported by extending and confining the gasket. If transparent material forms at least part of the gasket, these cells may be used for measurement of optical properties of materials to pressures greater than 10 GPa, and they form the basis of a large number of such studies.

1.4.2.2 Belt-Type Apparatus. Flat anvil devices may be heated externally as long as the temperatures remain below the softening points of the materials of construction. The very small dimensions of the compression space makes it difficult to use internal heating while keeping the anvil faces cool. A major improvement is provided by the so called "belt apparatus" (Bovenkirk *et al.*, 1959), which was used in the historic General Electric Company diamond synthesis. As shown in Fig. 4, the belt combines features of piston-cylinder and compressible-gasket cells, generating a larger and more isotropic sample space subjectable to both high temperature and high pressure while remaining somewhat thermally insulated from the stressed piston and pressure chamber walls.

1.4.2.3 Multiple-Anvil Designs. For reasons that form an interesting story in itself, Hall also reported the first of the multiple-anvil designs, the so-called tetrahedral anvil system (Hall, 1958). It consists of a set of four hydraulically driven tungsten carbide anvils oriented along normals to the faces of a regular tetrahedron. The anvils each have a triangular face and are shaped so as to leave an enclosure in the shape of a tetrahedron when they are advanced into mutual contact. In this case, the sample chamber is embedded in an oversized tetrahedron machined from pyrophyllite, and sample compression occurs by collapse of the tetrahedron. The structure is assembled so that the anvils uniformly contact corresponding faces of the sample block. Pressure is raised by advancing the rams, compressing the block. An internal electrical heating system may be used to generate high temperatures for geophysical studies. Experimentation requiring electrical leads is routine, and x-ray measurements have been

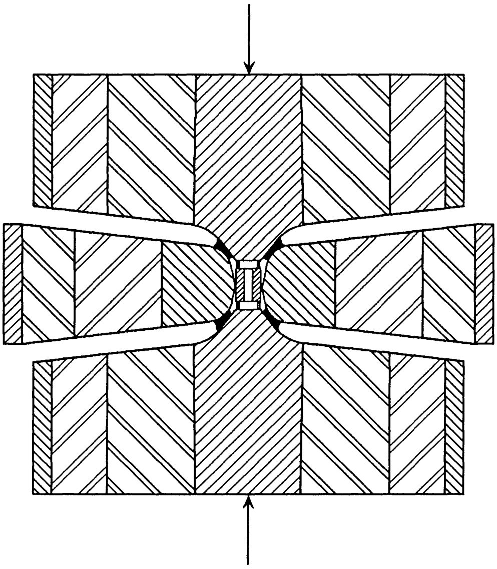

FIG. 4. Cross section of the General Electric "belt" apparatus. Note the tampered pistons and cylinders.

made by bringing the beams through the gasket material in the spaces between the anvils. More recently other multiple-anvil configurations have appeared, using six anvils in a cube configuration and, notably, an ingenious octahedral design involving eight relatively simple individual core anvils in the form of cubes with truncated corners enclosing a regular octahedron (Walker *et al.*, 1990). These devices provide electrical resistance heating of samples within the pyrophyllite octahedron. They are used extensively in geochemical studies.

1.5 Diamond-Anvil Cells (DACs)

Even though diamond-anvil cells are examples of the "anvil" format, a separate category is reserved for them because their application and refinement have been so extensive as to make them qualitatively different from other anvil systems (see Fig. 5). For example, they provide the highest static laboratory pressures. Commonly used techniques provide pressures in the 40-GPa range, while pressures above 400 GPa (Ruoff *et al.*, 1990) have been reported in some experiments. Laser heating has made possible studies to temperatures above several thousand kelvins for times less than a few milliseconds, together with pressures of several tens of GPa (Bassett and Weathers, 1987). In addition, a wide variety of dependent variables may be measured, not all, however, to the same ultrahigh pressures. There are several excellent and useful reviews available (Jamieson *et al.*, 1959; Jayaraman, 1983, 1986; Jephcoat *et al.*, 1987; Dunstan and Spain, 1989; Spain and Dunstan, 1989), and advances in technique appear very rapidly.

The fundamental reason that diamond is appropriate is that it has the highest compressive strength among known materials. The additional benefits of reasonable optical and

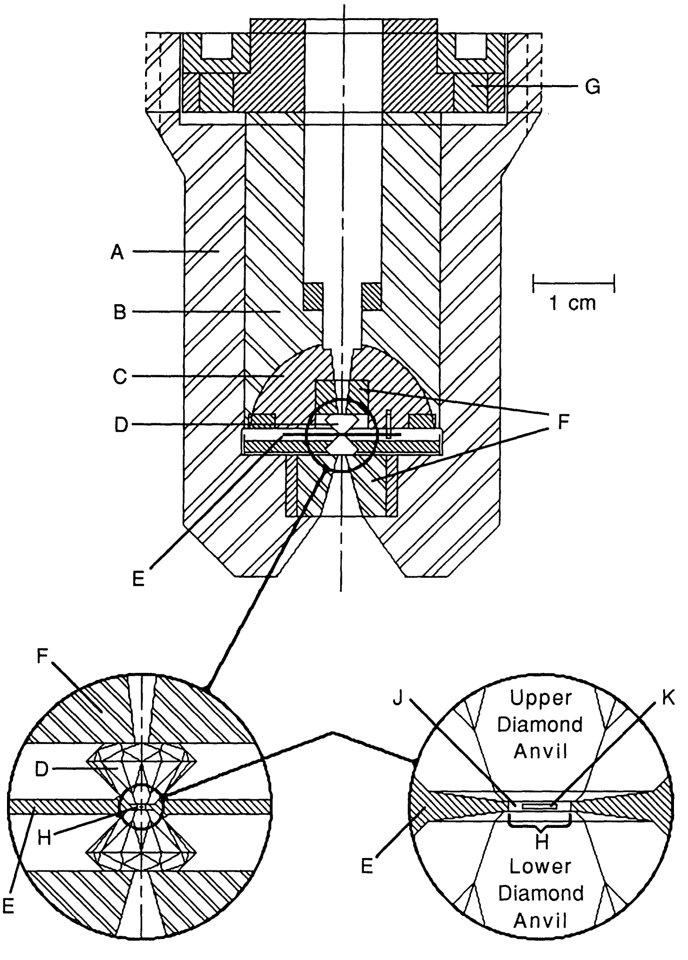

FIG. 5. Diamond-anvil cell, showing whole cell including screws used to generate the force between the diamonds, and successively enlarged details of the high-pressure regions. *A*, the cylinder, closely fitted to *B*, the sliding piston; *C*, the adjustment to make the anvil faces parallel; *D*, diamond anvil; *E*, gasket; *F*, tungsten carbide backing field; *G*, machine screws used to apply force to the diamonds; *H*, hole in gasket, to contain sample, pressure fluid, and ruby; *J*, ruby chip for pressure measurement; and *K*, sample. Most often the sample together with the ruby fills the entire gasket hole.

x-ray transparency over wide spectral ranges have made it a material of choice. Presence of a mature technology from the gemstone industry for shaping and polishing diamonds has also been a major positive factor. The advance to higher pressures has even seen selection of natural diamonds having appropriate impurities, e.g., nitrogen platelets, to provide higher strength. Design of details of the highly stressed tip of the anvil has advanced in a way reflecting collective experience. The ever-diminishing contact areas as attempts are made to reach even higher pressures reflect Auerbach's principle, which suggests that larger specific stresses can be applied without fracture to smaller objects than to larger ones constructed of the same material (Seal, 1984). Parallel development of lasers for optical studies and intense synchrotron sources for x-ray diffraction have helped mitigate the problems of diminishing sample volumes that have accompanied the advance to higher pressures. Referring to Fig. 4, the diamond-anvil cell consists of two diamonds, typically $\frac{1}{4}$ carat each, having the general form shown, mounted in a frame that permits alignment of the flat mutually contacting faces in both position and orientation. In addition, the frame provides a means of forcing those surfaces against one another. A substantial number of different configurations exist, but they share the essential features listed. Originally, samples to be studied were simply compressed between the small surfaces formed by grinding flats onto the culets (pointed ends) of two "brilliant cut" diamond gem stones mounted in opposition. Even this primitive process permitted x-ray-diffraction (Jamieson *et al.*, 1959) and infrared-absorption (Weir *et al.*, 1959) measurements to pressures of about 3 GPa, although pressures were neither very accurately determined nor very uniform. Subsequently, the "gasket" was developed at the National Bureau of Standards (now NIST) to contain the sample material, a pressure-transmitting medium (sometimes), and a tiny chip of ruby to serve as pressure sensor (Piermarini and Block, 1975). The procedure for preparing the system for experiment is as follows: first, position the diamonds and adjust their orientations to make the faces parallel; then, place a thin sheet of material (typically 300 μm thick) as the gasket between the faces and indent it with the diamonds. The indented gasket is removed and a small hole drilled in its center. The gasket is replaced on one of the diamonds; the sample, the pressure fluid, and a ruby chip are put in the hole; and the other diamond is brought into place. The pressure is raised by increasing the force pushing the diamonds together against the gasket-sample assembly. These developments and the addition of profiling (bevels) by the Carnegie group (Mao *et al.*, 1979) more or less completed the basic design shown in Fig. 5, which represents the crucial core of the DAC.

1.5.1 Pressure Measurement in Diamond-Anvil Cells. The earliest work depended on observation of phase transitions such as those in bismuth near 2.5 GPa and in various semiconductors. The invention of the ruby fluorescence method made the DAC a much more quantitative instrument (Barnett *et al.*, 1973). In this method, the pressure-dependent value of wavelength of sharp fluorescence lines in ruby (chromium-doped sapphire) crystal chips within the pressurized volume is measured. This fluorescence may be laser excited, and the wavelength measured using relatively straightforward spectroscopy to an accuracy of about 0.05 GPa at low pressure. The accepted method of calibration in the very high-pressure domain lies in connecting x-ray–determined equations of state of certain solids, for example gold and copper, with corresponding pressure-volume relations inferred from shock-wave studies—that is, setting $P_{\text{ruby}}(V) = P_{\text{shock}}(V)$, where the left-hand side of the equation involves static x-ray measurements of volume of a reference sample material together with the ruby fluorescence wavelength, while the right-hand side is a 300-K pressure-volume isotherm inferred from shock-wave compression experiments on the same material (Mao *et al.*, 1978). In a recent paper reporting pressures as high as 416 GPa, the x-ray measurements of volume of molybdenum and tungsten have *per se* been taken directly as the piezometric property to be calibrated by shock-wave equations of state (Ruoff *et al.*, 1990) at low pressures (<100 GPa). There is substantial agreement about the ruby scale, but its use in the domain above 200 GPa is the object of intense study and some controversy at this time (Ruoff *et al.*, 1991). Accurate measurement of pressure at high temperature remains a difficult problem, partly because of thermal effects on the ruby wavelength and increased spectral linewidth. Space limitations of this article force us to provide little more than a listing of the measurements that can be made in diamond-anvil cells and to give either reviews or recent articles as references.

1.5.2 X-Ray Studies. X-ray diffraction techniques, which may (in principle at least) uncover both crystal structures and equations of state, form a particularly important component of high-pressure research. Fortunately, diamond is a low–atomic-number material relatively transparent to x rays. For example, in pure diamond the $1/e$ intensity decay distance for molybdenum $K\alpha$ radiation is about 4 mm. Use of x rays as a probe in diamond pressure-cell studies dates from the earliest (Jamieson *et al.*, 1959) through some of the most recent work (Ruoff *et al.*, 1990) (which reports measurements to 416 GPa). Availability of synchrotron sources and energy-dispersive x-ray analysis have reduced data collection times and increased the general capability of the techniques by permitting very fine collimation ($\sim$4 μm) of the incoming beam (Ruoff *et al.*, 1990), and hence corresponding spatial resolution within the sample. Measurements reported in the highest pressure regimes have been made on relatively hard materials such as copper, gold, molybdenum, and tungsten. It is much more difficult to generate very high pressures in "soft" materials such as solid hydrogen and helium. For example, x-ray lattice parameter measurements in solid hydrogen (which is both "soft" and a weak x-ray scatterer) to 26.5 GPa represent a real tour de force (Hemley *et al.*, 1990).

1.5.3 Optical Studies. Typical natural diamonds used as anvils are transparent through most of the optical region of the spectrum. Specially selected diamonds at low pressures may be transparent from the near ultraviolet (5.5 eV) through 4 μm and from 5.5 to 10 μm in the infrared (Ferraro, 1984). However, most of the diamonds used for anvils are natural stones having a variety of impurities, nitrogen in particular, which dominate the optical properties. The optical absorption due to the impurities in fact forms the basis of classification of diamond types. The most common (Type I) diamonds only reach about 3.5 eV in the ultraviolet and show strong absorption in the 7–10-μm region. Optical transmission and reflectivity measurements as well as fluorescence and Raman and Brillouin scattering spectroscopies have been carried out. Raman spectroscopy, because it may be excited in the tiny samples by intense, fixed-frequency lasers, has been the most prominent of these techniques. Infrared spectroscopy suffers somewhat from the small sample geometry but, even so, has contributed significantly to high-pressure chemistry (Ferraro, 1984); and availability of synchrotron sources of infrared radiation promise to expand this area still further (Hanfland *et al.*, 1992). Reflectivity measurements in the visible and infrared have been extensively used as a diagnostic technique in recent studies of metallization of condensed permanent gases (Reichlin *et al.*, 1989). In addition to the various optical spectroscopies, microscopic imaging has been used to study growth and transformations of crystals at high pressures as well as direct estimation of volume changes under pressure. The combination of microscopy, video cameras, and recorders with diamond-anvil pressure cells has been especially useful in this regard.

1.5.4 Electrical Transport. Electrical conductivity measurements, historically an important probe in solids, have gained a new urgency in dealing with critical questions of the insulator-metal transition at high pressures. The status to about 1985 is reported in Jayaraman's review (Jayaraman, 1986). Most contemporary designs are based on use of MgO or alumina, Al_2O_3, either in sputtered form or as a powder in a matrix, as the stressed insulating material through which the conductors are led. In some investigations, microlithography has been used to form an array of electrical leads on the surface of the diamond itself (Grzybowski and Ruoff, 1984). Using the latter with Al_2O_3 in a sodium chloride matrix, conductivity measurements have been reported to 70 GPa in cryocrystals (van Straaten and Silvera, 1987). Major problems deal with open circuits in the stressed electrical wires and with the relatively low strength of insulating materials when compared with metals as gaskets.

1.5.4.1 Miscellaneous Techniques—Magnetic, Mössbauer, Nuclear Magnetic Resonance. The small sizes of samples in DACs make static magnetic measurements difficult, and in fact most of the magnetic susceptibility work has used larger-scale piston-cylinder pressure systems. Nonetheless, external coils have been used to measure static susceptibility using a SQUID (superconducting quantum interference device) detector to measure the small changes in magnetization (Webb *et al.*, 1976). Nuclear magnetic resonance (NMR) (Lee *et al.*, 1992) and electron paramagnetic resonance (EPR) (Bromberg and Chan, 1992) techniques have been used with DACs to pressures 5.2 and 10 GPa, respectively. ^{119}Sn Mössbauer measurements have been reported to about 29 GPa (Sterer *et al.*, 1990). These techniques have not yet seen as widespread application as x-ray and optical techniques, but do indicate the great versatility of the diamond-anvil cell.

2. DYNAMIC TECHNIQUES—SHOCK WAVES

Intense compression waves called shock waves may be generated in materials by explosives, by impact with high-velocity projectiles, or by absorption of intense light pulses (Holmes *et al.*, 1989; Cottet *et al.*, 1986). Shock pressures can be very high, exceeding 600 GPa. The high pressures in shocked material are accompanied by very high temperatures, ~2000–15 000 K. Shock waves are a transient phenomenon lasting typically $\sim 10^{-6}$ s. This requires data acquisition systems capable of measuring and recording physical phenomena on correspondingly short time scales. In spite of these difficulties, an impressive variety of measurements are made on shock-compressed material (see Solids, High-Pressure Effects in). Fundamental among these are measurements of pressure-volume-temperature (*PVT*) equations of state of materials. These data are based on the Rankine-Hugoniot equations that follow from conservation of momentum, mass, and energy in the response of the system to the impact. The equations take a simple form relating the thermodynamic variables pressure (P), volume (V), and energy (E) to the observable quantities shock propagation speed u_s and the particle speed (of the shocked material) u_p:

$$P_H - P_0 = P_0(u_s - u_0)(u_p - u_0),$$

$$V_H - V_0 = -(u_p - u_0)/(u_s - u_0),$$

$$E_H - E_0 = \tfrac{1}{2}(P_H + P_0)(V_0 - V_H). \qquad (4)$$

The subscripts 0 and H refer to initial and final conditions. The shock speed u_s is measured by timing the shock propagation over a known distance. The particle velocity is either inferred from collision properties of the impactor or obtained by observation of free-surface velocity as the shock wave emerges from the shocked material. Fast and accurate timing as well as well-defined planar shock fronts are required to produce accurate *PVT* data. Each shot, i.e., shock experiment, generates one point of the equation of state.

Other measurements that have been made under shock compression conditions include electrical resistance, laser x-ray diffraction, and spontaneous and coherent Raman scattering. Shock waves are also emerging as significant tools in materials synthesis and processing because the rapid quench rate can permit recovery of high-pressure phases such as diamond.

GLOSSARY

Cemented Tungsten Carbide: A composite material formed from tungsten carbide (WC) powder in a cobalt metal matrix.

Diamond: A tetrahedrally coordinated form of nominally pure carbon. Many of the characteristics of diamond crystals are dominated by impurities, e.g., nitrogen, which particularly affects its optical properties. The familiar "brilliant"-cut gem diamond has proved to be remarkably close to the ideal form for a diamond anvil if a small flat surface is cut at the pointed end of the stone (cf. Fig. 4).

Pressure Units: Pressure has units of force per unit area, or equivalently energy per unit volume. The SI unit of pressure is the pascal, Pa, defined to be one newton per square meter which is equivalent to one joule per cubic meter. The most commonly used high-pressure unit is the gigapascal (GPa), which is 10^9 Pa. The kilobar is 10^{-1} GPa. In English units, 1 GPa is about 9872 atm or 145 000 lb/in.^{2}.

Pyrophyllite: A naturally occurring hydrous aluminum silicate sometimes called Tennessee Grade A Lava.

Ruby: Chromium-doped sapphire crystal (see Sapphire below).

Sapphire (Corundum): A strong, hard (9 on Mohs scale) transparent mineral having the chemical formula Al_2O_3. In pure form it is transparent deeper into the ultraviolet region of the spectrum than diamond.

INTRODUCTION

The term "holography" refers to the procedure of reconstructing the amplitude and phase of a wave field from the recorded interference pattern between the wave and a known reference wave. Although the discipline is most commonly associated with optical waves and, in particular, with radiation from visible lasers, the wave field need not be an optical wave and can, for example, be an acoustic wave or even a quantum-mechanical (Schrödinger) wave function. The field of holography owes its origins to Gabor (1949, 1951), who called the holographic process "wave-front reconstruction," a term that is actually more descriptive than its popularized replacement term "holography." This latter term grew out of Gabor's usage of the term "hologram" for the recorded interference pattern, a term he chose to indicate that the interference pattern encodes the "whole message" contained in the field being recorded in the hologram.

Gabor's original application of holography was in electron microscopy of semitransparent objects. His goal was to perform electron microscopy via a two-step procedure, where in the first step a hologram of the electron wave field transmitted by the object was recorded on a photographic plate. This hologram consisted of the interference pattern between the electron wave incident on the object being imaged and the wave scattered by the object. In the second step the developed photographic plate (the hologram) was illuminated by a well-filtered and collimated thermal light source to generate an optical wave that could be shown to be a magnified and slightly distorted version of the original scattered electron wave. The overall procedure thus effected a "wave-front reconstruction," and the reconstructed wave front could be directly viewed to reveal a magnified virtual image of the original object. The major advantage of the imaging process over conventional electron microscopy was that it employed no lenses and, hence, was largely free of image defects introduced into electron microscopy by unavoidable aberrations of electron lenses. This advantage of holography over conventional imaging via lenses has led to the name "lensless photography" for the process of holographic image formation.

After the introduction of the laser in the 1960s the theory and applications of optical holography developed rapidly. One of these applications was in acoustics (Hildebrand and Brenden, 1972; Mueller, 1971), where the idea was somewhat analogous to Gabor's original idea:

1. make a hologram of an acoustic wave and
2. reconstruct the hologram with an optical wave.

What might appear somewhat odd about this idea is that Gabor was driven to holography by the fact that fundamental physics prevents one from directly measuring the phase of an electron wave, so that holography is *essential.* This is not the case in acoustics where both the amplitude and phase of an acoustic wave can, in principle, be directly measured. However, it must be remembered that although the measurements are possible in principle, they were, at the time of this early work, difficult in practice, and this fact provided the impetus for the work. Even with the advent of accurate acoustic detectors and detector arrays this original form of acoustic holography remains valuable and, indeed, forms the basis for one form of acoustic microscopy employed today (Way and Kessler, 1990).

With the advent of modern digital computers and microprocessors the discipline of holography rapidly expanded well beyond its original boundaries of being a procedure for wave-front reconstruction. Indeed, in today's usage the term "holography" encompasses the entire process of converting measured field data to an "image" of the source of the field. In this evolution the discipline, especially in acoustics and electromagnetics, has also shifted in emphasis away from its original form as an essentially experimental method for reconstructing wave fronts to an essentially computational method for reconstructing the three-dimensional structure of sources and scatterers from field data. As such the discipline of acoustical holography is today more closely associated with coherent imaging, inverse scattering, and tomography than it is with conventional optical holography.

1. FUNDAMENTALS OF HOLOGRAPHY

1.1 Acoustic Wave Equation

The wave fields employed in acoustical holography are narrow-band pressure or displacement waves that can be well approximated by purely monochromatic waves of the general form

$$u(\mathbf{r},t)=\Re\{U(\mathbf{r})e^{-i\omega t}\}, \tag{1}$$

where $\Re\{\cdot\}$ denotes the real part of the quantity in brackets, and ω is the acoustic frequency, t is the time, and $\mathbf{r}$ denotes position. The space-dependent amplitude U is a complex-valued scalar wave field that satisfies the inhomogeneous Helmholtz equation

$$(\nabla^2+k^2)U(\mathbf{r})=\rho(\mathbf{r}), \tag{2}$$

where $k=2\pi/\lambda$ is the wavenumber, λ is the wavelength, and ρ represents the space-dependent amplitude of a monochromatic acoustic source $q(\mathbf{r},t)=\Re\{\rho(\mathbf{r})e^{-i\omega t}\}$. The Helmholtz equation (2) assumes that the acoustic wave propagates in a homogeneous fluid of constant density and velocity and is purely monochromatic with frequency $\omega=ck$, where c is the acoustic velocity of the medium.

In certain applications discussed later, broad-band (pulsed) acoustic wave fields are employed rather than narrow-band fields of the form (1). The following discussion applies only to "traditional" holograms constructed with nearly monochromatic wavefields of the form (1).

The source term ρ in Eq. (2) generally represents a secondary (induced) source generated by the interaction of an incident (insonifying) wave with an object placed in the background medium. There are basically two types of objects of interest: surface scatterers and penetrable scatterers. Surface scatterers interact with the incident wave only on their surface, while penetrable scatterers allow the incident wave to penetrate into the interior of the object. A perfectly reflecting acoustic object is an example of a surface scatterer, while an acoustic object having different acoustic parameters from those of the background medium is an example of a penetrable scatterer.

Surface scatterers are represented by induced sources of the general form

$$\rho(\mathbf{r})=\tau(\mathbf{r})\delta(\xi(\mathbf{r})), \tag{3}$$

where τ is a quantity that represents the scattering strength at the point $\mathbf{r}$ and that depends, in general, on both the object and the incident wave, $\delta(\cdot)$ is the one-dimensional Dirac delta function, and $\xi(\mathbf{r})=0$ defines the surface of the object. Penetrable objects are defined via a *scattering potential* $V(\mathbf{r})$ via the equation

$$\rho(\mathbf{r})=V(\mathbf{r})U(\mathbf{r}), \tag{4}$$

where U is the acoustic wave field within the interior of the object. The scattering potential is related to the acoustic parameters of the object through the equation

$$V(\mathbf{r})=k^2[1-n^2(\mathbf{r})], \tag{5}$$

where k is the wave number of the background and $n(\mathbf{r})$ is the (generally complex) *index of refraction* of the object. The index of refraction can be further expressed in terms of fundamental acoustic parameters such as the bulk modulus and density of the object and for nonabsorbing objects is purely real and equal to the ratio of the background velocity c to the phase velocity of the object.

The induced-source representation of a penetrable acoustic object given in Eqs. (4) and (5) tacitly assumes that the object's density is constant and equal to that of the fluid background in which it is embedded. For variable-density objects the relationship is somewhat more complicated and, in particular, depends on the gradient of the object's density distribution and the gradient of the acoustic field U within the volume of the object (Devaney, 1983). We will restrict our attention to the simpler case of constant-density objects throughout this article since the incorporation of variable density does not affect the holographic process in any significant way (Devaney, 1983).

An important class of penetrable scatterers in acoustic holographic applications is composed of *semitransparent* objects. Such objects are characterized by an index of refraction profile $n(\mathbf{r})$ that is pointwise close to that of the background so that $|V(\mathbf{r})| \ll k^2$. The wave field $U(\mathbf{r})$ within the interior of such objects can be approximated by the incident wave $U_{\text{in}}(\mathbf{r})$ with the result that the induced source simplifies to

$$\rho(\mathbf{r})\approx V(\mathbf{r})U_{\text{in}}(\mathbf{r}). \tag{6}$$

The importance of approximation (6), known as the *Born approximation* (Cowley, 1984), stems from the fact that the induced source depends on the incident wave in a known and simple way. This allows imaging of the scattering potential associated with such sources to be performed in a simple and elegant manner (see Sec. 4).

1.2 Forming the Hologram

In its traditional form holography is a two-step procedure where in the first step the intensity (amplitude squared) of a wave field is recorded over some surface and in the second step a wave-front reconstruction is performed from the intensity data. The wave field being recorded consists of the sum of a known "reference wave" U_r and an "object wave" U_o associated with an induced source. The recorded intensity distribution (hologram) includes an interference pattern between the reference and object waves in which is encoded the phase of the object wave, and the goal of the holographic reconstruction procedure is to regenerate this phase and hence a reconstruction of the object wave from the recorded hologram.

The object wave U_o is usually generated by the scattering of an incident wave from a surface or penetrable scatterer and can be represented in the form

$$U_o(r)= \int d^3r'\rho(\mathbf{r}')G(\mathbf{r}-\mathbf{r}'), \tag{7}$$

where ρ is an induced source of the general form given in Eq. (3), (4), or (6), and $G(\mathbf{R})$ is the outgoing-wave Green's function for the Helmholtz equation. The incident wave is employed as the reference wave in Gabor holograms while off-axis holograms (see below) employ a separate wave for this purpose. The formation of a Gabor hologram is illustrated in Fig. 1, where a penetrable acoustic object is immersed in a liquid bath and insonified by a diverging spherical wave generated by a point transducer. In this case the transducer represents a primary source that generates both the wave incident on the object and the reference wave for the hologram (the incident and reference waves are the same). The total field is the sum of the spherical reference wave and an object wave (scattered

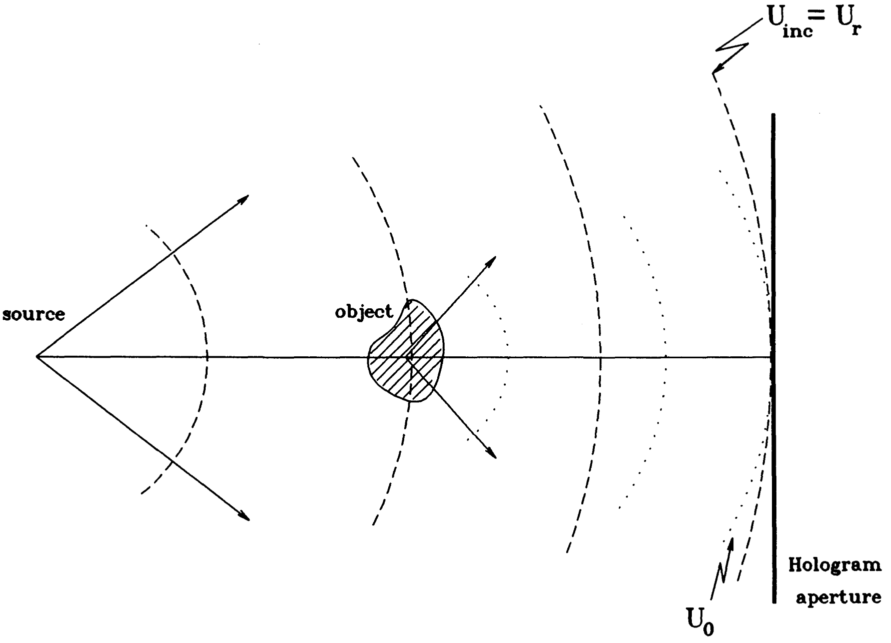

FIG. 1. Gabor hologram constructed using a spherical wave as both the wave incident on the object and the reference wave.

wave) generated by the scattering of the spherical wave from the object.

In its most basic form a hologram of the wave field $U = U_r + U_o$ is simply the intensity of this wave over some measurement surface and can be written in the form

$$\begin{aligned} I(\mathbf{r}_0) &= U^*(\mathbf{r}_0)U(\mathbf{r}_0) \\ &= I_r(\mathbf{r}_0) + I_o(\mathbf{r}_0) + U_r^*(\mathbf{r}_0)U_o(\mathbf{r}_0) \\ &\quad + U_r(\mathbf{r}_0)U_o^*(\mathbf{r}_0), \end{aligned} \tag{8}$$

where $\mathbf{r}_0$ denotes position over the measurement surface (e.g., hologram plane), the superscript asterisk * denotes the complex-conjugate operation, and I_r and I_o are the intensities of the reference and object waves, respectively. In writing Eq. (8) we have tacitly assumed that the wave field is perfectly spatially coherent over the hologram aperture. If this condition were violated, the interference terms as given by the last two terms in the equation would be modified and, in particular, would be replaced by the real part of the so-called *spatial coherence function* (Born and Wolf, 1980) between the reference and object wave fields. The narrow-band wave fields employed in acoustical holography are generated by sources having highly stabilized phases and are thus highly spatially and temporally coherent, so that Eq. (8) is a good approximation to the intensity distribution of an acoustical hologram.

The success of the holographic process depends on the presence and structure of the interference terms in the intensity distribution recorded in the hologram. In the best case the reference and object waves are perfectly coherent as assumed in Eq. (8), while in the worst case the two fields are perfectly incoherent resulting in no interference terms and hence no "hologram" and no possibility of wave-front reconstruction. Even if the field is perfectly coherent, the success of wave-front reconstruction is not guaranteed and depends on the relationship between the reference and object waves over the measurement surface.

1.3 Wave-Front Reconstruction

The second step in the holographic process is wave-front reconstruction. In Gabor's original work and in early acoustic and optical holography this was achieved in an analog fashion by physically illuminating the recorded hologram by an optical wave to generate the wave-front reconstruction. Consider,

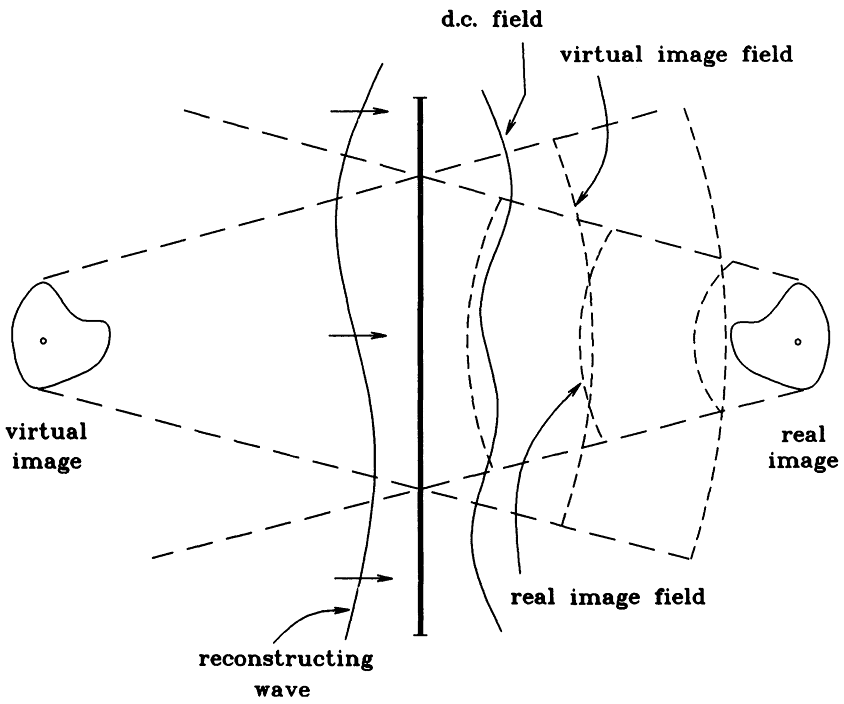

FIG. 2. Three components of the reconstructed wave field from a hologram.

for example, the situation illustrated in Fig. 2 where an optical wave is incident upon a planar transparency that has a transmittance function equal to the intensity distribution defined in Eq. (8). Within the scalar-wave Kirchoff approximation the wave field generated over the transparency plane by the interaction of the reconstructing (illuminating) wave with the hologram is equal to the product of the transmittance function and illuminating wave and is given by (Born and Wolf, 1980; Goodman, 1968)

$$\begin{aligned}\psi(\mathbf{r}_0) &= I(\mathbf{r}_0)U_r(\mathbf{r}_0)\\ &= [I_r(\mathbf{r}_0)+I_0(\mathbf{r}_0)]U_r(\mathbf{r}_0)+I_r(\mathbf{r}_0)U_o(\mathbf{r}_0)\\ &\quad + U_r^2(\mathbf{r}_0)U_o^*(\mathbf{r}_0),\end{aligned} \tag{9}$$

where we have selected the reconstructing wave to be the original reference wave and have, for the moment, neglected the difference between the acoustic and optical wavelengths.

The wave field ψ produced over the hologram surface is seen to consist of three terms:

1. the reconstructing wave spatially modulated by the sum of the intensities of the original object and reference waves,
2. the original object wave spatially modulated by the intensity of the reconstructing wave, and
3. the complex conjugate of the object wave spatially modulated by the square of the reconstructing wave.

Each of these components of the total wave ψ propagates away from the hologram plane in accordance with the wave equation and contributes to the total wave field observed, for example, by a viewer stationed to the right of the hologram. For virtually all cases of interest the intensities I_r and I_o are slowly varying functions of position over the hologram aperture while the phases of the reference and object waves can vary rapidly over this plane. It then follows that the character of the propagated components of the wave form are largely determined by the phases of these components on the hologram plane. The first term has a phase across the hologram equal to the phase of the reconstructing wave and thus would appear to a viewer stationed to the right of the hologram as a slightly distorted form of the reconstructing beam. The second term has a phase equal to the phase of the original object wave and thus would result in a wave that would appear to be very similar to the original object wave to a viewer. The third term is equal to the product of the square of the complex amplitude of the reference wave with the complex conjugate of the object wave. The complex-conjugate operation on the object wave has the effect of converting an outgoing (diverging) wave to an incoming (converging) wave. This third term then will result in a wave that focuses in the region to the right of the hologram. The three components of the reconstructed wave are illustrated in Fig. 2.

The three components of the reconstructed holographic field are termed the zero-order and first-order virtual and first-order real image fields, respectively. The success of the holographic process depends on the extent to which these components can be separated and, in particular, on the degree to which the first-order virtual image field can be isolated. Ideally, one would like the process to generate only the first-order virtual (or, in some applications, the first-order real) field. One limitation of Gabor's original (in-line) hologram is that these components achieve poor spatial separation so that a viewer looking into the reconstructed hologram would be distracted by the presence of the zero-order and first-order real image fields that would appear as background noise. The zero-order image field is sometimes referred to as the "dc" image field while the pair of first-order fields are sometimes termed the "twin" image fields.

The presence of the modulating factors associated with the reference and reconstructing wave fields in the reconstructed wave field over the hologram aperture introduce distortions into the first-order real and virtual image fields. These distortions manifest themselves as defects in the images generated by these fields and, in particular, cause the images to be stretched (or compressed) in directions orthogonal to the hologram plane (longitudinal magnification) and in directions lying in this plane (transverse magnification). The longitudinal and transverse magnification factors depend on the particular reference and reconstructing wave forms and on the ratio of the wavelengths of the two fields used in the holographic process. For the simplest case of plane reference and reconstructing waves, the transverse magnification is unity and the longitudinal magnification is constant and equal to $M_l = \pm\lambda_1/\lambda_2$, where λ_1 is the wavelength of the original wave field being recorded and λ_2 the wavelength of the reconstructing wave, and where the minus sign indicates that the image is formed in the space region occupied by the object (virtual image). The fact that the longitudinal magnification is negative for the real image means that this image is *pseudoscopic*, i.e., is mirror imaged relative to the hologram plane.

For the case of acoustic holography with optical reconstruction, the magnitude of the longitudinal magnification is on the order of 10^3 so that the real and virtual images experience considerable distortion in the reconstruction process. One way to minimize this distortion is to adjust the scale in the recorded hologram and thus artificially introduce a lateral magnification to balance the longitudinal magnification. Unfortunately, this process results in overall longitudinal and lateral magnifications having magnitudes on the order of 10^{-3} and hence in considerable demagnification and the consequent need for further optical imaging via a conventional imaging system (e.g., microscope). The use of direct optical reconstruction of acoustic holograms is thus of limited use in imaging applications.

1.4 Hologram Classification

Holograms are classified according to the manner in which they are recorded. There exist two major types of holograms termed, respectively, the Gabor or "in-line" hologram and the Leith-Upatnieks or "off-axis" hologram (Goodman, 1968; Leith and Upatnieks, 1962). Within each of these major categories the hologram is further classified to be a *Fresnel hologram* if it is recorded in the Fresnel region of the object or a *Fraunhofer hologram* if it is recorded in the Fraunhofer region or far field of the object. The Fraunhofer region of an object is roughly defined to be at distances $l \gg ka^2$, where $k=2\pi/\lambda$ is the wave number and a is the outer radius of the object (Goodman, 1968). Fraunhofer holograms are sometimes referred to as *Fourier-transform holograms* since the object wave in the Fraunhofer region (far field) is proportional to the spatial Fourier transform of this wave over a plane surface in the near field of the object (Goodman, 1968). Because of the relatively long wavelength of acoustic waves it is also possible to record acoustic holograms in the near field of an object (Williams and May-

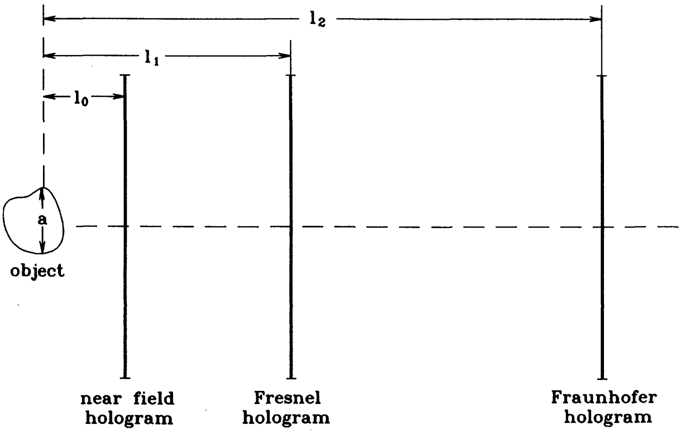

FIG. 3. A near-field hologram (left) is recorded at distances $l_0 \approx \lambda$ that are on the order of the acoustic wavelength, a Fresnel hologram (center) is recorded at intermediate distances $\lambda \ll l_1 \ll ka^2$, and a Fraunhofer hologram (right) is recorded in the far field $l_2 \gg ka^2$, where k is the wavenumber and a is the maximum transverse dimension of the object.

nard, 1980). Near-field holograms yield a reconstruction of the object field that includes evanescent plane-wave components of this field and can lead to "superresolution" in coherent imaging applications. We show in Fig. 3 geometries for the different types of holograms.

The Leith-Upatnieks off-axis hologram differs from the Gabor hologram in that the reference wave is specially selected to result in maximum separation between the three images generated in the reconstruction step of the holographic process. This is achieved by employing separate wave fields to illuminate the object and to act as the reference wave. Strictly speaking, the object wave in the Leith-Upatnieks hologram then consists of the sum of the wave illuminating the object plus the scattered wave. However, the object wave is usually generated in a backscattering configuration in off-axis holography so that the illuminating wave is effectively eliminated from the recorded hologram and the object wave then reduces to the scattered-field component defined in Eq. (7). The possibility of using a reference wave separate from the illuminating wave was not considered by Gabor because of the limited coherence of natural light sources and was realized only with the advent of the highly coherent optical laser. As mentioned earlier, narrow-band acoustic waves are by their very nature almost perfectly coherent so that generation of off-axis acoustic holograms poses no problem.

The freedom of selecting the reference wave in the off-axis hologram allows for the possibility of achieving good separation in the image fields generated in the reconstruction step of the holographic process. Consider, for example, an off-axis hologram constructed over the plane $z=0$ with a plane reference wave $\exp(ik\mathbf{s}_r \cdot \mathbf{r})$ propagating in the direction defined by the unit vector $\mathbf{s}_r$ and reconstructed with a plane wave $\exp(ikz)$ propagating normal to the surface of the hologram. The reconstructed wave field over the hologram surface is then given by

$$\psi(\mathbf{r}_0) = [I_r(\mathbf{r}_0) + I_o(\mathbf{r}_0)] + U_o(\mathbf{r}_0)e^{-ik\mathbf{s}_r \cdot \mathbf{r}_0} + U_o^*(\mathbf{r}_0)e^{ik\mathbf{s}_r \cdot \mathbf{r}_0}, \tag{10}$$

where $\mathbf{r}_0 = (x,y)$ denotes a point on the hologram surface (the plane $z=0$). The phases of the first-order real and virtual image fields are seen to include linear phase shifts of $k\mathbf{s}_r \cdot \mathbf{r}_0$ and $-k\mathbf{s}_r \cdot \mathbf{r}_0$, which cause these image fields to propagate as beams along the directions $\mathbf{s}_r$ and $-\mathbf{s}_r$, respectively, while the zero-order field propagates in the direction of the reconstructing wave. This then results in greater image separation than is possible with a Gabor hologram, where $\mathbf{s}_r = \mathbf{0}$ and the three image fields all propagate in more or less the same direction.

Good image-field separation will also occur if the off-axis hologram is reconstructed with either the original reference wave or the complex conjugate of this wave. In the first case a high-quality image of the virtual image field will be obtained while in the second case a high-quality image of the real image field will be obtained. Employing the reference wave or its complex conjugate as the reconstructing wave has certain advantages in optical holography due to the thickness of photographic emulsions (Goodman, 1968).

2. IMPLEMENTATION OF ACOUSTIC HOLOGRAPHY

2.1 Scanned Acoustical Holography

In this most basic form of acoustical holography the amplitude and phase of a spatially stationary acoustic wave field are recorded with a small (ideally a point) transducer that physically scans a measurement plane (Hildebrand and Brenden, 1972; Mueller, 1971). The recorded acoustic wave field is then converted into an intensity distribution on a photographic plate or film via a synchronously scanned light source as illustrated in Fig. 4. The reference wave in this type of hologram can be an actual acoustic primary wave that interferes with the acoustic object wave over the measurement surface (hologram surface) or can be electronically added at the output of the transducer prior to input into a square law detector (e.g., the photographic film). In either case an optical hologram is produced that has a transmittance function of the general form (8). The reconstruction is then performed using an optical reconstructing wave much in the same way that Gabor employed an optical wave to reconstruct holograms of electron wave fields.

An alternative form of scanned acoustical holography employs amplitude demodulation followed by low-pass filtering to convert the detected high-frequency, time-dependent, acoustic object wave to its spatial amplitude $U_o(\mathbf{r}_0)$ over the measurement plane. In this configuration no acoustic or electronic reference wave is used and the spatial amplitude of the object wave is directly stored on computer disk for later (digital) processing to generate a computer reconstruction of the acoustical wave field. In this form the use of the term "holography" might appear questionable since no reference wave is employed and the complex amplitude of the object wave is, in effect, directly measured. However, the process whereby the recorded object wave is "reconstructed" is mathematically the same as in holography with reference waves so that it is reasonable to consider this also to be a form of holography. An alternative and perhaps more accurate term for the process might be "synthetic aperture imaging" (cf. Sec. 5.1), although this latter term is usually reserved for reflection holography where the same transducer is employed both to transmit the illuminating wave and to detect the object (scattered) wave (Goodman, 1968).

A method closely related to scanned acoustical holography is fixed-transducer-array acoustical holography. In this method the hologram is not physically scanned with a single transducer but rather is recorded simultaneously with an array of transducer elements. The advantage of this method is speed of data acquisition, while its principal disadvantage is limited spatial resolution. In particular, the centers of the individual elements comprising the transducer array are physically separated by some minimum distance, and this distance then imposes a lower limit to the sample spacing employed in the recording of the hologram. Moreover, unless the separate array transducer elements are contiguous with each other, undersampling of the acoustic field being recorded can occur and result in aliasing being introduced in the reconstruction step.

FIG. 5. System for optical reconstruction of an acoustical hologram encoded in the surface deformation induced at a liquid–gas interface. The optical system generates an image field that is directly proportional to the acoustical intensity distribution over the interface.

2.2 Liquid-Surface Acoustical Holography

This form of acoustical holography makes use of the fact that an acoustic wave field propagating in a liquid bath induces a physical deformation at the liquid surface whose height is proportional to the intensity of the acoustic field. This deformation then acts as an optical phase grating to an incident optical wave and can thus be imaged using a specialized optical imaging system as illustrated in Fig. 5. The optical system converts the phase perturbation induced on the incident optical plane wave to an optical image field whose intensity distribution over an exit pupil is proportional to this phase. The optical system can be based on the central dark ground method of observation, the Schlieren method, or Zernike's phase contrast method (Born and Wolf, 1980). By selecting the acoustical wave to be the sum of a reference wave and object wave, the induced surface deformation is made proportional to the intensity pattern of an acoustical hologram taken over the liquid surface so that the optical field generated by the system has this same intensity profile and is thus an optical reconstruction of the (acoustic) hologram.

An interesting variation of liquid-surface acoustical holography is the scanning laser acoustic microscope (SLAM) (see MICROSCOPY, ACOUSTICAL). In its original form (Kessler and Yuhas, 1979) this microscope simply produced an optical image of the acoustic intensity distribution generated over a liquid–surface interface via a system such as that illustrated in Fig. 6. However, the device has recently been modified so as to generate holographic reconstructions by modulating the output of the photodiode with an electronic reference signal (Wey and Kessler, 1990). By

FIG. 6. Scanning laser acoustic microscope (SLAM). A scanning laser beam is modulated by the liquid surface perturbation and the scattered optical field is converted into an intensity proportional to the surface height by means of a knife edge.

means of this procedure it is possible to determine approximately the complex amplitude of the object wave over the liquid–surface interface; this is then used to generate an image of the object on a digital computer.

3. HOLOGRAPHIC IMAGE FORMATION

Images of the source ρ can be generated from holograms produced in any of the ways discussed above and of any of the types discussed earlier. Moreover, a high-quality virtual or real image of the source can be generated depending on whether the reconstructing wave is taken to be the original reference wave (virtual image) or the complex conjugate of this wave (real image). Of course in either case both real and virtual images as well as the "dc" image field will be present, but by appropriate selection of the reference and reconstructing waves it is possible to minimize the distortion in the desired (high-quality) image caused by the presence of these other image fields. In cases where the complex amplitude of the acoustic object wave is directly measured (e.g., by a scanned acoustical transducer or fixed transducer array) the unwanted image components will not be generated in the holographic reconstruction.

The acoustical image is formed by the conversion of the holographic boundary value field ψ as defined in Eq. (9) into an image field in the reconstruction step. The image field can be physically formed in an analog system or can be generated on a digital computer by appropriately processing the recorded hologram. In the case where the image is formed digitally there is of course more freedom in the image formation step than in the analog case where the image formation is determined entirely by the physics of wave propagation. However, even for the case of computer processing the image is largely determined by the physics of the problem and closely mimics what one would obtain via analog processing.

3.1 Analog Image Formation

To understand the image formation process in holography it is worth while to neglect, for the moment, the zero-order and first-order real image fields and to consider the spatial evolution of the object field U_o from its boundary value generated over the hologram surface by physical illumination of the hologram with the original reference wave. If we assume that the reference wave was a unit-amplitude plane wave, then this evolution is approximately described by the Rayleigh-Sommerfeld integral (Goodman, 1968; Stamnes, 1986)

$$U_o(\mathbf{r}) = \int_{\Sigma_0} d^2r_0\, \gamma(\mathbf{r}-\mathbf{r}_0) U_o(\mathbf{r}_0). \tag{11}$$

In this equation γ is a "propagator" that can be expressed in the form

$$\gamma(\mathbf{r}-\mathbf{r}_0) = \frac{\partial}{\partial n_0} G_d(\mathbf{r}-\mathbf{r}_0), \tag{12}$$

where G_d is the outgoing-wave Green's function for the Helmholtz equation that vanishes on the hologram surface and where $\partial/\partial n_0$ stands for the outward directed normal derivative to the hologram surface at the point $\mathbf{r}_0$. For a planar hologram this Green's function is well known to be twice the free-space Green's function G employed in Eq. (7) (Goodman, 1968; Stamnes, 1986). The integral is performed over the hologram surface, which we have denoted by Σ_0. We can express the virtual image field defined in Eq. (11) in terms of the source ρ by substituting for the boundary-value field $U_o(\mathbf{r}_0)$ from Eq. (7). We obtain

$$U_o(\mathbf{r}) = \int d^3r' h(\mathbf{r},\mathbf{r}') \rho(\mathbf{r}'), \tag{13}$$

where

$$h(\mathbf{r},\mathbf{r}') = \int_{\Sigma_0} d^2r_0\, \gamma(\mathbf{r}-\mathbf{r}_0) G(\mathbf{r}_0-\mathbf{r}'). \tag{14}$$

Equations (11) and (13) completely describe the formation of the virtual image in the reconstruction step. Equation (11) describes the evolution of the virtual image field from its boundary value over the hologram surface while Eq. (13) can be regarded to be an "imaging equation" that relates the virtual image field to the source ρ. With this interpretation the image kernel $h(\mathbf{r},\mathbf{r}')$ is thus identified as the *point-spread function* (PSF) of the imaging process. The virtual image will, of course, be concentrated in the region of space lying to the rear of the hologram and hence is not directly accessible. It can, however, be readily converted to a real image concentrated on the observer side of the hologram by a further image-forming step. Such a step is implemented, for example, by the human eye in viewing the reconstructed wave field generated in optical holographic reconstruction.

Equation (14) defining the PSF h is the well known Rayleigh-Sommerfeld integral representation (Born and Wolf, 1980; Goodman, 1968; Stamnes, 1986) of an outgoing spherical wave centered at the source point $\mathbf{r}'$ and diffracted by the hologram aperture. The PSF can thus be interpreted as being the (virtual) image of a point source located at $\mathbf{r}'$ and viewed through an aperture located over the hologram surface. The image formed by the source as given in Eq. (13) is then a coherent summation of such images weighted by the amplitude of the source $\rho(\mathbf{r}')$ at each source point. Because the PSF is not, in general, a function of the difference of the image and source vectors $\mathbf{r}$ and $\mathbf{r}'$, respectively, the image formation is *nonisoplanatic* (Born and Wolf, 1980; Goodman, 1968).

A real image is also formed in the holographic reconstruction step by the evolution of the first-order real image field. This evolution is described by Eq. (11), where, however, the boundary value of the first-order real image field is employed in place of U_o. When the reconstructing wave is taken to be the original reference wave, the image so formed will be corrupted by the presence of the square of the reference wave U_r^2 in the boundary value. For plane-wave illumination the phase of this quantity will cause the image location to shift laterally and will also introduce unwanted distortion in the image. To avoid this problem a reconstructing wave equal to the complex conjugate of the reference wave can be employed so that the boundary-value field ψ now includes a term equal to $I_r U_o^*$ that is not corrupted by the phase of the reference wave. For the usual case of plane reference waves this corresponds physically to illuminating the hologram from the opposite side from which it was recorded. However, as noted earlier, the image so generated will be pseudoscopic and will be an image of the complex conjugate of the source rather than of the source itself.

3.2 Computer Generation of Holographic Images

The image field $U_o(\mathbf{r})$ defined in Eq. (11) can be physically generated by actual illumination of the hologram by an acoustic (or optical) wave or can be mathematically computed by multiplying the recorded intensity pattern (hologram) $I(\mathbf{r}_0)$ by the reference wave and performing the integration (11) on a digital computer. Moreover, in the case of computer processing we are not limited to using the normal derivative of the Dirichlet Green's function G_d as the propagator in the image formation step, and we are free to choose this quantity to optimize image quality. We are thus led to a general image-formation procedure defined by an integral transform of the same general form as Eq. (11) but with an arbitrarily chosen propagator γ. The image formed in a computer reconstruction using a given propagator is related to the source by Eq. (13) with the PSF defined in Eq. (14).

The use of a computer to form the virtual-image field has certain advantages over analog image formation. For example, in cases where the complex amplitude of the object wave is directly recorded with either a scanned transducer or fixed transducer array, the virtual image field computed from Eq. (11) will not include the zero-order or first-order real image fields. In addition, it is possible to form a real image directly by *backpropagating* the virtual image field into the image space located *behind* the hologram plane. The backpropagation process can be thought of as an analytic continuation of the virtual image field from its value on the hologram surface *back* into the space region occupied by the source. This backward evolution can be achieved by the simple expedient of evaluating Eq. (11) directly for observation points $\mathbf{r}$ lying in object space (i.e., in the space lying to the rear of the hologram surface). However, it is important that the backpropagation be computationally stable, and so some care must be exercised in choice of the propagator γ. In particular, in the case where the Dirichlet Green's function is employed it is customary to exclude evanescent plane waves in the backpropagation computation. An alternative propagator that accomplishes the same purpose is given by the complex conjugate of the Dirichlet Green's function.

3.3 Holographic Image Quality

As discussed earlier, Eq. (14) defining the holographic PSF $h(\mathbf{r},\mathbf{r}')$ is the Rayleigh-Sommerfeld integral representation of an outgoing spherical wave diffracted by the hologram aperture (Goodman, 1968). This quantity can be approximated by the so-called Debye integral (Born and Wolf, 1980; Stamnes, 1986)

$$h(\mathbf{r},\mathbf{r}')\approx\frac{1}{4\pi}\int_{\delta\Omega} d\Omega\; e^{ik\mathbf{s}\cdot(\mathbf{r}-\mathbf{r}')}, \qquad (15)$$

where $\delta\Omega$ denotes the solid angle subtended by the hologram aperture when viewed from the point $\mathbf{r}'$ and the integration is over all unit vectors $\mathbf{s}$ within this solid angle. A further approximation is possible if the solid angle $\delta\Omega$ subtended by the hologram aperture is approximately constant for all source points $\mathbf{r}'$, as will occur, for example, if the hologram aperture is large compared to the size of the object. Within this approximation the PSF will only be a function of the difference $\mathbf{r}-\mathbf{r}'$ and the imaging will be *isoplanatic*. We will assume that this condition holds throughout the following discussion.

The quality of holographic image formation can be examined for various types of sources. Consider first a transparency $t(x,y)$ centered at $x=y=0$ on the plane $z=0$ and illuminated by a unit-amplitude plane wave e^{ikz} propagating along the positive z axis. In this case the induced source is given by Eq. (3) with the scattering strength $\tau=t(x,y)$ and $\xi(\mathbf{r})=z$. If the virtual image field generated by Eq. (11) is evaluated over the "image plane" $z=0$ we obtain an image $\hat{t}(x,y)$ of the transparency function given by

$$\hat{t}(x,y)=\int dx'dy'H(x-x',y-y')t(x',y'), \qquad (16)$$

where the image kernel H is equal to the holographic PSF h evaluated at $z=z'=0$.

The imaging equation (16) is most easily examined in the spatial frequency domain. In particular, taking the spatial Fourier transform of both sides of the equation we obtain

$$\tilde{\hat{t}}(K_x,K_y)=\tilde{H}(K_x,K_y)\tilde{t}(K_x,K_y), \qquad (17)$$

where the tilde denotes the Fourier transform. The spatial Fourier transform of the image kernel H is obtained from Eq. (15) upon setting $z=z'=0$ and converting from angular integration variables to the Cartesian spatial frequency variables K_x and K_y. If we assume that the holographic aperture is circular and centered at $x=y=0$ we obtain

$$\tilde{H}(K_x,K_y)=\begin{cases}\pi/k\gamma & \text{if } K_x^2+K_y^2\leqslant k^2\sin^2\theta,\\ 0 & \text{otherwise,}\end{cases}$$

where $\gamma=\sqrt{k^2-K_x^2-K_y^2}$ and where θ is the half-angular extent of the holographic aperture as viewed from the center of the transparency. The image (16) is seen to be a low-pass filtered version of the transparency function bandlimited to spatial frequencies lying within the circle $K_x^2+K_y^2\leqslant k^2\sin^2\theta$ and consequently has a spatial resolution of roughly $\lambda/(2\sin\theta)$.

A generalized version of the source considered above is generated by the scattering of an acoustic wave from a smooth object whose surface curvature is small on the scale of the acoustic wavelength. Such an object is a surface scatterer as defined in Sec. 1.2 and is characterized by an induced source of the general form given in Eq. (3). It is readily shown that the holographic image of this source is peaked at the surface of the object and yields a high-quality image of the scattering strength $\tau(\mathbf{r})$ as long as the acoustic wavelength λ is small compared with the scale over which τ and the surface profile vary.

Both of the sources considered above are two dimensional in that they are concentrated in a two-dimensional region of space (a plane in the first case and a general smooth surface in the second case). It is not surprising, then, that the images of these sources are of high quality since they are generated from the source's radiated fields recorded over the two-dimensional surface Σ_0. The recorded data (hologram) has two degrees of freedom, and hence can be expected to yield high-quality images of objects having this same number of degrees of freedom. The situation is considerably different for three-dimensional sources such as result from the scattering of an incident wave from a penetrable scatterer. Such sources have three degrees of freedom, and it is unreasonable to expect a holographic image of such a source to reveal a great deal of information concerning the source's three-dimensional spatial structure (Toraldo di Francia, 1969). We examine the quality of images of three-dimensional sources in the following section.

3.4 Ideal Holographic Images

In order to study the quality of holographic images of three-dimensional sources it is useful to consider an "ideal" holographic configuration (Porter and Schwab, 1971) that yields the best image theoretically possible. Such a configuration is obtained by letting the holographic surface Σ_0 completely surround the source ρ. In this case the PSF defined in Eq. (15) can be evaluated in closed form and we obtain

$$h(\mathbf{R})=\frac{\sin(kR)}{kR}=\operatorname{sinc}(kR), \tag{18}$$

where $R=|\mathbf{r}-\mathbf{r}_0|$. The PSF of the ideal holographic configuration is seen to be isoplanatic and spherically symmetric.

The lack of information content in the holographic image of a three-dimensional source is readily apparent from examining the three-dimensional spatial Fourier transform of the ideal image of such a source. The ideal image is given by Eq. (13) with the PSF given by Eq. (18),

$$\hat{\rho}(\mathbf{r})=\int d^3r' \operatorname{sinc}(k|\mathbf{r}-\mathbf{r}'|)\rho(\mathbf{r}'), \tag{19}$$

where we have denoted the ideal holographic image by $\hat{\rho}$. The three-dimensional spatial Fourier transform of the ideal image is found to be

$$\begin{aligned}\tilde{\hat{\rho}}(\mathbf{K})&=\int d^3r\,\hat{\rho}(\mathbf{r})e^{-i\mathbf{K}\cdot\mathbf{r}}\\&=(2\pi^2/k^2)\tilde{\rho}(\mathbf{K})\delta(K-k),\end{aligned} \tag{20}$$

where $\delta(\cdot)$ is the one-dimensional Dirac delta function.

We conclude from Eq. (20) that the ideal holographic image has a spatial Fourier transform that is concentrated on the surface of a sphere centered at the origin and having a radius equal to the wave number k. This image has only two degrees of freedom, corresponding to the two coordinates defining the surface of this sphere. Generation of high-quality images of such sources thus requires that new and independent data concerning the object being imaged be employed in the image formation process. We discuss two methods for generating such additional information in the following sections.

4. ACOUSTIC DIFFRACTION TOMOGRAPHY

We concluded in the preceding section that the virtual image formed of a three-dimensional source in acoustic holography contains limited structural information about the source. One method for constructing an image containing more information is to employ many holograms and to combine coherently the images generated from the separate holograms. However, for this procedure to succeed the separate holograms must contain independent or, at least, different information about the source. This then rules out the use of such a procedure with primary sources since an entire set of holograms of such a source contains no more information than that encoded in a single "ideal hologram" whose surface Σ_0 completely surrounds the source.

Although the use of multiple holograms yields no increase in image quality for primary sources, the procedure is applicable to induced sources that represent penetrable scattering objects and where the goal is to obtain a high-quality image of the scattering potential $V(\mathbf{r})$. For this class of objects it is possible to perform a suite of scattering experiments using different incident waves and to superimpose the holographic images generated in the set of experiments. Since the incident wave changes from experiment to experiment, each holographic image contains, in general, new information regarding the scattering potential, and an enhanced image of this quantity can thus be generated by properly combining the images produced by the separate holograms.

The procedure outlined above for generating high-quality images of the scattering potential of penetrable scatterers has become known by the name *diffraction tomography* (see ACOUSTICAL TOMOGRAPHY). This name is motivated by the fact that the data employed in generating the image arise from the diffraction (scattering) of incident waves by the object and that the coherent combination of the multiple holographic images is analogous to the combination of images used in computed tomography (CT) (Natterer, 1986) to generate a high-quality image of the interior of an object from multiple x-ray micrographs of the object. In diffraction tomography (DT) the holograms play the role of the micrographs and the holographic image formation process as encoded in Eq. (11) is the DT version of the image formation process in CT.

In order to understand the imaging procedure employed in DT, consider the geometry illustrated in Fig. 7 where a semitransparent acoustic object is insonified by a plane wave $\exp(ik\mathbf{s}_0\cdot\mathbf{r})$ and the scattered wave is measured over a holographic surface Σ_0 that is normal to the direction of propagation $\mathbf{s}_0$ of the insonifying plane wave and is large compared with the object's spatial extent. In most DT applications the wave scattered from the object will be highly concentrated within some small solid angle $\delta\Omega$ about the direction of propagation of the insonifying plane wave so that effectively an ideal hologram is formed as long as the recording surface Σ_0 is large enough to record the wave field within this solid angle. We will assume that this condition is satisfied in the following discussion.

The holographic image of the scattering potential is obtained by backpropagating the object wave (scattered wave) according to Eq. (11) and can be expressed, using Eq. (19), in the form

$$\hat{V}(\mathbf{r};\mathbf{s}_0) = \int d^3r'\, V(\mathbf{r}')e^{-ik\mathbf{s}_0\cdot(\mathbf{r}-\mathbf{r}')} \times \operatorname{sinc}(k|\mathbf{r}-\mathbf{r}'|), \tag{21}$$

where we have made use of Eq. (6) and where $\mathbf{s}_0$ has been included in the argument of the image to indicate its dependence on the propagation direction of the insonifying plane wave. If now multiple experiments employing insonifying plane waves having different directions of propagation are performed and the partial holographic images are coherently averaged over 4π steradians, we obtain the image

$$\hat{V}(\mathbf{r}) = \frac{1}{4\pi}\sum_{\mathbf{s}_0}\hat{V}(\mathbf{r};\mathbf{s}_0) = \int d^3r'\, H(\mathbf{r}-\mathbf{r}')\, V(\mathbf{r}'), \tag{22}$$

where

$$H(\mathbf{R}) = \operatorname{sinc}(k|\mathbf{R}|)\,\frac{1}{4\pi}\sum_{\mathbf{s}_0} e^{-ik\mathbf{s}_0\cdot\mathbf{R}}. \tag{23}$$

The quality of the image $\hat{V}(\mathbf{r})$ generated from the set of holograms increases monotonically with the number of experiments. In the ideal case where an infinite number of experiments are employed using insonifying unit vectors $\mathbf{s}_0$ completely covering the unit sphere, the summation in Eq. (23) becomes an integral over this sphere and we obtain

$$H(\mathbf{R}) = \operatorname{sinc}^2(k|\mathbf{R}|). \tag{24}$$

The image generated in this case is much superior to the image generated in a single or small number of experiments and is approximately equal to the image generated in a large number of experiments employing unit vectors equally spaced over the unit sphere. However, a further improvement is possible by post- (computer) processing so as to deconvolve the image kernel H from the image and thus arrive at a truly optimum image of the scattering potential. Alternatively, because of

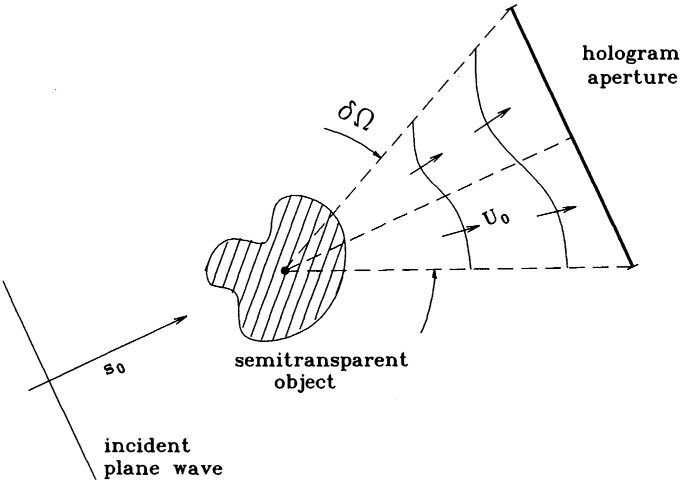

FIG. 7. Recording an effective ideal hologram in DT. In practice the scattered field will be highly concentrated within a solid angle $\delta\Omega$ centered on $\mathbf{s}_0$ so that the hologram surface Σ_0 need only extend over a limited region.

the linearity of the image formation process this postprocessing can be avoided entirely by *prespatial filtering* of the virtual image field on the measurement surface Σ_0 prior to backpropagation. When this is done the resulting image kernel is a three-dimensional δ function bandlimited to the interior of the so-called Ewald limiting sphere $|\mathbf{K}| \leqslant 2k$ familiar from x-ray crystallography (Cowley, 1984). In this case, then, an image of the scattering potential bandlimited to within this same sphere is obtained, corresponding roughly to a spatial resolution of a quarter-wavelength (Mueller *et al.* 1979; Wolf, 1969).

The image-formation process outlined above is seen to consist of three distinct steps:

1. spatial filtering of the holographic data (the scattered wave on the measurement surface Σ_0),
2. backpropagation of the filtered data according to Eq. (11), and
3. summing the partial images so obtained over the insonifying directions (view angles) $\mathbf{s}_0$.

This procedure has been called the filtered backpropagation algorithm (Devaney, 1983) and can be shown to be a generalization of the filtered *backprojection* algorithm (Natterer, 1986) of computed tomography (CT) to diffraction tomography. It is important to note that the spatial filters employed in the algorithm are independent of the object being imaged and only depend on the number and geometry of the holograms employed to record the scattered field data. The operation of the algorithm is illustrated in Fig. 8.

Diffraction tomography has been employed in a number of applications. Perhaps the first of these in acoustic tomography was studied by Greenleaf and co-workers (Greenleaf *et al.*, 1974) who used a simplified (nondiffracting) ray model similar to that employed in x-ray tomography. Later, Mueller and co-workers (Mueller *et al.*, 1979) replaced the ray model by the more accurate wave model that underlies diffraction tomography. Since this early work the theory and application of acoustic (ultrasound) tomography has progressed considerably (Greenleaf and Bahn, 1981), and at least one system is being readied for commercialization (Stamnes *et al.*, 1992). Acoustic diffraction tomography is also employed in geophysical tomographic applications (Devaney, 1984; Witten and Long, 1986) and also forms the basis for newer applications of the scanning laser acoustic microscope (Wey and Kessler, 1990).

4.1 Generalized Projection-Slice Theorem

Consider the partial image $\hat{V}(\mathbf{r};\mathbf{s}_0)$ defined in Eq. (21) of a semitransparent scattering potential formed from a hologram at some wave number k. A straightforward calculation shows that the three-dimensional spatial Fou-

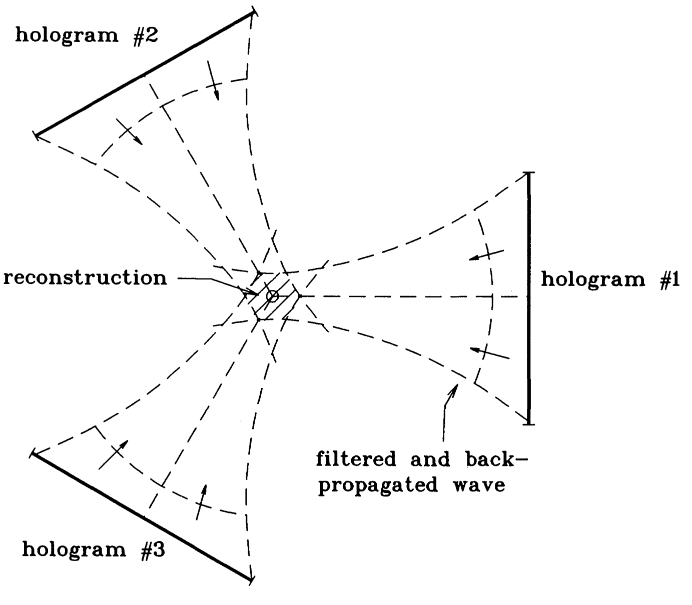

FIG. 8. Graphical illustration of the operation of the filtered backpropagation algorithm of diffraction tomography. The scattered wave recorded on each hologram is spatially filtered and backpropagated. The reconstruction is equal to the coherent sum of filtered and backpropagated images from the entire set of holograms.

rier transform of this image is confined to the surface of a sphere that is centered at the spatial frequency $\mathbf{K} = -k\mathbf{s}_0$ and has a radius equal to the wave number k. This sphere is the Ewald sphere well known from x-ray crystallography (Cowley, 1984), and the relationship between the spatial Fourier transform of the ideal holographic image and the scattering potential is a statement of the generalized projection-slice theorem of diffraction tomography (Mueller *et al.*, 1979).

In accordance with earlier discussion a single partial image $\hat{V}(\mathbf{r};\mathbf{s}_0)$ has only two degrees of freedom, corresponding to the two coordinates defining the surface of the Ewald sphere, and in order to obtain a high-quality image of the scattering potential it is necessary to "fill out" Fourier space by incorporation of additional data. In DT the filling-out process is achieved through the use of multiple Ewald spheres having different centers (different $\mathbf{s}_0$). In particular, the partial images generated at different propagation directions $\mathbf{s}_0$ of the incident plane wave define the Fourier structure of the object on different Ewald spheres, and by summing these images a reconstruction is generated that defines the structure over the union of Ewald spheres. In the ideal case where $\mathbf{s}_0$ completely covers the unit sphere, the object's structure is determined throughout the Ewald limiting sphere as illustrated in Fig. 9 and thus gives rise to a resolution of roughly a quarter-wavelength (Wolf, 1969). However, it should be pointed out that in practice only the forward-scattered field is recorded in DT (cf. Fig. 7), and this limits the ultimate resolution to be somewhat worse than this (Devaney, 1983; Mueller *et al.*, 1979).

5. MULTIFREQUENCY HOLOGRAPHY

The key to the success of diffraction tomography is the incorporation of data from multiple-scattering experiments into the image-formation process. In the case of DT each scattering experiment employs a narrow-band insonifying plane wave, and these "additional data" are generated by varying the direction of propagation of this plane wave. Another way to generate additional data is to employ a set of insonifying wave fields having different temporal frequencies ω or, equivalently, a single *broad-band* insonifying wave, in which case the "additional data" are generated by the various temporal frequencies ω within the band pass of the insonifying wavefield (Langenberg, 1987). However, for either of these latter procedures to be effective it is necessary that the object being imaged be nondispersive (i.e., frequency independent) or, at least, have a scattering potential that depends on temporal frequency in a known way.

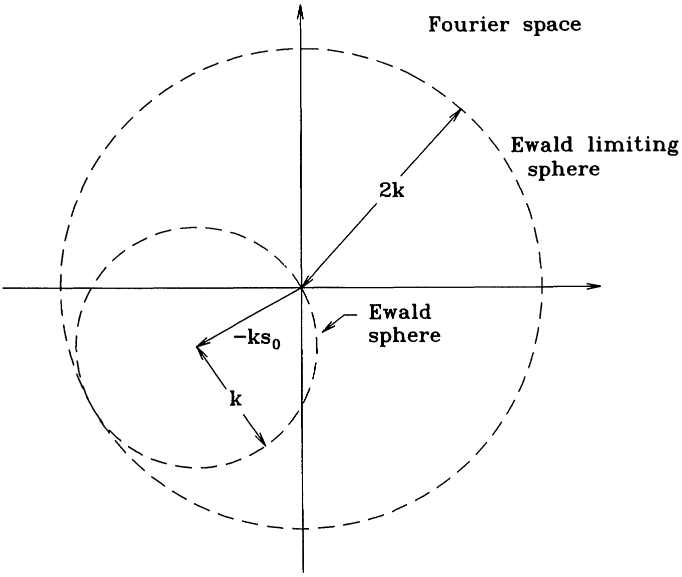

FIG. 9. The projection-slice theorem of DT. Each ideal hologram defines the spatial Fourier transform of the scattering potential *V*(**r**) over an Ewald sphere.

To examine the use of multiple frequencies in holographic image formation, consider the partial image $\hat{V}(\mathbf{r};\mathbf{s}_0)$ defined in Eq. (21) of a *nondispersive* semitransparent scattering potential formed from an ideal hologram at a single temporal frequency ω. As discussed above, the three-dimensional spatial Fourier transform of this image is confined to the surface of an Ewald sphere that is centered at the spatial frequency $\mathbf{K}=-k\mathbf{s}_0$ and has a radius equal to the wave number $k=\omega/c$, where c is the acoustic velocity in the background medium. A high-quality image of the object is obtained in DT by "filling out" Fourier space through the use of multiple Ewald spheres having fixed radii k but different centers (different $\mathbf{s}_0$). Alternatively, it is possible to employ multiple Ewald spheres whose centers are all aligned in the same direction $\mathbf{s}_0$ but which have different radii (different k). This then generates a Fourier coverage such as that illustrated in Fig. 10. A higher-quality reconstruction than obtainable from a single-frequency hologram is then possible by properly making use of these "additional data."

A multifrequency reconstruction can be generated in a manner completely parallel to the procedure employed in DT. In particular, the partial images $\hat{V}$ formed via Eq. (21) at each temporal frequency or wave number k can be coherently added to generate an image that is related to the scattering potential via Eq. (22) where the image kernel H is now given by

$$H(R)=\sum_k \operatorname{sinc}(k|\mathbf{R}|)e^{-ik\mathbf{s}_0\cdot\mathbf{R}}. \tag{25}$$

In this equation the summation is performed over the wave numbers employed in the set of experiments or in the passband of the acoustic insonifying plane wave pulse. As in the case of DT the multifrequency reconstruction can be further improved by deconvolving the image kernel (25) from the image $\hat{V}$. Alternatively, it is possible to prefilter the virtual image fields at each temporal frequency prior to the backpropagation step to obtain the same end result.

5.1 Synthetic-Aperture Holography

In synthetic-aperture holography a single point transducer located in the far field of the object is employed both to insonify the object and to record the scattered field as illustrated in Fig. 11. The measured object field is then the field *backscattered* by the object and, for semitransparent objects, is given by [cf. Eq. (7)]

$$\begin{aligned}U_o(\mathbf{r}_0)&=\int d^3r'\,V(\mathbf{r}')G(\mathbf{r}'-\mathbf{r}_0)G(\mathbf{r}_0-\mathbf{r}')\\&\sim\left[\left(\frac{1}{4\pi}\right)^2\int d^3r'\,V(\mathbf{r}')e^{-i2k\mathbf{s}_0\cdot\mathbf{r}'}\right]\\&\quad\times\frac{e^{i2kr_0}}{r_0^2},\end{aligned} \tag{26}$$

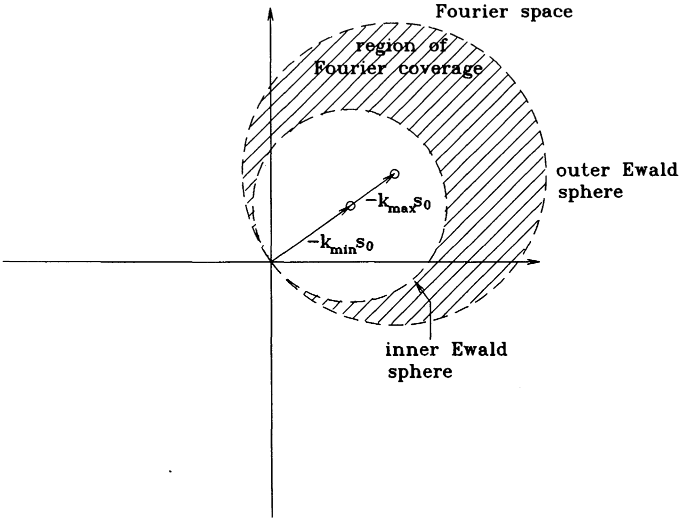

FIG. 10. Fourier coverage in multifrequency holography. The spatial Fourier transform of a nondispersive scattering potential is determined over the region bounded by an "outer" Ewald sphere of radius $k_{\max}$ and an "inner" Ewald sphere of radius $k_{\min}$, where $k_{\max}$ and $k_{\min}$ are the maximum and minimum wave numbers employed in the frequency range.

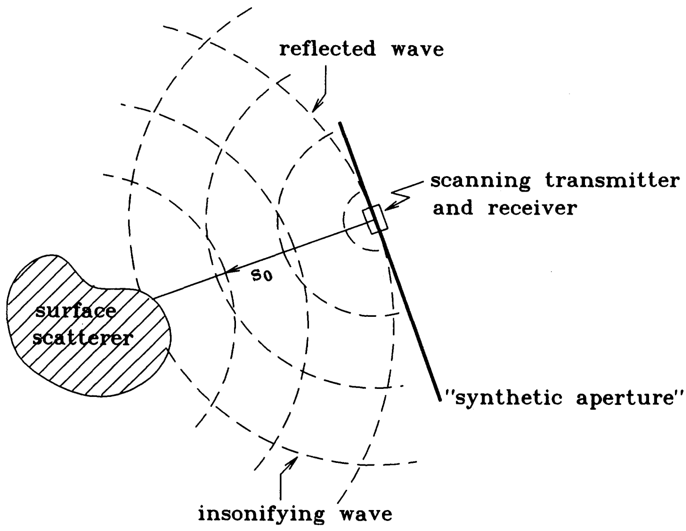

FIG. 11. Geometry for synthetic-aperture imaging.

where $\mathbf{r}_0 = r_0\mathbf{s}_0$ denotes the location of the transducer and where the far-field approximation has been employed. It is concluded from Eq. (26) that the measured object field determines the spatial Fourier transform of the scattering potential at the spatial frequency $\mathbf{K} = 2k\mathbf{s}_0$, which is a single point on an Ewald sphere having radius $2k$. Fourier space can then be filled out by using a broad-band transducer located at various points on some surface Σ_0. The result is similar to what would be obtained in multifrequency holography where the field is recorded over a holographic aperture lying on this surface. For this reason this imaging method is called synthetic-aperture imaging (Goodman, 1968).

ACKNOWLEDGEMENTS

The author wishes to thank Professor Jakob Stamnes and Dr. Alon Schatzberg for carefully reading the entire manuscript and making a number of suggestions that have improved the presentation of the material. He also wishes to thank Dr. Schatzberg for preparing the figures presented in the text.

GLOSSARY

Acoustics: The science of sound waves. Used in this article to denote applications where it is desirable to generate images of sources of sound waves usually at high (ultrasonic) frequencies.

Backpropagation: The mathematical process of computing the spatial distribution of a wave field within a source region from measured values of the wave field over an external aperture.

Born Approximation: A weak-scattering approximation used in scattering theory, valid when the scattering object has properties that closely match the background medium in which it is embedded.

Coherent Wave: Wave field whose amplitude and phase are nonrandom functions of time and position.

Computed Tomography (CT): The mathematical procedures used to reconstruct a multidimensional function from its set of projections. Used in x-ray tomography to compute a cross-sectional image of an object from multiple radiographs of the object.

Diffraction Tomography (DT): The mathematical procedures used to reconstruct a scattering potential from a set of scattering data.

Fraunhofer Hologram: A hologram recorded in the Fraunhofer region of the source. Same as Fourier-transform hologram.

Fresnel Hologram: A hologram recorded in the Fresnel region of the source.

Gabor Hologram: A hologram recorded using the illuminating wave as the reference wave. Sometimes called an "in-line" hologram.

Generalized Projection-Slice Theorem: The relationship between the spatial Fourier transforms of a source and the source's ideal holographic image.

Hologram: The recorded interference pattern between a wave generated from a source and a known reference wave.

Ideal Hologram: Hologram recorded over an aperture that completely surrounds the source.

Image: The spatial distribution of field amplitude generated by a lens or by a holographic reconstruction that resembles a source distribution. A *real* image is concentrated in space and is pointwise directly related to the source. A *virtual* image is not focused in space and can only be viewed after an additional imaging operation such as performed by a positive lens or on a computer via a backpropagation algorithm.

Near-Feld Hologram: A hologram recorded in the near field of a source. Such a hologram can include evanescent wave components of the source field and, hence, can lead to superresolution imaging.

Object Wave: The coherent wave generated by the source (object) that is to be imaged in holography.

Off-Axis Holography: A form of holography where the reference wave is different from the illuminating wave.

Reference Wave: The known wave (usually a plane or spherical wave) that is coherently added to the object wave to generate the interference pattern recorded in a hologram.

Scattering Potential: The spatial distribution of material properties determining the scattering of a wave from a penetrable object.

Synthetic-Aperture Holography: A specialized form of holography where a sequence of backscatter measurements is used to generate synthetically an image that would ordinarily be obtained from a hologram recorded over an extended aperture.

INTRODUCTION

Holography is a two-step imaging method. In the first step, an interference pattern between an object wave and a known reference wave is recorded on film as a hologram. Then the image of the original object is reconstructed in three dimensions by illuminating the hologram film with a light beam equivalent to the reference wave. When a light beam is used in the hologram formation process, it is called optical holography, and when a sound wave is used it is called acoustical holography. Electron holography employs electrons rather than massless particles such as photons.

Optical images can be reconstructed from holograms formed with electron waves, even though electron waves seem to be quite different from light waves. For example, an electron wave is described by a quantum-mechanical wave function, while a light wave can be described by classical electromagnetic fields. Electron and light wavelengths differ by a factor of about 100,000. However, there is no essential difference between the two waves with regard to interference patterns. The holographic imaging capability of such different waves is based on the fact that only the most fundamental features of waves, i.e., interference and diffraction, are used for this imaging.

1. BRIEF HISTORY

The principle underlying holography was devised by Gabor (1949) for breaking through the resolution limit of electron microscopes, which were restricted by limits resulting from the unavoidable aberrations of electron lenses. Optical reconstruction was tried from optical, electron, and x-ray holograms. However, the images obtained in those days were rather poor mainly because of the lack of coherent beams and the disturbance from the conjugate images inevitably produced in holography.

In the early 1960s, holography greatly progressed in the field of optics with the advent of laser beams. Furthermore, clear images were obtained by the introduction of the off-axis method to remove the effect of the conjugate images (Leith and Upatnieks, 1962). Since

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

that time, applications of optical holography have been greatly expanded.

The situation is similar in electron holography. Although the feasibility of electron holography was demonstrated in 1968 (Tonomura *et al.*, 1968; Möllenstedt and Wahl, 1968), new application fields, beyond the reach of conventional electron microscopes, were not opened until 1979 when a coherent field-emission electron beam was developed (Tonomura *et al.*, 1979). This article explains only electron holography, but the principle behind it is the same as that behind holography using other massive particles.

2. ELECTRON WAVES

The wave nature of an electron is described by the Schrödinger equation

$$\{(\hbar\nabla/i+e\mathbf{A})^2/2m-eV\}\psi=E\psi, \qquad (1)$$

where m, $-e$, V, $\mathbf{A}$, E, $\hbar$, and ψ are the electron mass, the electric charge unit, the electric potential, the vector potential, the energy, Planck's constant divided by 2π, and the wave function. The wave function is completely different from any classical wave in that it does not correspond to any physical reality, and this wave function itself can never be detected in any conceivable experiment. One observable property is the probability $|\psi|^2$ of detecting single particles. The accumulation of detection records gives the probability $|\psi|^2$.

This process is demonstrated well in the electron double-slit-like experiment shown in Fig. 1. The wavelength λ of an electron wave in a vacuum ($V=\mathbf{A}=0$) is obtained from Eq. (1) as

$$\lambda=h/\sqrt{2mE}=h/p, \qquad (2)$$

where p is the electron momentum. Let us take the example of a 100-keV electron beam, which has a wavelength of 0.04 Å. An electron wave emitted from a source propagates towards the electron biprism (Möllenstedt and Düker, 1955), which consists of a central thin filament and two grounded electrodes. The application of a positive electric potential to the central filament makes the two electron waves passing the filament (one on each side) overlap to form an interference pattern in the lower plane. Continuous wave fronts are drawn just like a water ring on a pond surface, as in Fig. 1. However, the actual situation in this experiment is quite different from this image. Two electrons never exist in this apparatus at the same time; there is only a single electron if any. So why can we observe an interference pattern between two waves passing the two sides of the biprism filament when two electrons do not overlap? There is no choice but to think that a single electron is split into two (one on each side) of the biprism filament, which interfere with each other. We detect only a single electron and never one of the halves. This can be explained using wave functions: an electron wave function can pass through the two sides of the biprism filament and give the measurement probability of the interference pattern at the observation plane. Single electrons are detected according to this probability.

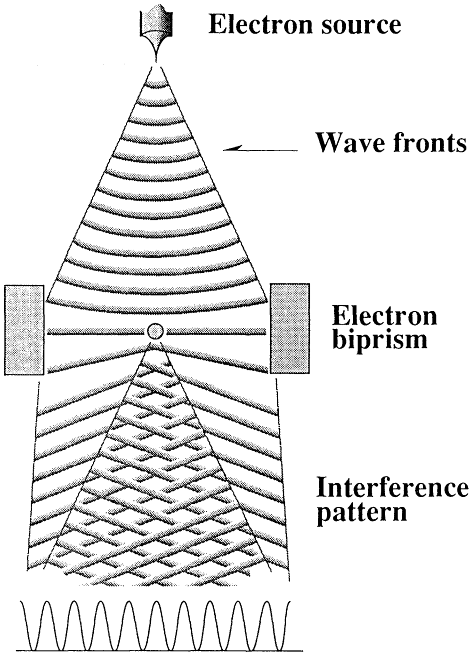

FIG. 1. Electron-wave interference. An electron wave emerges from a field-emission tip and propagates towards the electron biprism. Two waves, propagating on both sides of the biprism, overlap to form an interference pattern. Actually, however, coherent electrons are so sparse that only a single electron exists in the apparatus at a time.

This strange behavior of electron interference, recorded on videotape (Tonomura *et al.*, 1989), is shown in Fig. 2. Electrons are detected one by one as bright spots on the TV monitor. At first, their arrival seems quite at

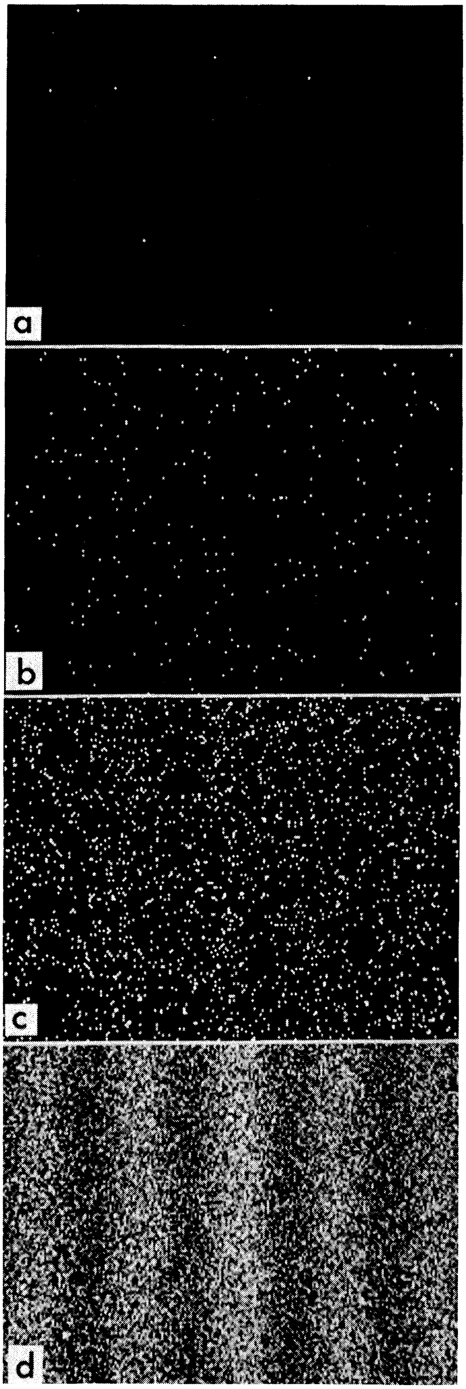

FIG. 2. Buildup of the electron interference pattern: (a) 8 electrons; (b) 270 electrons; (c) 2,000 electrons; and (d) 60,000 electrons.

random. Although the next electron is emitted long after an electron is detected, the accumulation of bright spots gradually forms the biprism interference pattern. Since the electron wavelength is extremely small, the fringe spacing is also narrow. For this reason, Feynman pointed out in his textbook that "this experiment has never been done in just this way, since the apparatus would have to be made on an impossibly small scale." However, such an experiment can now be performed using advanced technologies, such as two-dimensional single-electron counting systems combined with a field-emission electron microscope.

3. INTERACTION OF ELECTRON WAVES WITH OBJECTS

The interaction of an electron wave with an object is described by the Schrödinger equation (1). It can easily be seen from this equation that electrostatic potential V and vector potential $\mathbf{A}$ determine the behavior of the wave function. To take a specific example, the wave front of an electron plane wave incident on an object can be modulated through electromagnetic potentials as illustrated in Fig. 3. This modulation can be recorded in the interference pattern or the hologram as displacements of interference fringes if a reference plane wave is made to overlap this modulated wave. The modulation of the wave front, or the phase shift ϕ of an electron wave passing through weak electromagnetic potentials, is easily derived from Eq. (1) as

$$\phi=\frac{\sqrt{2me}}{\hbar}\int\left(\sqrt{V}-\sqrt{\frac{e}{2m}}\mathbf{t}\cdot\mathbf{A}\right)ds, \qquad (3)$$

where the integral is carried out along the electron trajectory, and $\mathbf{t}$ is the unit vector of the electron trajectory.

When an object is made of uniform material, the phase shift is caused by the change in the object's thickness. This is because when an electron passes through an object, it is accelerated by the inner potential V_0 and consequently its wavelength becomes a little shorter. The phase difference $\Delta\phi$ with and without the object is given by

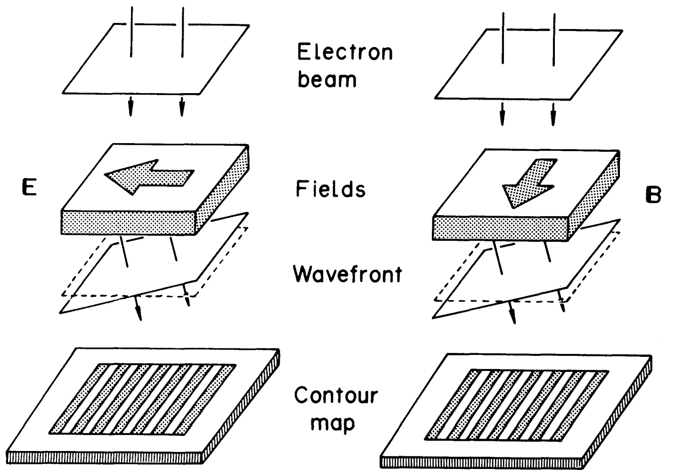

FIG. 3. Interaction of electron plane wave with electromagnetic fields: **E**, electric field; **B**, magnetic field. The transmitted wave front can be displayed as a contour map by overlapping a comparison beam (shown by dotted lines in the figure).

$$\Delta\phi=\frac{\sqrt{2\ \mathrm{MeV}}}{2\hbar}\int\frac{V_0}{V}\,ds=\frac{\sqrt{2\ \mathrm{MeV}}}{2\hbar}\frac{V_0}{V}\,d, \quad (4)$$

where d is the thickness of the object.

When an object is a magnetic field, the phase difference $\Delta\phi$ between two electron beams starting from one point and ending at another point is given by

$$\Delta\phi=-\frac{e}{\hbar}\int\mathbf{A}\cdot d\mathbf{s}=-\frac{e}{\hbar}\int\mathbf{B}\cdot d\mathbf{S}=-\frac{e}{\hbar}\,\Phi, \quad (5)$$

where the line integral is performed along the closed loop connecting the two electron trajectories and the surface integral in the second equation is performed over the surface enclosed by the loop. This equation indicates that the phase difference produced between the two beams is proportional to the enclosed magnetic flux even when the two beams never touch the magnetic field. This is called the Aharonov–Bohm effect (Aharonov and Bohm, 1959; Peshkin and Tonomura, 1989).

4. ELECTRON HOLOGRAPHY

4.1 Types of Electron Holography

Although the basic principle behind holography is very simple, many holography techniques have been developed, especially in the field of optics. Only a few of these techniques have been applied to electron holography.

Holography can be classified into two types according to how the reference wave is provided:

1. A background wave is used as the reference wave in in-line holography. Here, objects are restricted to a size small enough not to disturb the background wave. In addition, a hologram must be formed in a Fraunhofer diffraction pattern of the object in order to obtain a clear reconstructed image. In holography, an additional conjugate image is always produced since an interference pattern (hologram) can only record the absolute value of the phase, which reconstructs as twin images having amplitudes that are complex conjugates of each other. Therefore, the defocused pattern overlaps the reconstructed image, and in the early days, this was a persistent obstacle to holography. The effect of a conjugate image becomes a constant background near the reconstructed image in Fraunhofer in-line holography. Clear electron images were first obtained using this type of holography, since the coherence conditions of an electron beam are not stringent in this case. However, it is now used only for special purposes.
2. In off-axis holography, a known reference wave and an object wave are brought together at an angle. The twin images are reconstructed in different directions, which allows the twin image problem to be eliminated. There are no limitations on object size. Beam splitters are necessary to produce two coherent waves. Electron biprisms have usually been employed as beam splitters, but Bragg reflections at a single-crystalline thin film can also be used.

Holography can also be classified according to the plane of the object wave where holograms are formed, such as image-plane, Fresnel, Fraunhofer, and Fourier-transform holography. All of these types have already been demonstrated in electron holography.

If one classifies these techniques by the apparatus needed to form holograms, the standard one is the transmission electron microscope equipped with a coherent field-emission gun and an electron biprism. This is discussed in Sec. 4.2. Other types of apparatus include the scanning transmission electron microscope (STEM), the electron diffractometer (see Howie, 1990), and the projection electron microscope (Fink *et al.*, 1990).

4.2 Electron Hologram Formation

This section describes a typical experimental setup for forming an off-axis electron hologram using a transmission electron microscope (TEM).

Electrons are field-emitted from a sharp tungsten tip under an ambient pressure of 10^{-10} Torr (see Fig. 4). They are then accelerated through accelerating electrodes to, say, 100 kV, and illuminate an object with a collimation angle down to less than 1×10^{-7} rad, compared with 1×10^{-3} rad for conventional electron microscopes. A small illumination angle (2β) is crucial since this value determines the spatial coherence length, which is given by $\lambda/2\beta$. This has become feasible through the high brightness of a field-emission electron beam.

Hologram formation is schematically shown in Fig. 5. A collimated electron beam illuminates an object located in one half of the specimen plane, and the other half is for the reference beam. The image of the object is formed through the objective lens. The reference beam reaches the image plane without any disturbance from the object. These two beams are superimposed by the electron biprism situated below the objective lens to form an interference pattern.

The biprism is composed of a central thin filament and two grounded potential electrodes, one on each side. A positive potential up to 300 V is applied to the filament to make the object and reference beams deflect toward the center to overlap on the lower plane. The resultant interference pattern is

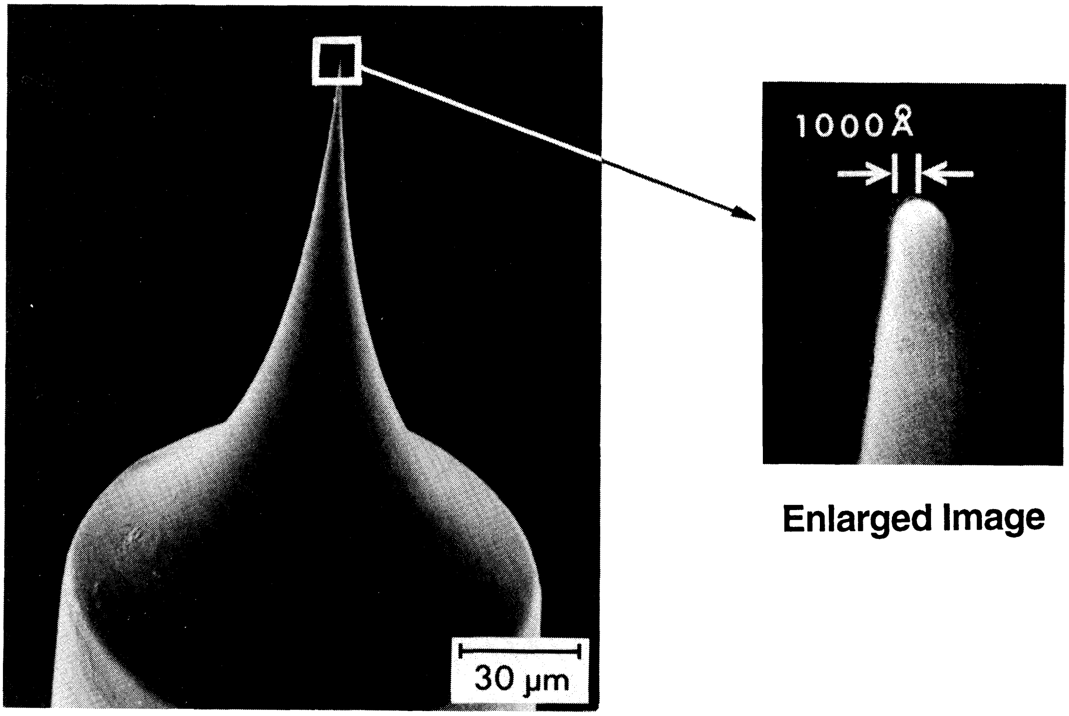

FIG. 4. Scanning electron micrograph of a field-emission tip.

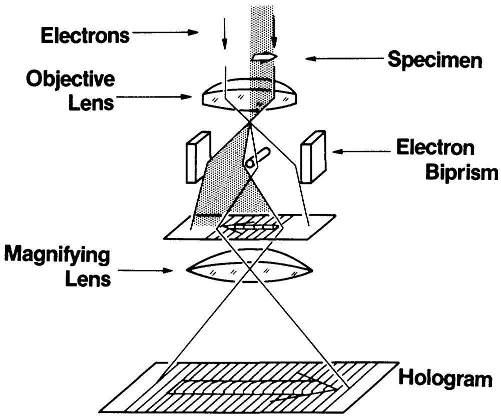

FIG. 5. Schematic diagram of electron hologram formation in an electron microscope.

enlarged through magnifying lenses and recorded as a hologram.

4.3 Optical Image Reconstruction

An optical image can be reconstructed in one of the two diffracted beams when a light beam corresponding to the reference electron beam illuminates a hologram. A conjugate image is also produced in the other diffracted beam. When the reconstructed image is photographed on film, only the intensity distribution is observed, which is equivalent to an electron micrograph.

The phase distribution is also reconstructed in an optical image, and consequently it can be displayed as an interference micrograph when an optical interferometer is combined in the optical reconstruction system as shown in Fig. 6. A light beam from a laser is split into two coherent beams by a Mach–Zehnder interferometer. The two beams, A and B, illuminate the electron hologram from slightly different directions. Each beam produces both a reconstructed image in its +1st-order diffracted beam and a conjugate image in its −1st-order diffracted beam. When only the transmitted beam (zeroth-order beam) of beam A and the first-order diffracted beam of beam B, or vice versa, are made to pass through the aperture to form an interference pattern between the reconstructed image and a comparison beam on the observation plane, an interference micrograph is obtained which displays the phase distribution (Fig. 6 does not show this case but the phase-amplification case described next).

In this interference micrograph, contour fringes appear at every phase change of 2π, and so the minimum detectable value is about $2\pi/4$. This precision is not always satisfactory for electrons, especially when we want to observe a specimen thickness variation on the order of atomic dimensions or a small magnetic flux. In such cases, however, a technique unique to holography can be employed to detect a smaller phase change. This technique uses the same optical system as in Fig. 6.

If the reconstructed image of beam A and the conjugate image of beam B, or vice versa, are overlapped by adjusting the interferometer, the resulting interference pattern produces doubly phase-amplified interference. This is because the phase difference between the twin images, which have phase distributions opposite in sign, is twice as large as that for a conventional interference micrograph. Higher amplification can be obtained when this procedure is repeated.

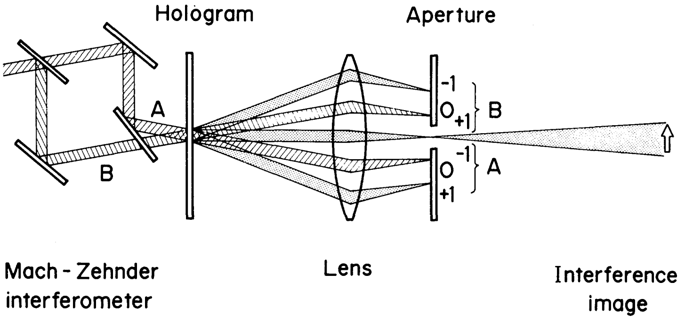

FIG. 6. Optical reconstruction system for interference microscopy.

4.4 Numerical Image Reconstruction

The image can be reconstructed by computation from holograms directly monitored with a TV camera. This method does not need wet processes such as film development. Consequently the time required for the reconstruction can be made much shorter, and even real-time observation becomes feasible when the computation time is short.

5. APPLICATIONS

This section introduces new application fields opened up by electron holography.

5.1 Interference Microscopy

An interference micrograph provides information which cannot be obtained by electron microscopy—phase information about the electron wave function as well as the intensity distribution. Furthermore, the precision in phase measurement can be increased from $2\pi/4$ up to $2\pi/100$ by using the phase-amplification technique. High-precision measurements and observation of unseen microscopic objects and fields have become feasible by holographic interference microscopy.

5.1.1 Measurement of Object Thickness Distribution. The phase shift of a uniform object is given by Eq. (4). For $V = 100$ kV and $V_0 = 10$–30 V, the object thickness for a phase shift of 2π is 200–700 Å. If the phase measurement precision is $2\pi/100$ as a result of phase amplification, the thickness precision is 2–7 Å.

An example for this application is shown in Fig. 7 (Tonomura *et al.*, 1985). The object is a molybdenite thin film. No contrast can be observed in a conventional electron micrograph. Even when observed as an interference micrograph (b), no fringe shift can be seen since the film surfaces are almost atomically flat. However, in the 24-times phase-amplified micrograph (c), fringe steps become recognizable along lines marked A, B, and C in the photography, which correspond to one, three, and five atomic steps on the surface. The thickness change of 6.2 Å due to the single atomic step A has become quantitatively observable, and it produces an electron phase shift of $2\pi/50$.

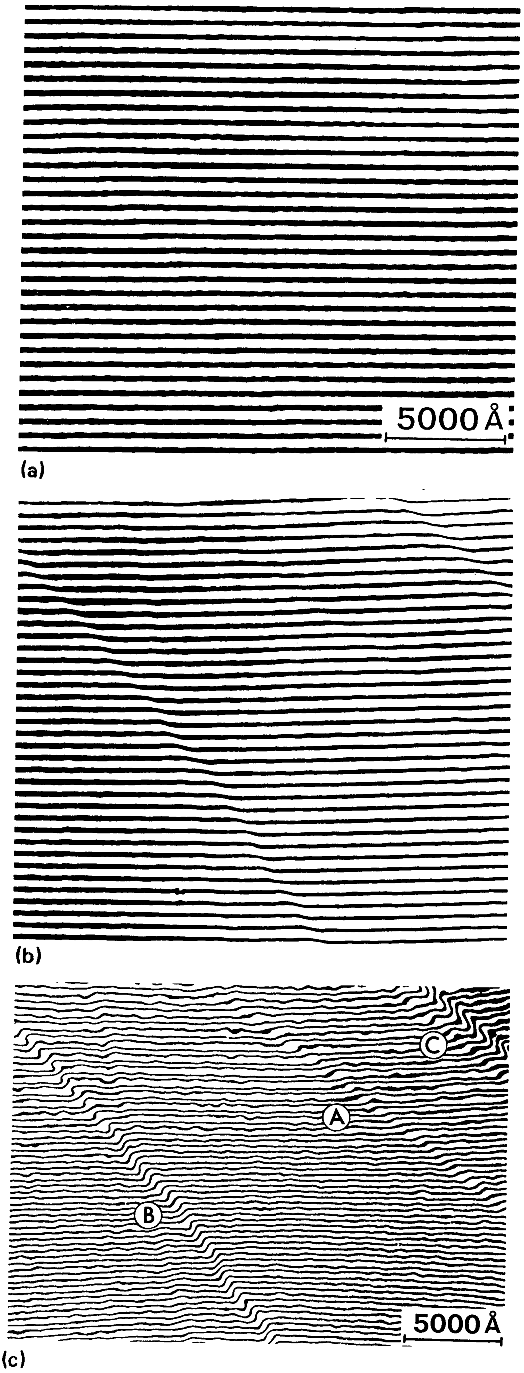

FIG. 7. Interference electron micrograph of molybdenite thin film: (a) conventional interference micrograph; (b) 4× phase-amplified interference micrograph; and (c) 24× phase-amplified interference micrograph. Fringe step A corresponds to a thickness change of monoatomic step height, 6.2 Å, and electron phase shift of $2\pi/50$.

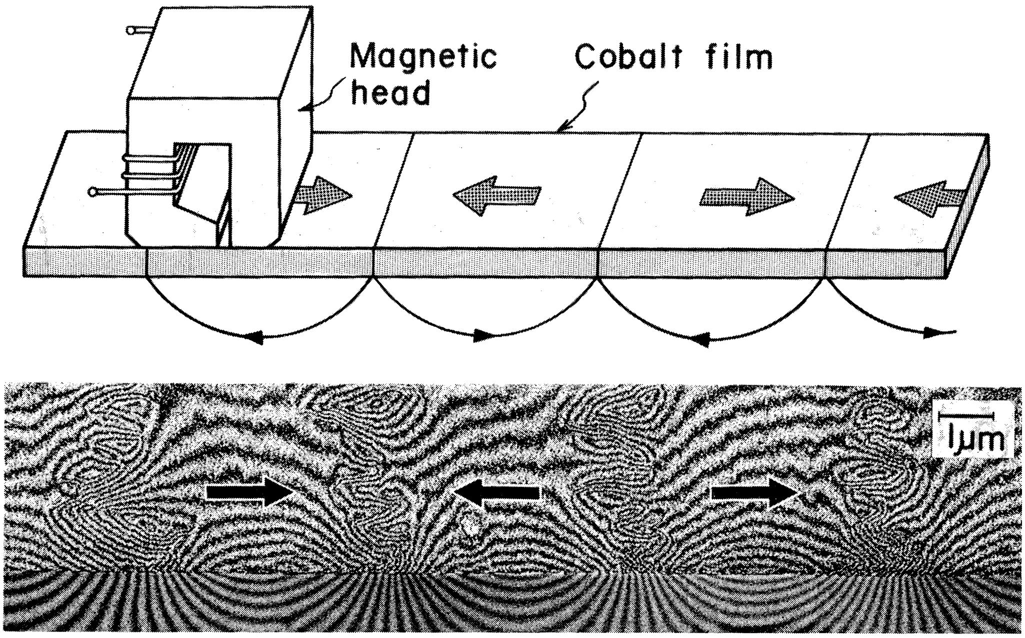

FIG. 8. Interference electron micrograph of recorded magnetic tape. A constant magnetic flux of h/e flows between two adjacent contour lines.

5.1.2 Observation of Magnetic Fields. An interference micrograph of a magnetic field can be interpreted in a straightforward way: contour fringes in an interference micrograph follow in-plane magnetic lines of force, and a constant magnetic flux of h/e ($=4\times10^{-15}$ Wb) flows between two adjacent contour fringes (Tonomura *et al.*, 1980).

An observation example of magnetic tape is shown in Fig. 8 (Osakabe *et al.*, 1983). A bit pattern was recorded on a cobalt film, and was observed as an interference micrograph. No contrast can be observed by electron microscopy, since this film is a pure phase object. However, in this interference micrograph, many fringes, i.e., magnetic lines of force, appear inside and outside the film. Two oppositely directed streams of magnetization collide head on, and produce vortices similar to those formed by streams of water. Such detailed observation is helpful for the development of high-density magnetic recording.

Another example is the observation of flux lines penetrating a superconducting thin film (Matsuda *et al.*, 1989). Figure 9 shows a doubly phase-amplified interference micrograph

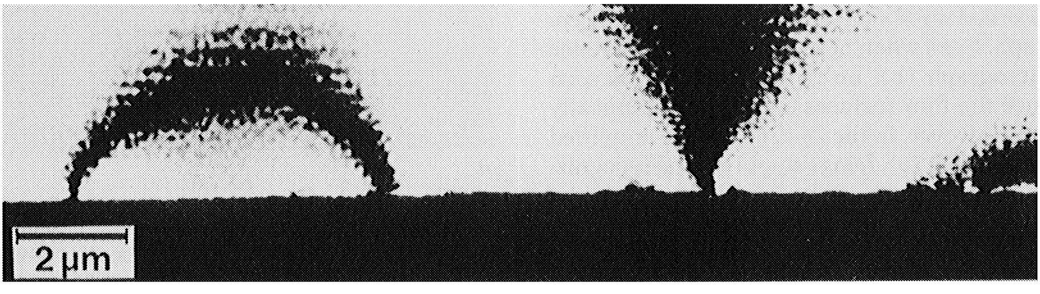

FIG. 9. Interference electron micrograph of single flux lines penetrating a superconducting Pb thin film 0.2 μm thick. One fringe corresponds to a flux of $h/2e$, i.e., a flux quantum, since the micrograph is phase-amplified by a factor of 2.

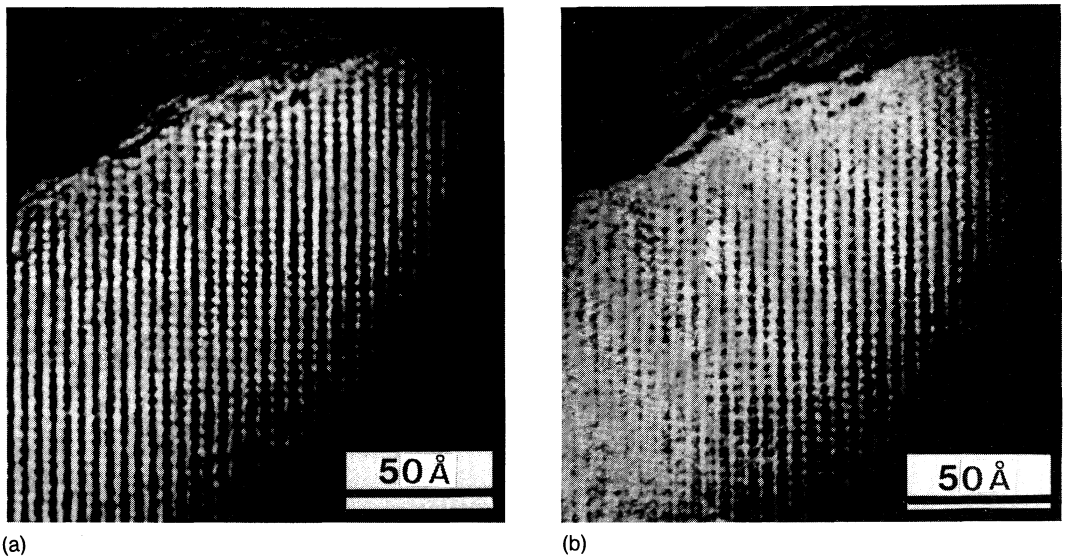

(a) (b)

FIG. 10. High-resolution image reconstruction: (a) reconstructed image of Nb_2O_5; (b) spherically corrected image (Lichte, 1986).

of Pb film 0.2 μm thick. When a magnetic field is applied perpendicularly to the film at 4.5 K, the magnetic field is excluded from the film due to the Meissner effect. A stronger field can penetrate it in the form of a thin filament, i.e., a flux line. An electron beam is incident perpendicular to the flux lines for observation. A single contour fringe in the picture corresponds to a flux line having a flux quantum of $h/2e$. A magnetic line of force is produced from a very small region (about 0.15 μm) of the film surface and fans out into the vacuum. In addition to this isolated flux line, an antiparallel pair of flux lines can also be observed on the left in the picture.

5.1.3 Observation of Electrostatic Fields. When the object is an electrostatic field, contour fringes in an interference micrograph indicate projected equipotential lines, as can be presumed from Eq. (4). This technique has been used to observe the microscopic distribution of electrostatic fields near *p-n* junctions for two values of applied reverse-bias voltages (Frabboni *et al.*, 1985).

5.2 High-Resolution Microscopy

The original objective of holography was to overcome image resolution limitations due to aberrations of electron lenses. Although electron microscope resolution has been greatly improved since the days of Gabor, the resolution is still limited by aberrations and not by wavelength. Aberrations such as spherical aberration and astigmatism in electron microscopes can be compensated for in the optical reconstruction stage.

Tonomura *et al.* (1979) attempted to compensate optically for a spherically aberrated image of a fine gold particle, and the lattice fringes of {111} planes (2.4 Å) and their half-spacing fringes (1.2 Å) were reconstructed inside the in-focus particle image. Lichte (1986) numerically reconstructed structure images of Nb_2O_5 crystals from electron holograms which had a 0.75-Å carrier fringe spacing, and obtained spherically corrected images for both phase and amplitude distributions (see Fig. 10). The carrier fringe spacing must be narrower than 1/3 of the required resolution. Spacings of 0.3 (Völkl and Lichte, 1990) and 0.09 Å (Kawasaki *et al.*, 1991) have been obtained for high-resolution purposes.

In spite of several trials, no images have yet been obtained that were unobtainable with conventional electron microscopes. We can expect that an ultrahigh resolution of better than 1 Å will be achieved with brighter electron beams.

GLOSSARY

Aharonov–Bohm Effect: Electron interference phenomenon where an electron wave passing through a field-free region receives an observable effect due to potentials.

Brightness: Beam current density per unit solid angle.

Carrier Fringe: Information about an object wave is recorded as the modulation of fine carrier fringes in off-axis holography.

Conjugate Image (Twin Image): An additional image inevitably reconstructed in the holography process. Its amplitude is the complex conjugate of the original amplitude.

Illumination Angle: The maximum variation of the propagation direction of a beam of particles.

Lattice Fringe: An electron microscope image of a crystalline thin film which is formed by the overlap of the transmitted electron beam and Bragg-reflected beams at some lattice planes. It provides an image of the lattice planes.

Abstract

Holography, a method of photography that produces highly realistic images, fully three-dimensional, with the normal parallax relations of the actual object, is described. Basics of the theory are presented from both a mathematical and a physical viewpoint. Various areas of application are given, including three-dimensional displays, complex spatial filtering, hologram interferometry for nondestructive testing and metrology, product authentication and counterfeiting security, holographic optical elements, and imaging through inhomogeneities using holographic phase conjugation. The various forms of white light viewable holograms are described, including the Denisyuk or volume type, the Benton or rainbow type, and the integral type. The diffractive properties of holograms are analyzed, including Bragg diffraction, i.e., diffraction from a volume hologram. The construction of commercial display holograms is discussed. The present state of commercial and artistic holography is discussed, along with expected future developments.

1
Introduction

Holography is a process of recording a complete wave field, both amplitude and phase. It differs from conventional photography in which only the amplitude or equivalently, the irradiance of the field is recorded. By recording the entirety of the wave, some rather remarkable effects are produced. In particular, the images formed with holography are startlingly realistic, being fully three dimensional and containing all of the parallax relations that are encountered in everyday seeing but which are lost when an image is recorded photographically.

Holography was invented by the Hungarian – British scientist Dennis Gabor in 1947. His aim was to improve the resolution of the electron microscope, which at that time suffered from noncorrectable spherical aberration [1–3]. The idea was to photographically record the complete wave field of the electron waves, both phase and amplitude, and then make reconstructions using visible light, that is, to produce light waves that were replicas of the electron waves, complete with aberrations. The aberrations could then be corrected by appropriately designed lenses. The idea, while bold and imaginative, was unsuccessful. However, since then holography has burgeoned and has found many applications, all quite remote from Gabor's original intent.

2
Holographic Principles

Photographic film is inherently insensitive to phase, as are indeed all detectors of radiation. Yet the holographic process requires the recording of the entire wave, phase as well as amplitude. This feat is accomplished by converting phase variations into amplitude variations, which the film can then record. The process is described with reference to Figs. 1 through 3. Figure 1 shows a plane wave of light reflecting off an object (equivalently, for a transparent object, it could be transmitted through the object). The reflected light is a complicated wave pattern; the waves are of irregular shape, and the amplitude (brightness) varies from point to point. The phase is essentially the shape of the wave front, and the irregularities of the wave front of Fig. 1 show a phase that changes rapidly from point to point. To record the phase means essentially to record the shape of the wave front. But the argument is just as before: photographic film is insensitive to the shape of the wave front.

Figure 2 shows how the introduction of a background wave can result in recording of the total field. For simplicity, we have sketched a rather simple object wave front, where the shape varies slowly across the recording aperture. This wave front is propagating toward the recording medium. Point A of the wave front is ahead of point B, and arrives at the recording plane first. But, as we stress, the recording plate is insensitive to the time of arrival of a wave front, being sensitive only to the amplitude; hence the photographic record has no information about the shape of the wave front. However, the introduction of a second wave called the *reference wave*, here a plane wave, effectively converts phase into amplitude through the process of interference. The interference of two beams of light produces a fringe pattern – a sequence of light and dark areas, where the two beams interfere constructively and destructively. The fringe spacing depends on the angle between the two beams. Hence, near the top of Fig. 2, where the angle between the waves is large, the fringe pattern is fine. Further down, where the two beams are nearly parallel, the fringe pattern is coarse. Finally, near the bottom, the angle has increased again, and the fringe pattern is again fine. Hence, one can, by observing the fringe pattern, gain an idea of the shape of the wave front. In short,

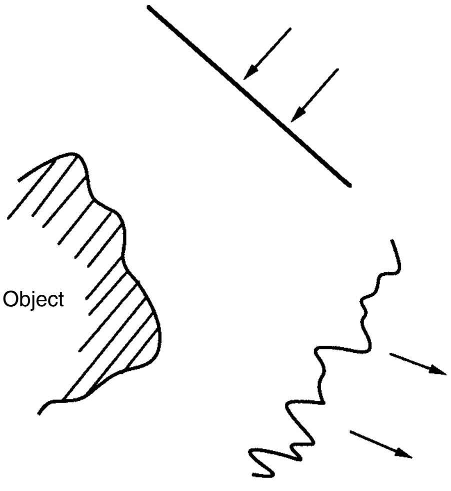

Fig. 1 Light reflecting off an object

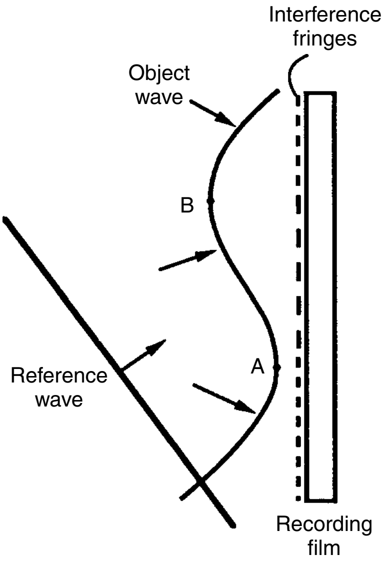

Fig. 2 Recording of a wavefront by interference with a reference wave

the effects of phase become visible. This phenomenon is, of course, the basis of all interferometry, including holography. The photographic film when developed becomes a hologram.

The hologram thus has, in an indirect way, made a record of the phase. The completion of the holographic process is the regeneration of the original wave front from the recorded pattern. We illuminate the hologram with a beam of light that, for simplicity, we take as a replica of the original reference wave. We think of the hologram now as a diffraction grating (Fig. 3), and consider that the angle of diffraction depends on the grating spacing – the closer the spacing, the greater the angle of diffraction. Then, at both the top and the bottom of the hologram, where the fringes are finest, the angle of diffraction is greatest. In the middle, where the fringes are coarser, the diffraction is at a smaller angle. Thus, the diffracted wave is a replica of the object wave that created the interference pattern when the hologram was recorded. The diffraction process is thus an inverse of the interference process, and the two processes in tandem lead back to the original wave front. Thus it is that phase can be recorded and wave fields reconstructed. This heuristic description of the holographic process basically says what mathematics says in a more quantitative and rigorous way.

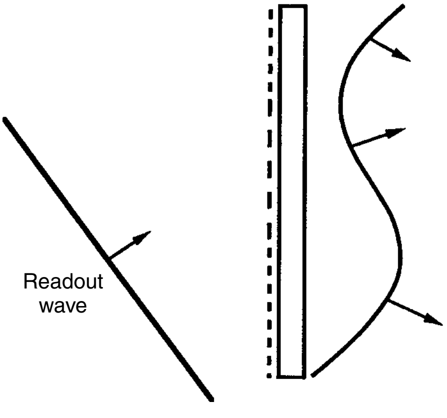

Fig. 3 Reconstruction of the wave by the process of diffraction. Only one diffracted order is shown

Consideration of the other diffracted order of the grating leads to a diffracted wave that is conjugate to the original wave; that is, in the conjugate wave, points A and B are reversed. On the original wave, as well as in the primary wave, which is the one we have described, point A is ahead of point B, that is, the phase at A leads that at point B. In the conjugate wave, this situation is reversed. Thus, the holographic process creates not just one image, but two, known as the *primary* and *conjugate images*. The conjugation results in the image forming downstream from the hologram, thus being a real image, as opposed to the primary, which is virtual. When the hologram is read out with a collimated beam of light, the two images lie in mirror-symmetric positions about the plane of the hologram, one image forming on the source side of the hologram and the other on the observer's side. However, this symmetry disappears when the illuminating beam is not collimated, and indeed, under illumination with highly divergent or convergent beams, it is possible for the images to be both real or both virtual. Hence, to call the two images the real and virtual images of the holographic process, as is sometimes done, can be misleading, and the terms primary and conjugate are generally preferred.

The existence of the extra image has been a problem in holography, since in the original Gabor process, where the reference beam was not introduced at an

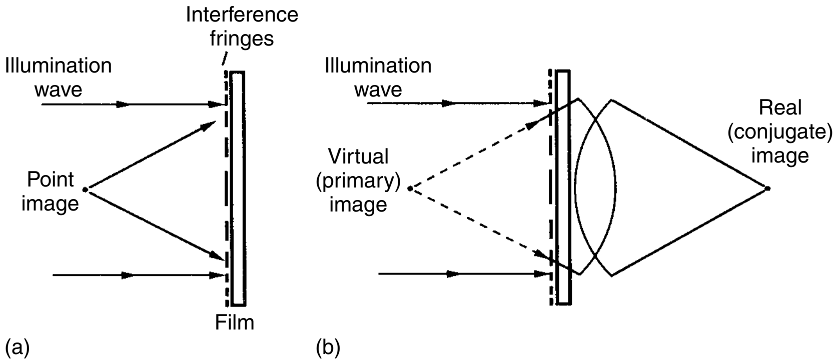

Fig. 4 Point image hologram made in the original Gabor configuration: (a) making the hologram; and (b) the reconstruction process, showing the emergence of two images

oblique angle, the images did not separate by propagation in different directions, but instead were superimposed, so that one image could be viewed only against the background of the other, giving a noisy reconstruction.

The origin of the twin image can be explained in various ways. A simple yet revealing way is described with respect to Fig. 4. Consider an object consisting of only a single point (a small opaque dot), and let this object be placed in a collimated beam of light. Most of the light passes undisturbed around the object, falls on the film, and serves as the reference beam. Light scattered by the object point also propagates to the recording film, where the interference between the two beams creates the interference pattern shown in Fig. 4(a). In the reconstruction process, with a collimated beam, we consider as before the hologram to be like a grating, one with a spacing (or spatial frequency) that changes with position. At each position, part of the incident light is diffracted in one direction and part in the opposite, at angles that depend on the spacing. The rays are seen to cross at two locations [Fig. 4(b)], one in front of the hologram and one behind. For the latter, the rays do not actually come together; rather, when projected back, they seem to emanate from a common point, thus producing a virtual image. Thus, the diffraction process has produced both real and virtual images, and the two images fall on top of each other so that one must always observe one image with the other giving an out-of-focus background, making the image noisy.

A somewhat philosophical way of explaining the origin of the twin image is to consider that a convergent wave of the same radius of curvature produces exactly the same interference pattern as the diverging wave when made to interfere with the planar background wave. Thus, the holographic process cannot distinguish between the two waves and cannot decide which wave produced the pattern. The reconstruction process resolves the quandary by reconstructing both.

Introducing a reference beam that passes around the object and impinges on the recording plate obliquely, as we have seen, sends the two reconstructed beams in different directions, thereby solving the problem.

3
Mathematical Theory

We offer a mathematical treatment that places the above viewpoint on a more rigorous basis (see also WAVE OPTICS).

The original theory, as developed by Gabor, assumed a transparent object s, which when illuminated with a coherent beam of light, that is, a monochromatic field from a point source, transmits some portion of the light without scatter and the remainder with scatter (Fig. 5). At some distance z_0 downstream from the object, let the field consist of a uniform component u_0, the background or reference wave, due to the unscattered portion of the wave, and u, the object beam produced by scatter from the object. The field has an irradiance $|u_0 + u|^2$. The field is recorded, typically by photographic film. If for simplicity we assume that the film has a transmittance proportional to the irradiance, thus ignoring the nonlinearity of the film and the contrast reversal that occurs upon recording, which makes the brighter parts of the field darkest on the record, we have the transmittance

$$\begin{aligned} t = I &= |u_0 + u|^2 \\ &= |u_0|^2 + |u|^2 + 2u_0|u|\cos\phi, \quad (1) \end{aligned}$$

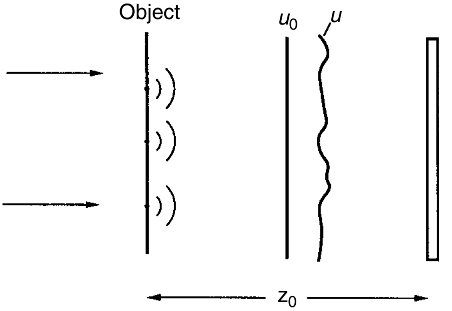

Fig. 5 Making a hologram in the Gabor configuration. The light transmitted by the object consists of a scattered wave u and an unscattered wave u_0

where we have dropped constants of proportionality and have assumed that u_0, the background wave, is uniform in amplitude and phase across the field, and that the varying part of the field, u, can be written in polar form as $u = |u|\exp(i\phi)$, where $|u|$ is the amplitude variation across the field and ϕ is the phase variation.

Upon illumination with a plane wave of monochromatic light of, for simplicity, unity amplitude, and at normal incidence, the field emanating from the hologram is

$$\begin{aligned} u_{\mathrm{EM}} &= |u_0|^2 + |u|^2 + u_0|u|\mathrm{e}^{i\phi} \\ &\quad + u_0|u|\mathrm{e}^{-i\phi}, \quad (2) \end{aligned}$$

where the final term of the film transmittance has been written in terms of the two complex components. The first term of Eq. (2) is just a uniform background. The second term is a noise term sometimes called the intermodulation product term, or sometimes the self-interference term. It is produced by interference among the various scattered waves that make up the object beam. If most of the light that passes through the object is unscattered, then u_0 will be much larger than u, and the quantity $|u|^2$ will be small and can be neglected. The term $u_0|u|\mathrm{e}^{i\phi} = u_0u$ is the replication of the original wave, and projects back to form a virtual image at the position occupied originally by the object. The final term is the complex conjugate of the original wave and can be written as u_0u^*. If, for example, the original object were a point scatterer, then u is a spherical wave centered on the object point. Similarly, u_0u^* is then a spherical wave with opposite curvature and is centered on a point lying downstream from the hologram. It thus forms a real image.

The conjugate image can be disturbing, as we have noted. Since the two image terms have the same energy, the reconstructed image will generally have a signal-to-noise ratio of unity, which is unacceptable for most applications.

The twin image of holography was a serious problem that resulted in considerable effort to remove it. Many of the early papers on holography suggested ways to eliminate the twin image. The problem is more than merely an imperfection; it is in fact rather fundamental. The complete wave front (ignoring polarization effects, which usually are of no concern) can be written as $u = |u|e^{i\phi}$, a product of an amplitude (or irradiance) part and a phase term. The ordinary photographic process records only the amplitude $|u|$, being totally insensitive to phase. The holographic process records both, but incompletely. That it is a rather fundamental defect can be appreciated by considering that, just as a complex quantity u can be written in the polar form $|u|e^{i\phi}$, so it can also be written as the summation of a real term and an imaginary term, $u = |u|\cos\phi + i|u|\sin\phi$. Inspection of Eq. (1) shows that the holographic process has recorded only the real part of the field. Thus, in a basic sense the process has failed to record any more of the total wave than does conventional photography; the mix is simply different. The holographic process has recorded part of the phase, at the expense of recording only part of the amplitude. This missing information manifests itself as the twin-image problem.

Gabor had a complete solution to the problem. He proposed to make two holograms, with one having the background shifted by 90°, which can readily be done by various phase-shifting means. The second hologram would have an information-bearing term of the form $u_0|u|\sin\phi$, which is just the missing information. The two holograms would be placed in separate branches of a two-beam interferometer and upon readout, would produce two reconstructed waves that are combined by the interferometer. If the interferometer has a 90° phase shift in one branch, then the reconstructed beams would combine in what is called *quadrature*, that is, with a 90° phase shift between them, giving a complete reconstructed image wave $u_0|u|\cos\phi + iu_0|u|\sin\phi$, which is the complete field.

This solution has practical difficulties. To make a pair of phase quadrature holograms and reconstruct them in quadrature in an interferometer would require a precision of phase control rather difficult to achieve in practice. In particular, the holograms would have to be recorded on optical flats with a uniformity much better than half a wavelength of the light over the entire hologram.

It would be preferable to have the entire field on a single hologram. The Leith–Upatnieks solution [4] arises from the recognition that the recording process has an aliasing, in that a spatial frequency component, $e^{i2\pi f_1 x}$, physically manifested as a plane wave propagating at an angle θ to the normal, and another spatial frequency component, $e^{i2\pi f_1 x}$, physically manifested as a plane wave propagating at an angle $-\theta$, produce exactly the same fringe pattern when interfering with the background wave. The solution is to modulate the entire wave field u onto a carrier. Each spatial frequency component of the object should be preserved, but should be shifted in spatial frequency, so that all spatial frequencies are of the same sign. Then after recording, the ambiguity would have been removed – every spatial frequency of the object wave will produce a different fringe pattern. In the reconstruction process, all of the positive spatial frequencies will belong to one image, and all negative

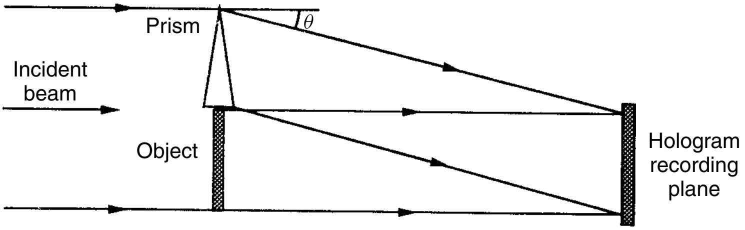

Fig. 6 Making of off-axis reference beam hologram

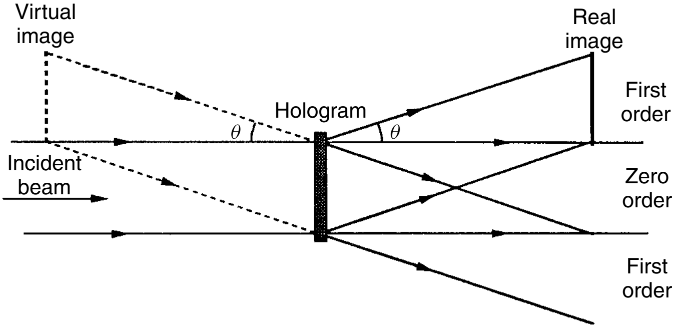

Fig. 7 Viewing of off-axis hologram. Low-quality images occur on hologram axis. High-quality images occur in the first-order diffracted waves

spatial frequencies to the other, and the images thereby become separable.

To accomplish this objective, the reference beam is introduced obliquely, as in Fig. 6. We let the reference beam be $a_0 \exp(2\pi i f_0 x)$, which describes a wave impinging obliquely on the hologram. Equation (1) then becomes

$$t = I = |u_0|^2 + |u|^2 + 2a_0|u|\cos(2\pi f_0 x - \phi). \quad (3)$$

The final term is on a spatial carrier f_0. The aliasing has been removed, in that the two previously noted spatial frequency components $\exp(2\pi i f_1 x)$ and $\exp(-2\pi i f_1 x)$ now produce distinguishable fringe patterns, one of spatial frequency $f_0 + f_1$ and the other of spatial frequency $f_0 - f_1$. In the reconstruction process, the two images, primary and conjugate, of Eq. (2) become $a_0|u|\exp[i(2\pi f_0 x - \phi)]$ and $a_0|u|\exp[-i(2\pi f_0 x + \phi)]$, which signify waves propagating in different directions. If we think of the hologram as being a diffraction grating, then the two terms become respectively the −1 and +1 orders of the grating, wherein the other extraneous term, $|u_0|^2 + |u|^2$, becomes the 0th order. Thus, as shown in Fig. 7, the beams representing the various terms become fully separated after some propagation distance. Thus, the complete wave field has been recorded and perfectly recovered.

4
The Rise of Modern Holography

The introduction of the off-axis or carrier-frequency technique in 1961 marked the beginning of the era of modern holography. In 1963, the technique was perfected and high-quality holographic imagery was reported, which created renewed interest in holography. Shortly thereafter [5], the formation of holograms of reflecting three-dimensional (3-D) objects, as opposed to the simple, two-dimensional transparencies that had been previously used in holography, was reported. In the reconstruction process, the observer looks into the hologram and sees an image that is a perfect likeness of the original object, fully three dimensional, with all of the normal parallax relations of real life. The observer, by moving his head, observes the same parallax relations that were observable in the original object scene. When looking from a near to a far point in the image, the observer must refocus his eyes. The observer can peer around objects to see what lies behind. The image, in short, is optically indistinguishable from the original object.

The hologram of the 3-D reflecting object, that is, the usual, real-world object, was made possible by the laser with its considerable coherence length compared with that of the mercury arc source that had been used in the prelaser era.

Coherence length is an important property of a light source used for holography and for interferometry in general (see INTERFEROMETRY). If a beam of light is split into two parts, which are then brought back together, the two beams have the possibility of producing interference effects. If the beams travel equal paths so that they are combined without a path difference being introduced, strong interference effects can be produced. If one beam travels a longer path than the other, the capability for interference diminishes. The amount of path difference that can be introduced without destroying the ability to interfere is called the *coherence length* and is determined by the spectral width of the source. A laser, being typically highly monochromatic, has a long coherence length, typically in the range of many centimeters. The mercury arc source, by comparison, has a coherence length of less than 1 mm.

Holograms of transparencies can easily be made with the mercury arc source, since the coherence length required for the basic holographic process is fairly small and can be handled very readily by the Hg arc source. However, the use of a reflecting, 3D object causes an increase of required coherence that can easily be several thousandfold. The problem is that in making a hologram of such an object, light reflected from all parts of the object must be coherent with the reference beam. If the object has a depth of 100 mm, which is fairly typical, then since the nearest point and the deepest points of the object, as well as all points in between, must interfere with the reference beam, the source must have a coherence length of the order of twice the object depth, or about 200 mm. This additional coherence length requirement, which has really nothing to do with the basic holographic process, is superimposed on the basic coherence requirement of the holographic process, which is typically about 0.1 mm. Thus, the transformation from 2-D objects to 3-D reflecting objects at once increases the needed coherence length to a level that can be met only with the laser.

Following the above events, interest in holography exploded, and holography became a research area in numerous laboratories throughout the world. Theory was developed, new ideas were conceived, and applications were sought.

In the meantime, Denisyuk in the Soviet Union described (in 1962) the volume hologram (see Sect. 7.2), in which the recording medium is sufficiently thick as to have a profound effect on the diffraction characteristics of the hologram. The Denisyuk, or volume hologram, is one of the main pillars of modern holography.

5
Some Early Applications

5.1
Imaging Through Inhomogeneities Using Holographic Phase Conjugation

The conjugate image of holography had traditionally been its greatest problem. Leith and Upatnieks [4] not only offered a practical way of avoiding the problem, but also proposed a use for the twin image: imagery through inhomogeneous media, such as highly aberrated lenses or scattering media, even as severe as frosted glass. Reduction to practice was reported in 1965 [6, 7].

Figure 8 shows a hologram-forming system in which a distorting medium has been placed between the object and the hologram. When the distorting medium is, as depicted, a diffuser such as ground glass, the object is not visible from the recording position. Similarly, from the hologram thus produced, the object cannot be imaged; the hologram reproduces only what can be seen from the recording plane. The hologram will, of course, form an image of the diffuser. Let the diffuser be described by a phase function $\exp[i\theta(x, y)]$, where θ is a noiselike function that describes the phase retardation introduced by the diffuser. The real image formed by the hologram is $\exp(-i\theta)$, since the real image is conjugate to the original object.

Placement of the original diffuser in the position where the holographic real image is formed, results in the superposition of the diffuser and its conjugate image, and the phase of one is cancelled by the complementary phase effects of the other or, mathematically, $\exp(-i\theta)\ \exp(i\theta) = 1$. The diffuser thus seems to disappear, and the object previously obscured by the diffuser is now revealed.

The process has an intriguing interpretation. As shown in Fig. 8, the readout beam retraces the reference beam path, but in reverse. The conjugate wave similarly retraces the original object beam path, but again in reverse. In the object beam, point

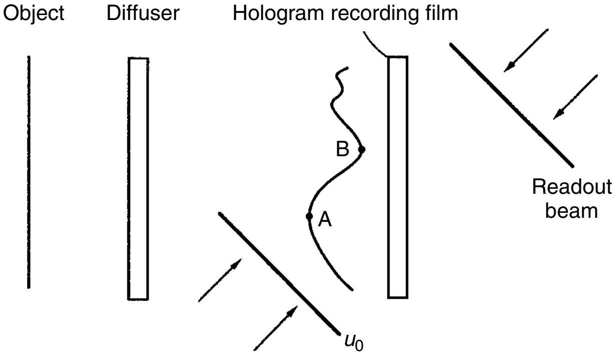

Fig. 8 Imaging through inhomogeneity, showing the hologram being made with a reference beam u_0 and subsequent readout with a beam retracing the original reference beam path

B led point A in phase. The reconstruction beam has exactly the same shape, but travels in the opposite direction. Therefore, point B now lags behind point A in phase; this is the meaning of conjugation. The wave travels over the original object beam path, and at each position along its path it assumes the same shape as the object beam did at that position, until finally it arrives at the object position, whereupon the wave forms an image. The process is somewhat analogous to time reversal. In a time-reversal situation – for example, a movie running backward – curious things happen. Scrambled eggs leap out of the pan, back into the shells, which then become whole again. Here, analogously, the wave front that had been mutilated by passage through the severe inhomogeneity is made whole again. The process has thus sometimes been called *wave-front healing.*

The process languished for many years; most of the envisioned applications involved the correction in real time of inhomogeneities that were constantly changing, such as atmospheric turbulence. Photographic film, however, needs processing and thus does not operate in real time. Phase conjugation eventually became an important area of research beginning in the 1970s, with the development of light-sensitive crystals and other devices that permitted the phase conjugation to be carried out on a much faster time scale than was possible with photographic film. Phase conjugation, today, is an important area of optics, and image formation through inhomogeneities is one of the major applications.

5.2
Complex Spatial Filtering

Holography has greatly enhanced spatial filtering technology by making practical the construction of spatial filters with arbitrary phase and amplitude control over the filter transfer function.

Spatial filtering is an optical analog of electrical filtering. An electrical signal can be decomposed into a collection of individual frequencies, and a simple filter selectively attenuates or rejects these frequencies; a very simple example is the frequency control on an audio system, which can, for example, be adjusted to emphasize the higher-frequency components of the signal. More sophisticated filters can be designed, which can not only operate on the amplitude of the frequency components but can also alter the phase relations among these components. Similarly, optical signals, such as object and image distributions, can be decomposed into spatial frequencies, and optical spatial filtering systems can be devised to alter the frequency components.

A basic filtering system is shown in Fig. 9. An object amplitude distribution s_0, typically a photographic transparency, is imaged to form the light distribution s_i. Under coherent illumination, there occurs at the common focal plane of the two lenses a light distribution that is Fourier transform–related to the object distribution. Put another way, the various spatial frequencies that constitute the

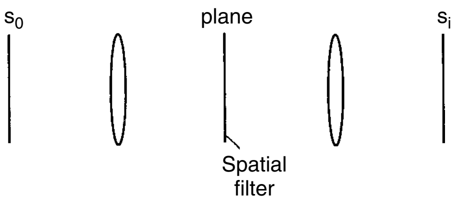

Fig. 9 A spatial filtering system. Object s_0 forms an image s_i, and the spatial frequency spectrum is modified by an attenuating and phase-shifting structure (a spatial filter) in the Fourier transform plane

object are displayed as a spectrum in that plane. For example, if the object is a simple sinusoid on a bias, $s_0 = \frac{1}{2} + \frac{1}{2}\cos 2\pi f_0 x$, the light distribution at the common focal plane consists of three points; the point on axis represents the bias term, and a pair of off-axis points represents the spatial frequency f_0. More precisely, if we write $\cos 2\pi f_0 x = \frac{1}{2}\exp(i2\pi f_0 x) + \frac{1}{2}\exp(-i2\pi f_0 x)$, that is, if we divide $\cos 2\pi f_0 x$ into its positive and negative complex frequency terms, the one off-axis point of light corresponds to the positive-frequency term and the other to the negative-frequency one.

A mask that alters the light distribution at this plane, either attenuating it or shifting its phase, is a spatial filter, and its behavior is analogous to that of an electrical filter. For example, a mask consisting of a small opening on axis is a low-pass filter, because it passes only the light representing low spatial frequencies. Similarly, a stop on axis would be a high-pass filter; such a filter in microscopy produces the well-known phenomenon of dark-field illumination. Other common spatial filters give rise to schlieren imagery and phase-contrast microscopy. In analogy with electrical systems, the optical spatial filtering system can be described in terms of a transfer function $H(f_x, f_y)$, which specifies how the system passes the various spatial frequency components (f_x, f_y).

The spatial filter mask can thus alter the object spatial frequency components by attenuating various spatial frequencies; this is accomplished by making the mask with an appropriate attenuation pattern. Similarly, the phase of the spectrum can be altered by making the mask with an arbitrary phase-delay pattern. Specifically, if the required transfer function is to be $H = |H|\exp(i\phi)$, with $|H|$ the amplitude part and ϕ the phase part, in principle, we need only to make a mask whose transmittance varies in accordance with $|H|$ and whose optical thickness varies in accordance with ϕ; the thicker the mask, the greater the phase delay.

The historical problem has been that, although amplitude control is easy, phase control is not. In principle, one could make an arbitrary phase characteristic $\exp(i\phi)$ by generating an arbitrary thickness function on some transparent material. Such precise thickness control is possible only in some simple cases, such as the Zernike phase-contrast filter.

A hologram, on the other hand, can easily produce exactly the needed transfer function, both in amplitude and in phase [8, 9]. The required transfer function $H = |H|\exp(i\phi)$ can be produced as a hologram having the transmittance $t = s_b + |H(f_x, f_y)|\cos[2\pi\alpha f_x + \phi(f_x, f_y)]$, where s_b is a bias term and where we use f_x and f_y as the variables, since the hologram is to be placed in a plane that displays the spatial frequency spectrum. The operation of the filter is described with reference to Fig. 10. The object s_0 is Fourier transformed, and the light emerging from the spatial filter mask H represents the product $S_0 t$, where S_0 is the Fourier transform of s_0. In expanded form, this product is written as

$$\begin{aligned} S_0 t = {} & S_0 s_b + \tfrac{1}{2} S_0 H \exp(2\pi i\alpha f_x) \\ & + \tfrac{1}{2} S_0 H^* \exp(-2\pi i\alpha f_x), \end{aligned} \qquad (4)$$

where the cosine term is written in exponential form.

The first term is of no interest, it simply represents a uniform filter that passes all spatial frequencies with uniform attenuation. The second term constitutes the object acted on by the complex filter $H = |H|\exp(i\phi)$ and multiplied by a factor $\exp(2\pi i\alpha f_x)$. Next, we see the usefulness

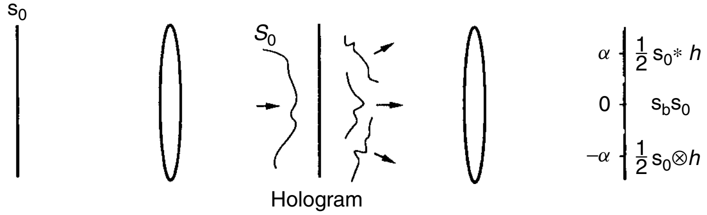

Fig. 10 Use of a hologram as a spatial filter

of this final factor. Similarly, the final term represents the object acted upon by a conjugate filter, $H^* = |H| \exp(-i\phi)$, and multiplied by a term $\exp(-2\pi i f \alpha_x)$. Thus, the holographic process has succeeded in producing an arbitrary transfer function H, as well as the conjugate transfer function H^*. We show that these three terms are physically separated in the image plane, just as the basic terms of the conventional hologram are separated. The second lens Fourier transforms these terms, yielding an image distribution

$$\begin{aligned} I_{\mathrm{im}} &= \mathrm{s_b s_0}|_{\text{centered on axis}} \\ &\quad + \tfrac{1}{2}\mathrm{s}_0^* h|_{\text{centered on }} x = a + \tfrac{1}{2}\mathrm{s_0} \\ &\quad \otimes h|_{\text{centered on }} x = -a, \qquad (5) \end{aligned}$$

where we have used some basic Fourier transform relations in obtaining this result. Here, * represents the well-known convolution, and ⊗ represents cross correlation. The latter is a mathematical method of comparing the similarity of two functions. Specifically, it is defined as

$$\begin{aligned} \mathrm{s_0} \otimes h = \int\!\!\int \mathrm{s_0}(x' + x, y' + y) \\ \times h(x', y')\, \mathrm{d}x'\, \mathrm{d}y'. \qquad (6) \end{aligned}$$

If $\mathrm{s_0}$ and h are very similar, then the integral will have a large value when $x = y = 0$, that is, when $\mathrm{s_0}$ and h are in alignment. We say then that $\mathrm{s_0}$ and h are highly correlated.

The term $\exp(2\pi i\alpha f_x)$ has resulted in a displacement α, a result following from a well-known theorem of Fourier transforms, namely, that linear phase shifts Fourier transform into displacements. From a physical viewpoint, the linear phase-shift terms represent wave-front tilts, and, consequently, the lens brings them to a focus at an off-axis location. If α is sufficiently large, the three terms will be completely separated, just as the various images are completely separated in conventional holography.

The matched filter is of special interest. A filter is said to be matched to a signal $\mathrm{s_0}$ if its transfer function is the complex conjugate of the object Fourier transform, or $H = S_0^*$. Matched filters are used for recognizing the presence of a particular signal that may be immersed in noise or other signals and therefore not readily seen. Pattern recognition is a common application of matched filtering.

To construct a matched filter for an object $\mathrm{s_0}$, a Fourier transform hologram is made of that object. The hologram is then used as a spatial filter, just as we have described above, with $H = S_0$. The output image is

$$\begin{aligned} i_{\mathrm{im}} \mathrm{s_0 s_b}|_{\text{centered on axis}} + \tfrac{1}{2}\mathrm{s_0} * \mathrm{s_0}|_{\text{centered on } \alpha} \\ + \tfrac{1}{2}\mathrm{s_0} \otimes \mathrm{s_0}|_{\text{centered on} -\alpha}. \qquad (7) \end{aligned}$$

The second term, generally uninteresting, is the self-convolution of the object.

The final term is the autocorrelation function of the object. It is typically a small, bright spot of light located at a position on the image corresponding to the position of the object.

Figure 11 shows experimental results using a matched filter of the letter *q*. In Fig. 11(a), we show a transparency containing an array of nine letters and numbers (alphanumerics), including *q*. The transparency is placed in the system shown in Fig. 10, with the aperture restricted so that only the letter *q* is illuminated. The Fourier transform of *q* [Fig. 11(b)] is formed at the frequency plane. A hologram of this distribution is formed by bringing in a reference beam. The hologram after development is placed back into its original position, and the array of nine letters is imaged through the hologram. Figure 11(c) shows an image of the correlation-forming first diffracted order. Each letter has been imaged as a light distribution that represents the cross correlation of that letter with the letter *q*. Since the letter *q* correlates strongly with itself, we see a very strong, concentrated spot of light at the position for *q*. The other letters are considerably different in structure from *q*, and the correlation is therefore much lower. A threshold detector, adjusted to respond only when the light level rises above some predetermined value, could then automatically recognize the presence of the letter *q*.

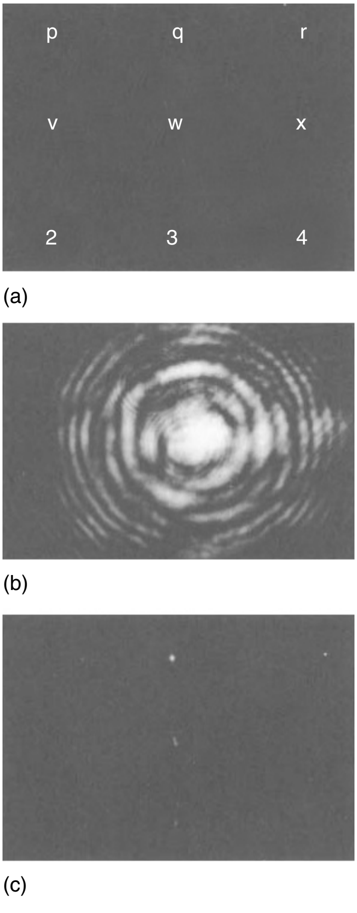

Fig. 11 Experimental results of matched filtering: (a) object, an array of numbers and letters; (b) Fourier transform of letter *q*; and (c) image formed by imaging object through the matched filter for the letter *q* and viewed in the correlation sideband of the filter

To give insight, a physical way of describing the operation of a matched filter is shown in Fig. 12. For simplicity, we show only the part of the filter mask. The spatial frequency spectrum S_0 of the object impinges on the filter mask as a wave front with some complex amplitude and phase distribution, the latter being depicted as wave-front irregularities. The wave passes through the spatial filter, where each part of the wave is phase adjusted so as to eliminate the irregularities. The wave emerges from the filter with uniform phase, essentially a plane wave; although, in general, not with uniform amplitude. This plane wave is then focused by the second lens into a small spot that is in fact the autocorrelation function we have previously described.

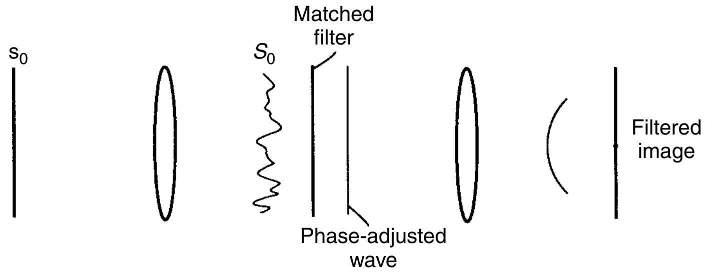

Fig. 12 Operation of a matched filter

The use of a hologram as a complex filter and, in particular, of a Fourier transform hologram of an object as a matched filter for that object was developed at the University of Michigan Willow Run Laboratories in the period 1961–1963 under military secrecy. The initial suggestion was given by C. J. Palermo and the initial reduction to practice was by Kozma and Kelly [9], who produced a matched filter for compression of a coded pulse of the sort used in radar systems. VanderLugt [8] extended the technique to pattern recognition and character reading, and in the process made some very sophisticated matched filters.

5.3
Hologram Interferometry

Hologram interferometry is another major application used primarily in scientific and engineering areas. There are three principal forms of hologram interferometry: time average, double exposure, and real time.

The earliest form, time average, was first reported by Powell and Stetson [10], who made holograms of vibrating objects. The reconstructed images were found to be overlain with light and dark bands. Such an occurrence is readily explained. It is well known that holography, being an interference process between two beams, requires stability in order that the fringes remain stationary. Thus, if the object moves during the exposure, the fringes will also move and will tend to be washed out, especially those fringes originating from portions of the object where the motion is greatest. Thus, motion of the object results in dark regions on the holographic image. A pessimistic assessment would conclude that the hologram is ruined. On the other hand, one might recognize that the banded pattern superimposed on the holographic image contains valuable information about how the object moved during the exposure.

In the case of the vibrating object, the pattern overlying the object depicts the vibration amplitude. In regions where the object is stationary (the nodes of the vibration pattern), the image is bright. Other object regions reconstruct less brightly. The strength of the reconstructed image is related to the vibration amplitude by a zero-order Bessel function, which is oscillatory in nature. Hence, the image is overlaid by a fringe pattern, the fringe peaks and valleys corresponding to contours of constant amplitude (Fig. 13). Thus, inspection of the image enables the vibrational amplitude of each point on the image to be accurately determined.

Double exposure is a second form of hologram interferometry. Typically, a

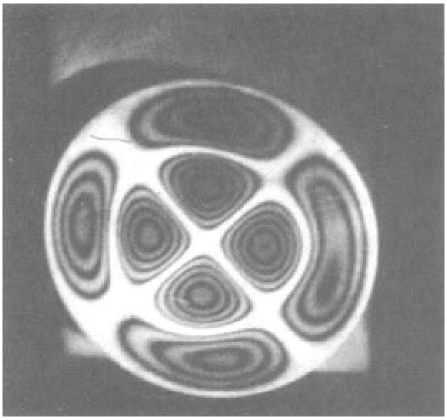

Fig. 13 Holographic image of a vibrating object, a flat plate held stationary at circumference

hologram is made of an object in an undistorted state, and then the object is distorted slightly, for example, by being stressed or heated. Then, a second exposure is made on the same photograph. On readout, two reconstruction fields are produced, one forming an image of the undistorted object, the other of the distorted object. The two wave fields interfere, forming an image with an overlay of fringes. In places where the object underwent no displacement, the two wave fields will be identical and will add in phase; the reconstruction will therefore be bright. At a position where the object shifted slightly, so that the two image waves are out of phase, destructive interference occurs and the image will be dark. Thus, the fringe pattern contains information about how the object distorted in response to the disturbance.

In the third basic form of hologram interferometry, a hologram is made of an object; then the hologram is placed back in its original position, while the object remains in its original position under continued illumination, and the reconstructed wave interferes with the object wave. The observer looking through the hologram thus sees a superposition of the object and the reconstructed image. Disturbing the object, by pressure, heating, and so on, produces a mismatch between the object wave and the reconstructed wave, causing a fringe pattern to be superimposed on the observed object–image combination. The result is akin to double-exposure hologram interferometry, except that the interference process occurs in real time, and the object can be distorted at will in many different ways. This process is appropriately called *real-time hologram interferometry*.

From the viewpoint of traditional interferometry, hologram interferometry is most remarkable. No longer is it necessary to bring two wave fields simultaneously into superposition in order to produce interference between them. The two waves can exit at different times or different places, and they can effectively be made to interfere simply by recording them holographically, thereby preserving both the amplitude and phase of each of the waves. In the context of conventional interferometry, such a process is absurd; interference could never be brought about by first recording one wave front and then at a later time and at another place, recording a second wave on the same film. Yet holography accomplishes exactly this feat.

Hologram interferometry, since its invention in 1965, has become a tool for science and engineering; its practical uses include the study of vibrations in automobile engines, the detection of defects such as cracks and debonds in airplane wings, the testing of tires, and the study of vibrational modes in musical instruments, such as violins.

Nowadays, hologram interferometry is generally carried out with a CCD (charge coupled device) camera as the recording medium, with computer reconstruction;

this method has significant advantages over photographic film. The recording can be done at lower light levels, and the hologram data can be available within a few seconds. The problems of wet film processing, including development, fixing, and drying are thus avoided. Also, with the computer, sophisticated image-processing procedures can be carried out. The CCD recording system is incorporated into an instrument consisting of a laser, beam splitter, and so on that are the usual parts of a hologram-forming system. The entire process can be carried out by persons unskilled in optics. Such systems are lightweight, highly portable, and relatively inexpensive. They have made hologram interferometer systems attractive for outside the laboratory, for example, in factory environments. The limitation of the CCD camera, which is of low resolution, is not a significant problem for hologram interferometry, since the large resolution requirements for holography are typically not present in hologram interferometry applications. The high-resolution requirements of holography arise from the recording of three-dimensional images with full parallax, and in hologram interferometry one is generally not required to form images that exhibit three dimensionality and parallax.

5.4
Holographic Optical Elements

Holograms have found a use very different from the production of fascinating three-dimensional imagery. They can be used as a special kind of optical element, analogous to lenses, but operating on the principle of diffraction instead of refraction.

A hologram of a point object made with a collimated reference beam can be illuminated with a collimated beam that duplicates the reference beam, whereupon a virtual point image is formed. Alternatively, the hologram can be illuminated with a conjugate reference beam that is collimated but counterpropagating, and the hologram will form a real point image. An alternative way of viewing the reconstruction process is to consider that the hologram is acting like a lens, bringing a collimated beam to a focus. Similarly, illuminating the hologram with a duplicate of the object beam reproduces the collimated reference beam. Now the hologram is a collimating lens. Finally, the hologram can be illuminated by light reflected from an extended object, and it will form an image of this object, just as does a lens. This phenomenon is not surprising if one considers that the hologram of a point object is just a Fresnel zone-plate lens, a commonplace device described in basic texts on physical optics.

As a lens, the point-object hologram is hardly competitive with a conventional lens since it has, because of its diffractive nature, severe chromatic aberrations, and therefore it is suitable only for use with monochromatic light. Besides, the zone-plate lens has all the basic aberrations of a simple refractive lens, such as spherical aberration, coma, and so on.

However, there are many specialty niches for the holographic optical elements. Diffractive elements disperse light in a way opposite to refractive lenses; that is, red is bent the most in a diffraction process, whereas the refraction process bends violet the most. Therefore, the hologram can sometimes be used to correct the dispersion of a glass lens, producing an achromatic combination [11]. In some situations, this method can be more effective than the usual method of using glasses of different dispersiveness for color correction. The holographic lens is especially effective in combination with refractive lenses to produce a compound Fourier transforming lens in which the dispersion requirements are quite different from those of image formation. Holograms can also be used as corrector plates to remove aberrations from a lens system [12]. Diffraction gratings are nowadays often made by recording on photoresists the interference of two collimated beams of light; these are usually called *holographic gratings*, although it is questionable whether the recorded patterns of interference of two plane waves should be called *holograms*. However, if one of the two beams contains some special irregularity that is to be incorporated into the grating, then hologram would be an appropriate term.

6
Volume Holography

The hologram has generally been treated as a two-dimensional structure with negligible thickness. Denisyuk [13] and van Heerden [14] departed from this view by describing holograms in which the thickness of the photographic emulsion, or other recording material, is sufficiently great to influence the diffraction properties of the hologram. When the recording material is sufficiently thick, the diffraction process is of a type known as *Bragg diffraction*.

The interference fringes formed when two light waves interfere are generally thought of as a two-dimensional pattern of light and dark lines, perhaps straight, perhaps curved. This is the way they are seen when viewed on a screen placed in the light path. However, it should be recognized that the interference typically occurs throughout the entire volume of space where the beams overlap, and the fringes are in fact three dimensional, being surfaces of brightness interspersed with surfaces of darkness. When the recording medium is thick, the recorded fringes become surfaces within the material. Figure 14 shows the two basic regimes of such recorded fringes. In the first, the two interfering beams impinge from the same side of the recording medium; in the second, from opposite sides. The fringes bisect the angle between the two beams and have a spacing that depends on the angle between the two beams. In the first regime, the fringes thus cut across the recording material and may have a spacing from very coarse to about λ, the wavelength of the illumination. In the second regime, the fringes are fine, on the order of $\lambda/2$ in spacing, and lie more nearly parallel to the emulsion surface, being exactly parallel to the surface when the beams are traveling exactly in opposite directions and normal to the surface. The criterion that distinguishes a thick recorded fringe pattern (i.e., a thick hologram) from a thin one is roughly that to be thick, the spacing between the fringes should be less than the thickness of the emulsion or other recording material. When two beams interfere with an angle of 5° between them and are recorded by a

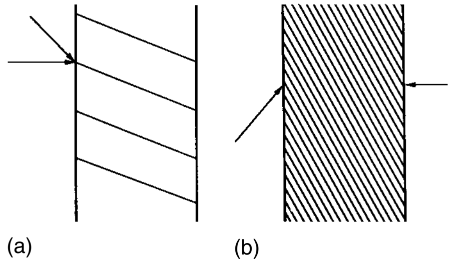

Fig. 14 Two regimes of volume-recorded fringes: (a) two beams impinging from same side of the recording medium; (b) two beams impinging from opposite sides of the recording medium

photographic emulsion of thickness 6 μm, a typical thickness, the fringe spacing is much greater than the thickness, and the law of diffraction for thin gratings holds. At an angle of 30°, the recorded fringes will usually be sufficiently fine to produce Bragg diffraction.

Bragg diffraction can be described in various ways. A simple approach is to consider it to evolve from conventional diffraction. Figure 15 shows diffraction from a thin grating. The incident beam strikes the grating at an angle θ_i to the normal and is diffracted at an angle θ_r from the normal. The diffraction angle can be calculated from the basic consideration that the first diffracted order occurs at an angle such that the optical path from a point on the impinging wave front to a point on the diffracted wave front is one full wavelength longer (or shorter) through one slit opening than through the adjacent one, from which we readily obtain $d_1 + d_2 = \lambda$, or $\sin\theta_\mathrm{i} + \sin\theta_\mathrm{r} = \lambda/d$, where d is the grating spacing. For the other diffracted order, the result is similar, except that one of the sine terms is negative. In either case, we require constructive interference between the light rays from the various openings. Examination of this diffraction equation shows that for a given angle of incidence, there will generally be a diffracted wave, whose angle changes with the incidence angle.

Now, suppose we let the emulsion become thick, and, for simplicity, let the fringes be normal to the emulsion surface (Fig. 16). The recorded fringes become surfaces. We consider each surface to be like a mirror that reflects some of the light incident on it, while the remainder is transmitted and undergoes partial reflection at the next surface. The diffraction process now takes on reflection properties. However, the same process that led to the previous diffraction equation still holds; the diffracted wave is still at the angle that leads to constructive interference from adjacent openings. Now, however, the openings have become surfaces that behave like mirrors, so that now the mirror law, that the angle of reflection equals the angle of incidence, must also apply. Thus we require also that $\theta_\mathrm{i} = \theta_\mathrm{r}$, causing the diffraction equation to become $2\sin\theta_\mathrm{i} = \lambda/d$, which describes Bragg diffraction. According to this equation, a beam of light falling on

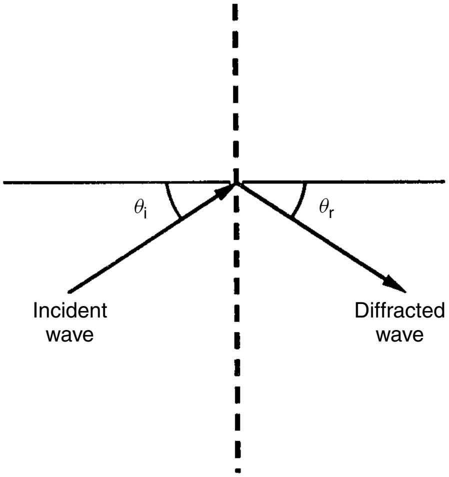

Fig. 15 Diffraction by a grating, arbitrary angle of incidence

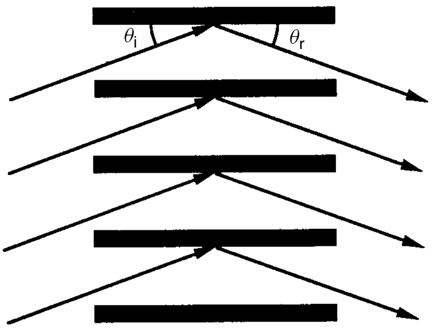

Fig. 16 Diffraction from a thick grating (Bragg diffraction)

the diffracting structure at an angle θ_i produces a diffracted wave if the equation is satisfied, but if the angle θ_i is changed, the diffracted wave does not change direction; it simply ceases to exist since the Bragg equation will not be satisfied. Thus, a Bragg-regime hologram must be illuminated at the proper angle in order to produce a diffracted wave. This effect is readily observed with holograms illuminated with a monochromatic source such as a laser beam. At the proper angle the image is bright, but rotation of the hologram by perhaps 5° or 10° will result in the disappearance of the image.

Alternatively, if the hologram is illuminated by a beam of white light, then in a given direction of viewing, only a narrow band of wavelengths will satisfy the Bragg angle close enough to give diffraction. Thus, the hologram can form an acceptably sharp image when viewed with white light; the hologram simply selects a narrow band of light for forming the image, while discarding the remainder.

In order that the band $\Delta\lambda$ of diffracted light be sufficiently narrow to form an acceptably sharp image, the hologram should be made with the object and reference beams coming from opposite sides of the film. Theory shows that the spectral width of the diffracted image depends on the number of fringe surfaces that contribute to a diffracted ray, in accordance with the equation $\Delta\lambda/\lambda = 1/N$, where N is the number of contributing surfaces and λ is the midband wavelength of the diffracted light (Fig. 17). This number is greatest when the reference and object beams are introduced from opposite sides since the fringes are finer, and the incident beam encounters more partially reflecting surfaces as it propagates through the emulsion.

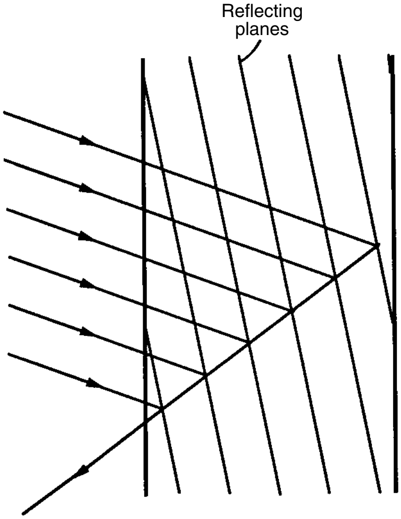

Fig. 17 Bragg diffraction from many surfaces. The diffracted ray is formed from many incident rays

Another characteristic of the hologram made with the beams coming from opposite sides of the plate is that the image is viewed from the same side of the hologram from which the illumination comes, as seen in Fig. 15. Hence, such holograms are sometimes described as *volume reflection holograms*. More often they are known as *Denisyuk holograms*. The reflection direction of the holograms can readily be seen by noting that the fringes are almost parallel to the emulsion; hence, considered as mirrors, they reflect the light back toward the source.

The most common way to make a Denisyuk hologram is shown in Fig. 18. A beam of laser light shines through a photographic plate to illuminate an object located on the other side. Light reflected from the object then is reflected back to the plate. Thus, the same beam of light exposes the plate twice, serving as the reference beam on the first pass

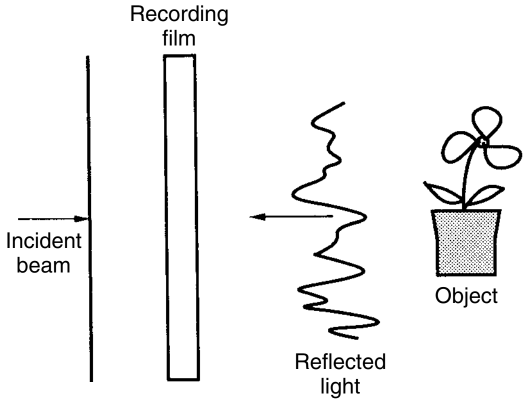

Fig. 18 Making of a Denisyuk hologram

and as the object beam on the second, a configuration that is both simple and effective.

7
Display Holography

7.1
The Beginnings

Display holography began in 1963, when holograms of 3D, diffusely reflecting objects were first made, as opposed to simple transparencies as objects. Such holograms were the first that could be viewed without the aid of eyepieces. Images such as these had never been produced previously, and people viewed them in astonishment.

However, it took many years for display holography to develop into a viable commercial activity. There were two principal problems. First, the early holograms had to be viewed with coherent sources, such as lasers or mercury arcs. Such sources were rather expensive. Second, the holograms themselves were rather expensive, since there were no ways to mass produce them. A hologram was made either as an original or by photographically contact printing from a master. In recent years, both limitations have been overcome, with the result that display holography, in many different forms, has prospered.

7.2
The Denisyuk Hologram

To be a successful display device, the hologram had to be white-light viewable. The first white-light viewable hologram, the volume reflection hologram of Denisyuk, had been described as early as 1962 [13], and high-quality Denisyuk holograms had been demonstrated by 1965. However, the early Denisyuk holograms lacked brightness, and the brightest ones were often afflicted with high levels of scattered light. The problem was one of chemistry; techniques of photographic development were required that would produce high diffraction efficiency with low noise scatter. These problems were gradually overcome over a period of many years, and today, bright, crisp, low-noise Denisyuk holograms are commonplace. A variety of recording media exist today for producing high-quality Denisyuk holograms. They can be made with very fine-grain emulsions and very special development techniques that have been perfected over many years. In addition, non–silver halide materials, such as dichromated gelatin and photopolymers, compete with silver halide and have captured a respectable percentage of the Denisyuk display hologram market. Denisyuk display holograms are generally the most expensive, since they are not easily mass produced. However, they certainly are the highest quality of display hologram. They seldom appear on covers of magazines, but rather are typically displayed in galleries and exhibitions.

The quality of the hologram is strongly dependent on the recording medium, especially for the Denisyuk holograms, since such holograms are the pinnacle of hologram perfection. The principal factors for judging hologram quality are: the brightness, or diffraction efficiency, the level of scattered light, or ambient background, and for color holograms, the degree of color saturation. Diffraction efficiency in holograms recorded on silver halide photographic plates is determined by the form of chemical processing used in the development and bleaching procedures. In general, as the diffraction efficiency is increased, the scattered light level increases, so the aim is to produce the highest diffraction efficiency in combination with the lowest light scatter. With color holography, the problem is especially critical since the blue light produces significantly higher scatter than the longer wavelengths. New photographic emulsions coming into use have silver grains smaller than the wavelength of light, and consequently provide extremely low levels of scatter, resulting in holograms of significantly higher quality that were available a decade ago. In such holograms, a portion of the image that should be black appears in these new holograms as being very black indeed.

7.3
The Benton Hologram

In 1969, a second kind of white-light viewable hologram, known as either the *rainbow* or *Benton hologram*, was invented [15]. The construction method has two steps (Fig. 19). First, a conventional laser transmission hologram is made. Next, a second hologram is made, using as the object the real image from the first hologram. In this process, a narrow horizontal slit is placed

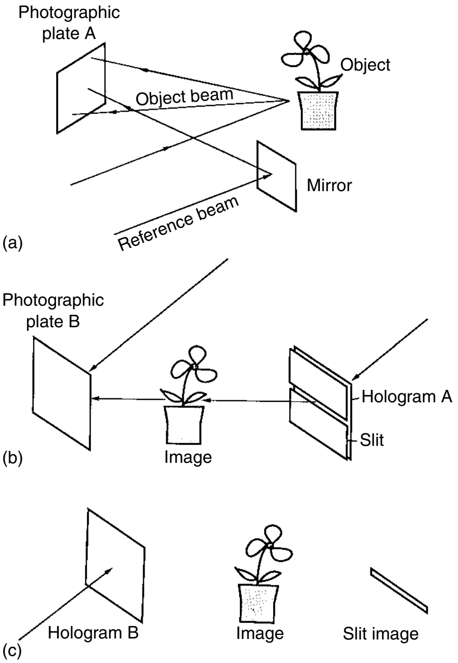

Fig. 19 Making and viewing of a Benton hologram. (a) First step, making a conventional hologram. (b) Second step, making a second hologram from real image of the first hologram. (c) Illumination of the second hologram (with monochromatic light). An image is formed both of the object and of the slit. Illumination with polychromatic light forms a spectrum at the slit image position. An observer places his eye somewhere in the spectrum; consequently, he sees an image in monochromatic light, and the image is therefore sharp

at the first hologram, thus eliminating all parallax in the vertical plane. The second hologram, under coherent illumination, forms an image of the original object, either virtual or real, as well as a real image of the slit. To see the image, the observer must place his eye at this slit image. If he moves his head vertically, the image disappears; hence there is no vertical parallax. The image, however, can be quite bright; all the light that ordinarily would be spread over a vertical distance of perhaps 1 m at the observer's position is now confined to the slit image, and the brightness increase can be several hundredfold.

There is, however, an even more important advantage to this method: white-light viewability. If one were to illuminate the hologram with light of two different wavelengths, the lateral dispersion would result in two vertically displaced slit images, one for each color. The observer would see the entire image in one color when he positioned his eyes at one slit image and in the other color when he positioned them at the other slit image. Extrapolating this process to white-light illumination, where the slit image would be smeared into a continuous spectrum, one finds that to view the hologram the observer may position his eyes at any location on the spectrum, whereupon he will see a sharp, clear image in the color corresponding to that part of the spectrum. As he moves his head vertically, the image changes color but remains sharp and clear. If his head is not in the image plane of the slit, he will still see the entire image, but the color will change from top to bottom. Appropriately, such holograms have been called *rainbow holograms*.

In exchange for giving up vertical parallax while retaining normal horizontal parallax, one has obtained holograms that can be viewed in white light without the thick emulsion requirement. The Benton hologram thus offers a favorable tradeoff, in which the comparatively unimportant feature of vertical parallax is exchanged for the important white-light viewing capability.

7.4

The Multiplex and Related Holograms

Another important development, the composite or multiplex hologram, overcomes some of the basic limitations of the more conventional holographic techniques. Here, a hologram is synthesized from a large number of ordinary photographs made in a conventional way. The pictures, made from different positions, constitute many views of the object, and they have in total all the essential information contained in a hologram. The composite method synthesizes the many pictures into a single hologram.

Composite holograms were first reported by various groups, including Pole [16], McCrickerd and George [17], and DeBettito [18]. In the next few years, many advances were made, culminating in a system perfected by Lloyd Cross and his colleagues. In the Cross method, the object is placed on a slowly rotating platform and a motion picture camera makes hundreds of pictures, just as in conventional cinematography. The pictures could then be made into a single hologram as follows. The first picture could be imaged onto a screen consisting of a piece of frosted glass. The light transmitted by the screen would be recorded as a hologram in the form of a long thin strip about 1 mm wide and perhaps 20 cm long, the purpose of the frosted glass being to direct light from all parts of the image to a recording slit that controls the width of this hologram. The actual system differs from this in that, instead of the diffuser, a large cylindrical lens at the image plane is used for directing the light to the slit; this method uses the light more efficiently and reduces laser speckle. After one frame is recorded as a hologram, the next frame is similarly projected, the recording film is moved one slit width, and a second hologram is made in an adjacent recording position, and so on.

The resulting hologram, the collection of all of the individual slit holograms, is then wrapped into an arc corresponding to the angle of rotation of the object and is illuminated as a conventional hologram. Each component hologram projects a virtual image without depth or parallax, just like the image from which the hologram was made. When an observer views the filmstrip, however, each eye looks at an image point through different holograms. The image formed on the retina of each eye is slightly different, as in a stereoscopic viewer, and consequently a three-dimensional image is perceived. As the observer moves his head laterally, different images are seen, thereby producing parallax. The Cross technique can be combined with the Benton technique, thus allowing white-light viewing. Essentially nothing is given up in so doing, since the composite holograms lack vertical parallax anyway.

In a variant of this method, the recording camera is translated laterally instead of the object rotating, resulting in what is called a *flat integral*, since the hologram is no longer curved into an arc for viewing. This flat integral can be used as a master for making a second hologram, where the image can be brought into the plane of the hologram, thus relaxing the viewing light source size requirements and giving a sharper image.

7.5
Construction of Commercial Display Holograms

Commercial holograms, whether for display on magazine covers, on credit cards, or in galleries, should be white light viewable. Various standard techniques have been developed for the production of commercial display holograms, all based on either the Denisyuk or Benton white-light viewing methods.

Typically, a master hologram is made as a conventional laser transmission hologram. The conjugate image may then be used as an object to produce a volume reflection hologram. The resulting hologram has an image that straddles the hologram, being partly in front of it and partly behind it, thus giving a sharper image than if the image were entirely on one side of the hologram. One of the limitations of the white-light-viewable hologram is that the image sharpness decreases with the distance of the image from the plane of the hologram.

Portrait holography can be done using this method, in which case the master hologram will have to be made with a short-pulsed laser so as to freeze object motions, since a living person cannot ever be stationary enough to be holographed, unless the exposure time is much less than 1 ms.

For inexpensive, mass-produced holograms, such as those found on magazine covers, and so on, the Benton technique is used, since Benton holograms do not require any volume effects for white-light readout and, consequently, can be readily produced by embossing methods, which are inherently surface phenomena.

To mass produce a Benton hologram, the original laser-produced master hologram is used to form a real image, which is then used as the object for making a second hologram of the Benton type. This hologram is recorded on photoresist, which when developed forms a surface relief pattern. This hologram is placed in a plating bath, where nickel is plated onto the hologram surface; when the photoresist is removed, a surface relief hologram made of nickel remains. This can be used in an embossing process, where the hologram is mounted in a press and used to stamp the surface relief pattern onto a sheet of heated plastic. Such holograms can be produced at a fast rate, thousands per hour, and the total production run can be in hundreds of thousands or even millions. These holograms can be bonded to paper by hot-stamping methods. This mass production method has made display holography a significant business.

8

Holography Today

Holography today is a relatively small but thriving and expanding business. Display holography is probably the leading commercial application area. Artists are employing holography as a new medium, and their works are displayed in museums and galleries. Increasingly, color holograms, as opposed to monochrome, are being seen.

The largest commercial activity is the mass production of Benton-type holograms in magazines, in advertising, for Christmas cards, for baseball cards, and so on, and as security devices on valuable objects such as credit cards and money.

Holographic optical elements are of ever-increasing importance in such applications as diffraction gratings and beam splitters. Head-up displays on fighter aircraft commonly use holograms. Holograms play a significant role in the development of all-optical or hybrid-optical electronic digital computers, an area of current intense research. Holograms have potential as memory elements in such computers, and as interconnections to connect various storage and processing elements of the computer. Other factors being equal, the more interconnections, the more powerful the computer, and holograms offer the possibility of an enormous number of interconnects in a very small volume.

Hologram interferometry continues as a solid area, with use in scientific and engineering applications. It shares its application areas with other new, laser-based types of interferometry, such as speckle interferometry and shearography.

Various other minor applications of holography exist that do not fall into these categories, but have the potential for becoming major applications. The outlook for further holographic application development is bright.

Glossary

Amplitude: For a light wave, the magnitude of the electric field, or equivalently, the square root of the irradiance (or intensity).

Bragg Diffraction: Diffraction from a volume, or thick, grating, characterized by a diffracted beam being produced only for certain incidence angles of the illuminating beam.

Coherence Length: The path difference allowable between two interfering beams before interference no longer occurs.

Coherent Light: Light that is monochromatic and derived from a point source, or equivalently, which can be focused to a point. Laser light is highly coherent; nonlaser light (e.g., Hg arc source light) can be made moderately coherent by passing it through a filter and a pinhole.

Composite Hologram: A hologram formed from a number of individual subholograms, each formed from a separate image.

Convolution: The convolution of two functions $g(x, y)$ and $h(x, y)$ is the mathematical operation

$$g(x, y) * h(x, y) = \iint_{-\infty}^{\infty} g(\alpha, \beta) \times h(x - \alpha, y - \beta)\, \mathrm{d}\alpha\, \mathrm{d}\beta$$

When an object is imaged through a spatial filter, the resulting image is the convolution of the object with the point spread function h of the filter, where the point spread function is the image produced by a point object.

Cross Correlation: Somewhat similar to a convolution, the cross correlation of two functions $g(x, y)$ and $h(x, y)$ is the mathematical operation.

$$\iint_{-\infty}^{\infty} g(\alpha, \beta) h^*(\alpha - x, \beta - y)\, \mathrm{d}\alpha\, \mathrm{d}\beta.$$

Diffraction: The tendency of light to spread out when passing through narrow apertures, or to bend when passing near an obstruction, such as a knife edge.

Fourier Transform: Mathematically, the Fourier transform of the spatial function $g(x, y)$ is defined as the integral

$$G(f_x, f_y) = \iint_{-\infty}^{\infty} g(x, y) \times \exp[-i2\pi(f_x x + f_y y)\, \mathrm{d}x\, \mathrm{d}y,$$

where f_x, f_y are new variables resulting from the transformation. More physically, a decomposition of the signal $g(x, y)$ into its spatial frequency components.

Frequency Plane: A plane in a coherently illuminated optical system where the light distribution is Fourier transform–related to the object light distribution.

Hologram Interferometry: A form of holography in which multiple images (two or more) of the same object are stored on the same recording medium, and in which, on readout, interference effects occur among the various recorded images.

Interference: The tendency of two or more light beams in superposition to combine in a reinforcing way at some positions to form a resultant intensity greater than the sum of the two intensities individually, and to produce cancellation effects at other positions.

Matched Filter: An important type of filter, used for detecting the presence of signals immersed in noise, clutter, or competing signals.

Multiplex Holography: A particular type of composite hologram, distinguished primarily by its cylindrical shape.

Phase: For a signal $a \cos(2\pi f_0 \tau + \phi)$, a is the amplitude, ϕ is the phase, and f_0 is the carrier frequency. The phase may be roughly described physically as the shape of the wavefront.

Phase Conjugation: The operation of changing a complex signal $u = a(x, y) \times \exp[i\phi(x, y)]$ into its complex conjugate $a(x, y)\exp[-i\phi(x, y)]$.

Spatial Filter: A mask placed in a plane in an optical imaging system where the light distribution is Fourier transform–related to the object distribution. The mask modifies the spatial frequency content of the image by attenuating or phase shifting the various spatial frequency components of the object.

Transfer Function: The transfer function of a system describes the way various frequency components of a signal pass through the system, that is, how much attenuation and phase shift the frequency components undergo. The system may be quite complicated, being formed from many elements, or it may be, in the simplest case, simply a filter.

27.1
Radiation as a Diagnostic Probe

Medicine is devoted to preventing disease or injury, detecting and diagnosing what is wrong when disease or injury may be present, and treating the patient to alleviate pain, restore function, and, when possible, cure the problem. Diagnosis is often a major challenge, because the patient's symptoms are frequently relatively unspecific and could be caused by a variety of conditions. Meeting this challenge usually requires conducting a variety of tests, including laboratory analyses and imaging procedures. These tests are nearly all products of technological advances in the practice of medicine that occurred in the twentieth and so far in the twenty-first century.

Before then, physicians were severely limited in the tools available to help them arrive at a correct diagnosis. Most of what they could learn came from a verbal description of symptoms by the patient, combined with the patient's history and of the physician's detection of abnormal odors, visual appearances, sounds, and feel in accessible organs. Indicators such as temperature, pulse and respiratory rates, and visual and muscular reflexes sometimes contributed to the process, as did rudimentary analysis of blood, urine, and so on. Exploratory surgery was a common but risky procedure that often contributed more to the problem than to the solution. On many occasions, the physician could provide little more than sympathetic understanding and emotional support.

Wilhelm Roentgen, a physicist at the University of Wurzburg in Germany, discovered X-rays in 1895, and thereby provided medicine with an astounding and totally unanticipated new life-saving tool for examining the inside of the body without having to cut into it (Figure 27.1) (Röntgen, 1895). And in the year following Roentgen's monumental finding, Henri Becquerel in Paris stumbled upon radioactivity and, in particular, the β-rays that it creates (Becquerel, 1896). While it was not apparent when they were discovered by Villard in 1900, γ-rays would also come to play an invaluable role in medicine.

Diagnostic X-rays are produced by an X-ray tube while γ-rays are emitted from radioactive materials, but they differ only in their origin: once in existence, they are identical. X- and γ-rays are a form of electromagnetic (EM) radiation similar to infrared (IR), visible, and ultraviolet light, except orders of magnitude higher in frequency and

energy. Unlike lower-energy forms such as IR and visible light, γ- and X-rays have three critically important characteristics: they can penetrate substantial thicknesses of biological materials, with the degree of penetration depending on the nature of the tissue; they cause the emission of points of light (*scintillations*) when individual photons strike a fluorescent medium; and they ionize the tissues through which they pass. Their diagnostic usefulness depends crucially on the first two of these attributes, and the risk they pose arises because of the third.

27.1.1
Creation of an Image

Technology has long been propelling itself forward at an ever-faster pace, and medical imaging technology has been at the front edge of the changes, especially since the mid twentieth century. Today, methods to produce medical images involve the use of physical probes that are created, affected by the body, and detected in strikingly different ways. Some methods, such as X-ray imaging, computed tomography (CT), diaphanography, and tissue impedance tomography function by detecting how many of the probes pass through regions of the patient without interaction. Others, such as nuclear medicine (including single photon emission computed tomography (SPECT) and positron emission tomography (PET), thermography, electroencephalography (EEG), and magnetocardiography (MCG)), create images from extremely faint signals emerging from different regions of the body. Waves of ultrasound (US) energy are reflected from tissue interfaces and moving blood. Magnetic resonance imaging (MRI) involves the transmission of pulses of radio frequency (RF) EM radiation, their interaction with the protons of tissue water in a strong external magnetic field, and reception of RF signals the protons themselves subsequently produce. And an increasing number of optical imaging techniques employ visible or near-visible light to provide image information about patients.

Photons of all energies (X-ray, γ-ray, ultraviolet, optical, IR, microwave, and RF), weak electric and magnetic fields, US waves, and other probes differ substantially in their ability to penetrate the body, the types of background noise with which they must compete, and the ease with which they can be detected and localized. These factors, along with concerns related to radiation dose, acoustic power, intensity of static and dynamic magnetic fields, and so on, can influence the level of image contrast achievable among healthy and diseased tissues, the spatial and temporal resolution possible, the presence of noise or artifacts, and the overall clinical utility of an imaging modality. As a result, there are a number of widely accepted technologies to choose from in posing and addressing a particular clinical question; indeed, part of the task of the clinician is to be adept at selecting the imaging technology with the greatest likelihood of providing the correct diagnostic answer safely and at acceptable cost.

Biomedical research is becoming ever more interdisciplinary, as it depends increasingly on cross-fertilization between the physical sciences and engineering on the one hand, and biology and clinical medicine on the other. Examples of the fruits of such collaboration abound – such as recent developments in molecular imaging, biomedical informatics, nanobiotechnology, computer-aided detection (CAD) and computer-aided diagnosis (CADx), and the convergence of diagnosis and therapy in applications such as image-guided intervention. These issues comprise the subject of this chapter.

27.2
X-ray Imaging

There are two general categories of imaging with the high-energy photons produced by X-ray tubes. With either method, image information is obtained in the form of shadows cast in a uniform X-ray beam through differential attenuation by materials in the body that vary in thickness, density, or chemical composition (i.e. atomic number), leading to the creation of a two-dimensional X-ray shadowgram by tissues actually distributed in three dimensions. The first, in the form either of conventional *radiography* or of *fluoroscopy*, displays the resulting shadow information directly on a flat image receptor (such as a screen-film cassette, fluoroscopic image-intensifier tube plus electronic optical camera combination, or digital solid-state flat-panel imager) as a *planar* (flat), two-dimensional image. The second, X-ray transmission *CT*, captures the shadow with a bank of tiny radiation detectors, and then *reconstructs* the data to produce a true three-dimensional representation of the internal structures of the body – although clinical images are traditionally presented as transverse or other pancake-like tissue *slices*.

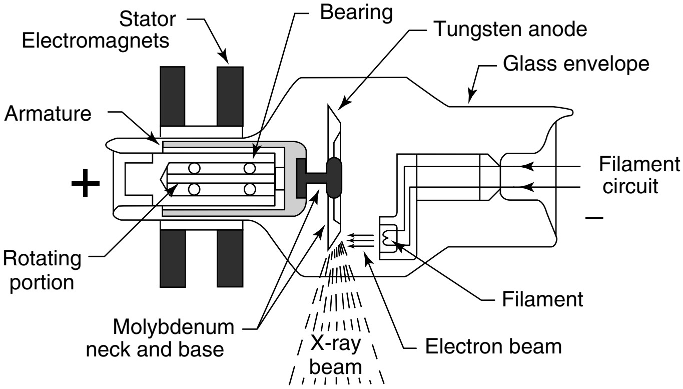

Fig. 27.2 Simplified X-ray tube with a rotating anode and a heated filament. (From Hendee, W.R. and Ritenour, E.R. (2002) *Medical Imaging Physics*, 4th edn, John Wiley & Sons, New York.)

27.2.1
Nature and Production of X-Rays

To generate clinically acceptable medical images, a source of X-rays has to provide a sufficient number of X-ray photons efficiently and in a reproducible fashion and, for radiography, in a short interval of time. The operator must be able to select the beam intensity, the exposure duration, and the maximum photon energy. And, of course, the device is legally bound to meet current standards of safety.

The standard source almost universally employed for X-ray imaging is the X-ray tube (Figure 27.2). As electrical current (on the order of several amperes) heats a tungsten filament in the cathode, electrons are "boiled off" (*thermionic emission*) and, when no high voltage is being applied, form an electron space-charge cloud near its surface; the emission causes the cathode to become slightly positive and that, along with the mutual repulsion among the electrons, prevents the cloud from spreading far. The situation changes radically when a potential of 20 000–150 000 V (20–150 kVp, where (*kVp*) denotes the *peak kilovoltage*) is applied directly between cathode and anode. Electrons are swept through the high vacuum and strike the thin tungsten target (high melting point) bonded to the surface of the massive copper anode (high thermal conductivity), all with a maximum kinetic energy (in *electron volts*[2], eV) numerically equal to the kVp setting on the tube's generator. A focusing cup around the filament helps direct the electrons onto the small *focal spot,* which traces out a narrow annulus on the rapidly rotating anode. Most (>99%) of the electron energy is expended through resistive heating of the target and anode; the massive anode disk rotates at several thousand revolutions per minute to spread the heat over a larger area of target metal, to keep its temperature below its melting point. The remaining 1% of the electron energy arriving at the focal spot is transformed into X-rays by two quite different mechanisms.

---

[2] The electron volt is a unit of energy equal to that gained by an electron accelerated through a potential difference of 1 V. keV stands for kilo-electron volt.

The first process, the creation of *bremsstrahlung* (from the German for "braking," as in hitting the brakes of a car), occurs through a mechanism similar to that which gives rise to radio waves. RF EM energy is radiated from a radio antenna when electrons are driven back and forth in it by the high alternating voltage produced by a radio transmitter. Likewise, the electrons striking the anode of an X-ray tube undergo Coulombic interactions with strongly charged nuclei of the target atoms, and are often deflected widely and also slowed down abruptly. Their rapid deceleration causes the emission of EM energy but, since the electron energies are so much higher, so also are the energies of the emitted X-ray photons. A bremsstrahlung spectrum is distinctive: although all electrons reach the anode with close to the maximum energy of kVp eV, only a tiny fraction of the resulting X-ray photons have the maximum energy, and the intensity of an "ideal" X-ray beam increases linearly with decreasing photon energy (Figure 27.3). Preferential absorption of low-energy photons by the anode itself, added *filtration*, and other materials *harden* the beam, causing the drop-off in beam intensity at low photon energies. Since the low-energy photons are not sufficiently penetrating to be of diagnostic value, but would deposit potentially harmful energy (dose) in a patient's tissues, their removal from the beam is a highly desirable effect.

The other mechanism for X-ray production involves the interaction of

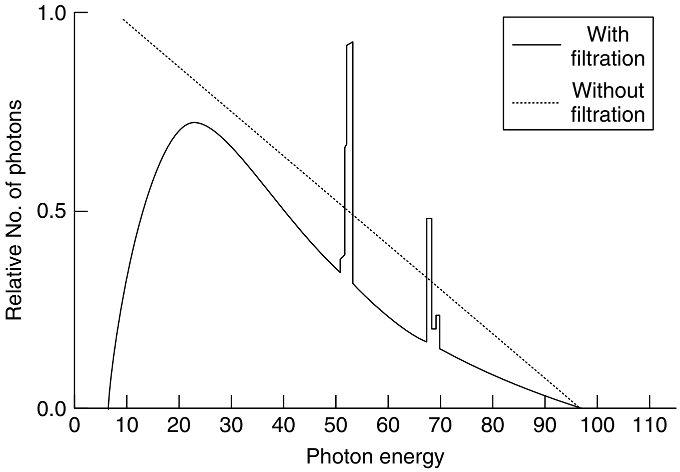

Fig. 27.3 Emission spectrum for a tungsten target X-ray tube operated at 95 kVp. Characteristic X-ray emission occurs for tungsten whenever the tube voltage exceeds 69 keV, the K shell binding energy for tungsten. The *dashed line* represents the theoretical bremsstrahlung emission from a tungsten target. The *solid line* represents the spectrum after self, inherent, and added filtration. The area under the spectrum represents the total number of X-rays. (From Hendee, W.R. and Ritenour, E.R. (2002) *Medical Imaging Physics*, 4th edn, John Wiley & Sons, New York.)

the incident, high-energy electrons with the orbital electrons, rather than the nuclei, of the target atoms. Target atoms are ionized with the ejection of inner-shell electrons, and X-ray photons are released as the affected atoms regain stability: outer electrons drop down into the vacancies, with a reordering of the electron shells, and emit photons in the process. These photons are termed *characteristic X-rays* because their energies are characteristic of the target metal material. Shown in Figure 27.3 are the 58- and 67-keV characteristic X-rays of tungsten.

For X-ray beams in nearly all medical applications, bremsstrahlung is a much more important contributor than characteristic X-rays. A notable exception is the primary role played by molybdenum characteristic X-rays in mammography (imaging of breast tissue), an application discussed later. Either way, X-rays are released in all directions as the electrons interact in the target. The X-rays are restricted by shielding and by collimators outside the X-ray tube to a beam to be directed at the anatomic region of interest in the patient. The tube is contained within an oil-filled shielded housing that provides electrical insulation and prevents X-rays from emerging in unwanted directions. Only about 1% of the original electron beam's energy is transformed into X-rays, and only a fraction of these X-rays escape through the tube window and housing to reach the patient.

During an X-ray exposure, the *technique factors* [tube voltage (kVp), tube current (mA), and exposure time (ms)] are controlled carefully to prevent overheating of the target and other components.

27.2.2
Interactions of X-rays with Matter

For a parallel, monoenergetic beam of X-rays, the intensity, I, of X-rays transmitted through a material of thickness z obeys de Beer's law:

$$I = I_0 \exp \int_0^{Z} \left[-\mu(z') dz' \right] \tag{1}$$

where the line integral is taken across all tissues along a "ray" of the X-ray beam, I_0 is the intensity with no material present, and $\mu(z)$ is the *linear X-ray attenuation coefficient* of the material, typically in units cm^{-1}. The linear attenuation coefficient depends on the effective energy of the beam, and on the density and effective atomic number of the material through which it passes, so it may vary along the path. If the material varies in composition laterally, as well, the intensity of the transmitted X-rays will vary across the face of the previously uniform X-ray beam, casting a shadow in it. This pattern of transmitted X-rays, which now bears information about the patient, can be captured on film, a fluorescent screen, or digital array detector, yielding a projection radiograph.

The linear attenuation coefficient is the sum of coefficients for several different types of X-ray interactions that may occur in the material. For the diagnostic energy range (20–150 keV), two of them are dominant: the photoelectric effect, described by the photoelectric linear attenuation coefficient, τ, and the Compton scatter effect with Compton linear attenuation coefficient, σ.

In a *photoelectric interaction*, the X-ray interacts almost always with a tightly bound electron in an inner shell of

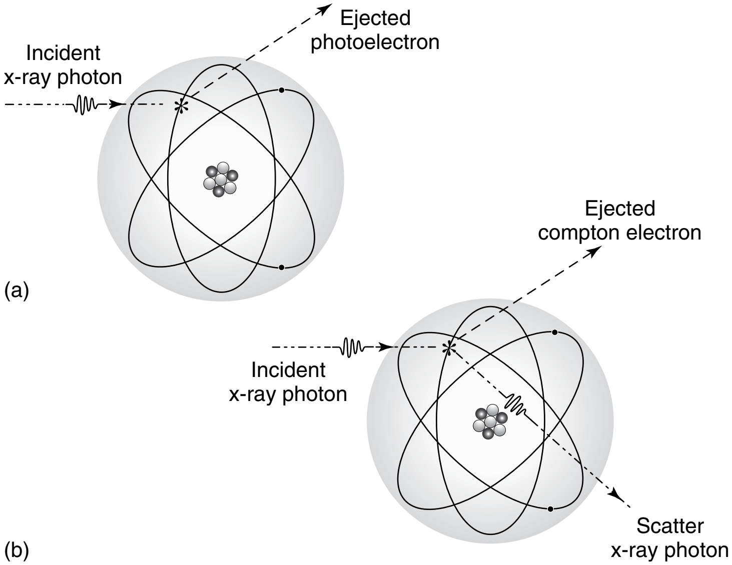

Fig. 27.4 (a) Photoelectric absorption of a photon with energy $h\upsilon$. The photon disappears and is replaced by an electron ejected from the atom with kinetic energy $E_k = h\nu - E_b$, where E_b is the binding energy of the electron. Characteristic radiation and Auger electrons are emitted as electrons cascade to replace the ejected photoelectron. (b) Compton scattering of an incident photon, with the photon scattered at an angle ø; the Compton electron is ejected at an angle θ with respect to the direction of the incident photon.

an atom of the tissue (Figure 27.4a). Photoelectric interactions are strongly influenced by the atomic number Z, with the probability of photoelectric interaction per unit mass of material varying with the third power of the effective atomic number of the material, as $\tau \sim Z^3$. In a collision, all the energy of the X-ray is transferred to the electron, which is ejected from the atom with a kinetic energy E_{KE} of

$$E_{\mathrm{KE}} = E_{\text{X-ray}} - E_b \tag{2a}$$

E_b is the binding energy of the ejected electron, and $E_{\text{X-ray}}$ is the X-ray energy, which can also be expressed as $h\nu$, where h is Planck's constant (6.62×10^{-34} J s) and ν the frequency of the wave-like X-ray. Since the X-ray is pure energy, it disappears during a photoelectric interaction and is essentially replaced by an ejected high-speed electron and an ionized atom. Photoelectric interactions occur predominantly with low-energy X-rays, and decrease in likelihood at higher energies ($\tau \sim (h\nu)^{-3}$). Overall, the probability of a photoelectric event occurring depends on density, atomic number, and photon energy as

$$\tau \sim \rho(Z/h\nu)^3 \tag{2b}$$

A *Compton interaction* results in the scattering of an X-ray in a new direction at reduced energy, rather than complete absorption of the X-ray (Figure 27.4b). Compton scattering produces scattered radiation that degrades the quality of

X-ray images. In this type of interaction, the X-ray photon collides with a loosely bound electron in an outer shell of an atom of the absorbing material. The electron is ejected with an energy equal to the difference in energy of the incoming and scattered X-rays, since the binding energy of the ejected electron is usually small enough to be neglected. Because the interaction occurs almost always with outer, loosely bound electrons, the Compton interaction is nearly independent of the atomic number Z of the absorbing material. The linear Compton attenuation coefficient is also nearly independent of photon energy in the diagnostic range, and becomes dominant at higher energies simply because of the rapid decline in photoelectron events.

The linear attenuation coefficients τ and σ are, in effect, probability rates for mutually exclusive events – that is, a photon that is removed from the beam by a photoelectric collision cannot also undergo a Compton scatter – so

$$\mu = \tau + \sigma \tag{3}$$

Depending on the kVp setting, an X-ray beam may yield a projected image that accentuates or suppresses effects due to differences in atomic number among different tissues, which can be of great advantage in imaging. Low-energy X-rays can be used to amplify small differences in soft tissue composition, as is standard practice in mammography. On the other hand, high-energy X-rays may be needed to suppress the consequences of relatively large differences in tissue composition, so that subtle features of soft tissue are not obscured by the shadows cast by strongly absorbing structures. In chest imaging, high-energy X-rays are used to penetrate the ribs and other strongly absorbing structures to reveal the intricacies of the underlying lung parenchyma (Figure 27.5).

For X-rays at any energy, those that are not transmitted through are absorbed or scattered in the patient. This results in energy deposition in the tissues, where the ionizing energy deposited per unit mass of absorbing material is

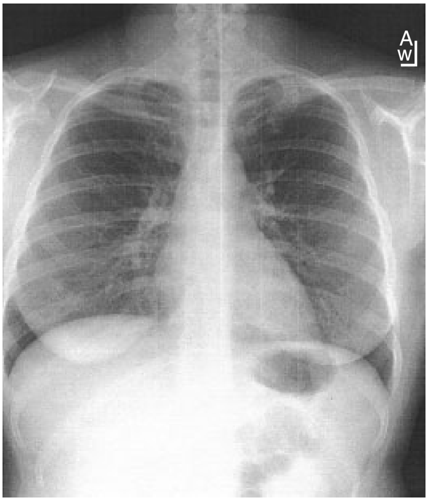

Fig. 27.5 A normal chest radiograph (courtesy of Lacey Washington, MD, Medical College of Wisconsin).

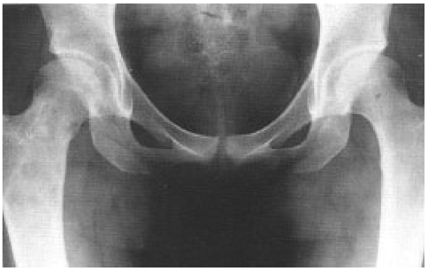

Fig. 27.6 Various appearances of fibrous dysplasia. Young adult with a sclerotic, osteolytic, and intracompartmental lesion confined to the femoral neck and proximal diaphysis. There is a fracture in the medial aspect of the femoral neck that accounts for symptoms. (From Bragg, D., Rubin, P., and Hricak, H. (eds) (2002) *Oncologic Imaging*, 2nd edn, W.B. Saunders Company, Philadelphia, with permission).

known as the *absorbed dose*. Because dose, like image quality, depends on beam energy, the choice of kVp requires the optimization of the balance between the two. This is but one of many trade-offs one confronts in medical imaging.

27.2.3
Creation of an X-Ray Image with a Screen and Film

When a diagnostic X-ray beam is directed into a region of the body, variations in thickness, density, and chemical makeup (effective atomic number) create shadow patterns in it, the relative shades of gray of which are influenced also by the effective energy of the beam. These spatial variations in intensity can be captured on a radiation-sensitive *image receptor* such as a light-tight *film cassette,* which sandwiches a sheet of X-ray film between a pair of flat *fluorescent screens,* currently almost always made of rare earth materials.3) When a screen is struck by an X-ray photon, it emits a point of light that exposes a microcluster of silver iodobromide crystals in the film's emulsion. The bits of silver halide that are exposed to sufficient light are later converted into flakes of pure silver upon chemical development, making the film darker. The resulting film is a negative, in a sense, since a part of the body where attenuation is small gives rise to a darker portion of film.

In the X-ray film of Figure 27.6, the bony structures are lighter because bone is a strong absorber of X-rays, and the portion of film behind it experiences less X radiation. Distinctions among the various soft tissues are much less obvious, however, because their attenuation coefficients are nearly the same. A major degrading influence on contrast is the incidence on the detector of Compton-scattered radiation in the patient, a form of random noise. Scatter can be reduced by placing a mechanical *grid* between the patient and the detector. A grid, consisting of thin metal foil sheets separated by very narrow gaps, allows unscattered X-rays to pass through to the detector, but obstructs scattered X-rays that have been deflected from their original paths through the patient.

The spatial resolution of a typical radiograph is exceptionally high, on the order of a tenth of a millimeter. This is so, in part, because the origin of the X-rays,

---

3) The sole purpose of the screens is to reduce patient exposure. This can be achieved very effectively, but unfortunately it also diminishes image sharpness somewhat. As in many situations in imaging, the operator is faced with a trade-off in selecting the screen, having to choose between higher sensitivity versus finer resolution.

the focal spot, is nearly a point source, on the order of a millimeter across, and the primary X-rays are projected from it in straight lines through the patient onto the image receptor. The blur that does arise comes mainly from the small but finite size of the focal spot (penumbra), motion of the patient or equipment, and the finite thickness of the fluorescent screens, within which fluorescent light can bounce about and, before exposing the film, diffuse away from the point where the X-ray struck.

27.2.4
Screen-Film Mammography

One of every eight women will develop breast cancer over the course of her lifetime, and some will die as a result. The most effective measures for early detection, and hence more likely cure, of this disease are frequent self-examinations and periodic X-ray screening of the breasts, which may detect a cancer before it has spread. X-ray imaging of the breasts is referred to as *mammography*.

A mammogram (an image of the breast) must be able to reveal very subtle irregularities in the composition of soft tissues, as well as the presence of tiny ($<100\,\mu m$) *calcifications*, specks of calcium hydroxyapatite that may (depending on their sizes and shapes) suggest the presence of malignant cells. That is, mammographic images must be able not only to reveal slight variations in contrast against a noisy background, but also to provide the exquisite detail needed to reveal the microcalcifications. Mammograms must depict the relatively thick tissues near the chest wall without loss of detail in the thinner regions near the edge of the breasts. And they must do so at low doses, so as not to induce new malignancies while searching for existing ones. These requirements place inordinate demands on breast imaging systems, and also necessitate stringent periodic evaluation of image quality and radiation dose by a physicist experienced in inspection and quality control specifically for mammography units.

A mammography device is like a radiography unit but with several significant differences. Subject contrast is enhanced in mammography by using low-energy X-rays that interact strongly with tissues by the photoelectric process. Low-energy X-rays yield the greatest differences in transmission among structures that are similar, although not identical in chemical composition. Mammography is performed most commonly with special, dedicated X-ray tubes with a molybdenum X-ray target. Operated at 20–35 kVp, these units produce predominantly K X-rays of 17.4 and 19.8 keV characteristic of molybdenum (Mo), superimposed on a bremsstrahlung X-ray spectrum. The X-ray beam is filtered with a thin sheet of molybdenum that is relatively transparent to the Mo characteristic X-rays but strongly absorbent of higher-energy photons because of the Mo K-absorption edge just above 20 keV. The image receptor consists of single-sided film within a single-screen cassette designed specifically for mammography. Screen-film mammography is exquisitely sensitive, but is being displaced by systems with digital detectors, which substantially improve the contrast sensitivity, an advantage that outweighs a slightly lower spatial resolution.

In earlier years, there was concern that screening large numbers of asymptomatic women for breast cancer could induce as many cancers as are cured

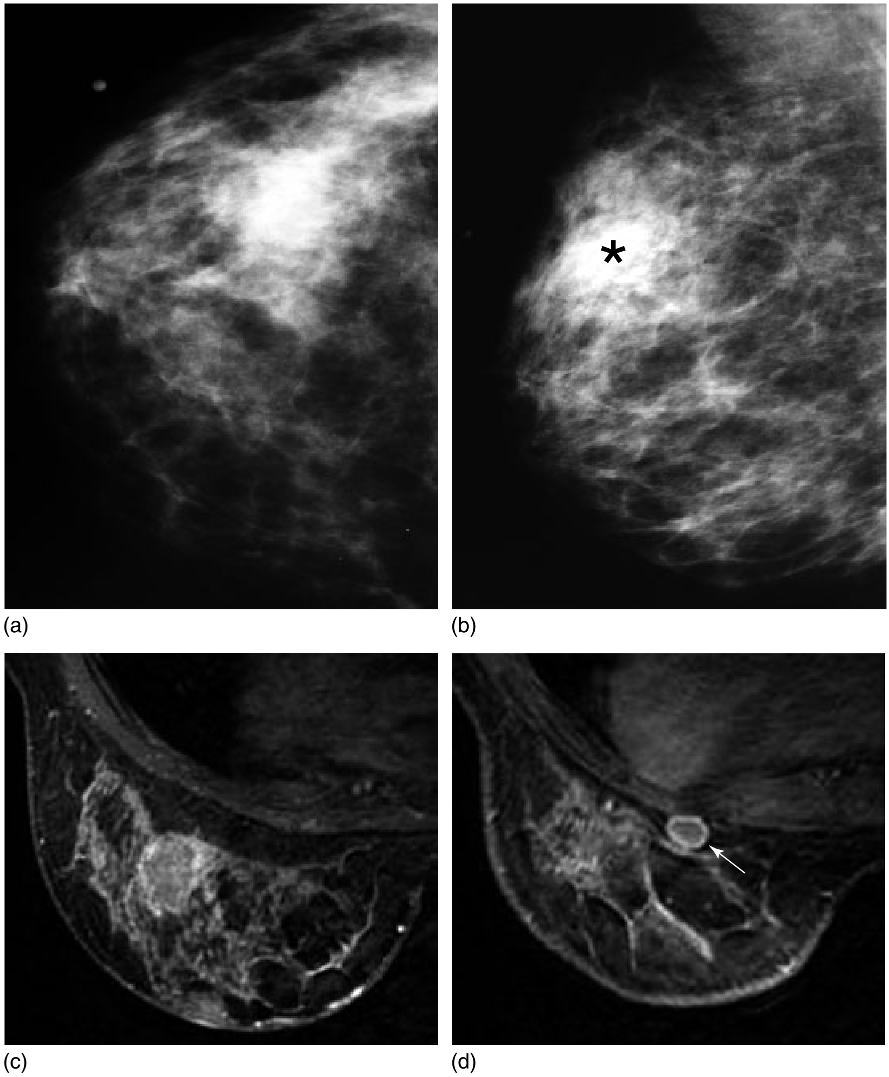

Fig. 27.7 Mammography and MR imaging of the breast. (a) Left craniocaudal and (b) left mediolateral oblique mammograms demonstrate an irregular high-density mass. Overall, breast tissue density is heterogeneous, which is consistent with the patient's age (35 years). Biopsy results show the mass to be grade III invasive ductal carcinoma. (c and d) Transverse three-dimensional fast spoiled gradient-echo MR imaging was performed to assess remaining breast tissue. (c) Enhancing mass corresponds to the known biopsy-proved breast cancer. (d) Incidental mass (arrow) was found posteriorly in the same breast. Biopsy was performed later with US guidance, and the mass found to be grade I invasive ductal carcinoma. This mass was not evident on the mammogram, either initially or in retrospect. (Image courtesy of Lonie Salkowski, MD, Medical College of Wisconsin, Milwaukee, WI.)

through early detection. This concern was primarily a result of the relatively high doses delivered to patients with earlier, much less sensitive methods of image production. With today's ultrasensitive screen-film combinations and digital image receptors, together with the use of low-energy, highly filtered X-ray beams for mammography, the induction of cancer is much less likely. The overwhelming balance of benefit over risk in screening programs for older women has largely dispelled concern over the possible induction of cancer in the screened women. Many voluntary and professional organizations now recommend annual screening with X-rays for women 50 years of age and older, and some recommend screening every 1–2 years for women between 40 and 50 years of age.

Nevertheless, efforts to reduce radiation dose further in mammography should be continued until each examination uses no more than the essential number of X-rays to reveal underlying pathology. Alternatively, there is evidence that (much more expensive) breast MRI (Liberman, 2004; Kriege *et al.*, 2004) is as effective in detecting malignancies as is dedicated mammography. It is especially promising for women who are at high risk for breast cancer or who have unusually dense breast tissue, which presents a severe visualization challenge to screen-film and digital mammography (Figure 27.7).

27.2.5
Analog Tomography

In a conventional radiograph, all structures within a three-dimensional volume of tissue are projected in focus onto the two-dimensional image receptor. As a result, an anatomic structure of interest may be obscured by the shadows of objects that lie above or below it. Removal of these shadows can greatly improve the visibility of the structure of interest. Two approaches, planar tomography and CT, are available to remove the shadows of overlying and underlying objects. Both are normally carried out digitally now, although some older planar tomography systems are still film based.

Planar tomographic images are produced by varying the geometry so as to keep structures in the selected image plane within the patient in focus while blurring out the images of everything above and below the image plane. The X-ray tube and image receptor are translated relative to one another during the exposure about a pivot (fulcrum) in the image plane (Figure 27.8). The image plane has a finite thickness (and is referred to more properly as an *image section*) that can be reduced by increasing the angle of motion. The location of the section within the patient may be moved up or down by positioning the patient higher or lower relative to the pivot. Tomosynthesis is a type of limited-angle (compared with CT) tomography that has relatively poor resolution in the depth direction. The level of detail in the imaging plane, however, can be superb.

Although the shadows of overlying and underlying structures are blurred, they are not removed completely from the image, and frequently appear as ghostlike artifacts. In addition, analog tomography has the standard limitation of film that it cannot distinguish small differences (1–2%) in the intensity of incident radiation, with implications for achievable contrast. Also, the use of wide-area X-ray beams in analog tomography creates problematic scatter

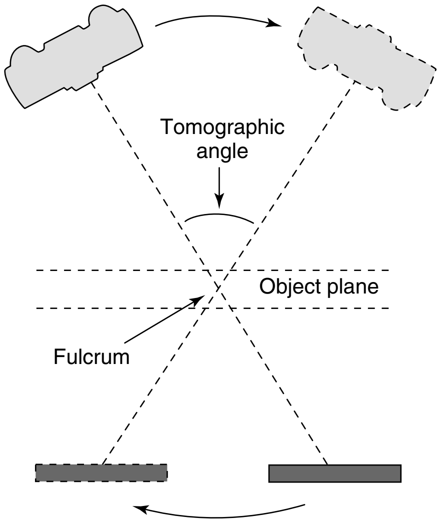

Fig. 27.8 Relationship of the fulcrum, object plane, and tomographic angle. (From Bushong, S.C. (2001) *Radiological Science for Technologists: Physics, Biology, and Protection*, 7th edn, Mosby, St. Louis, with permission.)

radiation. Planar tomography is still used for certain applications such as a complement to chest radiography, but for the most part is being displaced by tomosynthesis and the considerably more effective but expensive CT.

27.2.6
X-ray Fluoroscopy and Angiography

Analog *fluoroscopy*, unlike film, can capture dynamic X-ray images in studies where the organs and tissues are in motion, as with the heart and great vessels and the gastrointestinal tract.

A traditional fluoroscopic device is similar to a screen-film system except that the screen-film image receptor is replaced with an *image-intensifier* vacuum tube. The II converts the faint, life-sized X-ray pattern emerging from the patient into a bright and much smaller (2–4 cm in diameter) visible image, suitable for input into a TV or a charge-coupled device (CCD) electronic optical camera, which feeds signals into a computer. In systems marketed today, the II-tube plus optical camera combination is being replaced by a solid-state flat-panel imager.

The front end of the evacuated II tube is a fluorescent screen, usually CsI, coated with a thin veneer of photoemissive material that emits an electron when struck by a visible-light photon. Electrons liberated in this manner are accelerated toward the anode and compressed by focusing electrodes to strike the small output fluorescent screen at high velocity. The brightness ratio of the output screen compared with the input screen is known as the *brightness gain* of the intensifier, and is typically 3000–4000. It is a product of two factors: the minification gain accomplished by decreasing the size of the image and the electronic gain achieved by accelerating the electrons to high energy before the output image is produced.

From time to time during a fluoroscopic procedure, it may be necessary to record a few higher-quality static images.

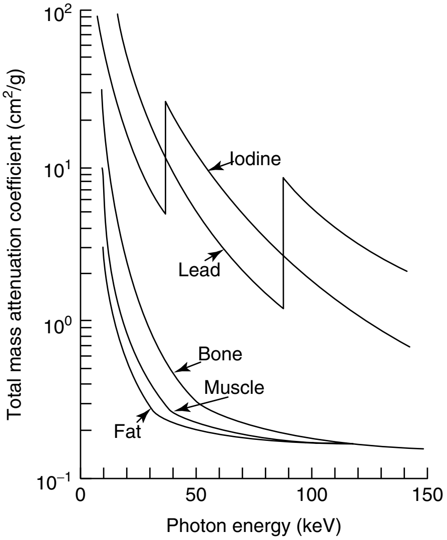

Fig. 27.9 Mass attenuation coefficients for fat, muscle, bone, iodine, and lead as a function of photon energy. (From Hendee, W.R. and Ritenour, E.R. (2002) *Medical Imaging Physics*, 4th edn, John Wiley & Sons, New York.)

Inserting a film cassette momentarily between the patient and the II provides a static *spot film*. Alternately, the light image from the output screen of the intensifier may be deflected briefly into a 100-mm *photospot camera*. Another option is to capture the image with a CCD or television camera and digitize the signal.

X-ray imaging is applied widely in real-time studies of the functioning of the heart and cardiovascular system. In studies of the circulatory system, for example, fluoroscopy can depict normal anatomy and identify abnormal conditions such as circulatory malformations, dysfunctional heart valves, coronary artery disease, atherosclerotic plaques, blood clots, circulation changes caused by injuries and diseases such as cancer, and a wide spectrum of other conditions. Because of the similarity of their X-ray attenuation characteristics, blood-containing vessels usually are not distinguishable from muscle and other soft tissues. This situation can be improved by filling the vessels with a high-atomic number contrast agent that has the same physical density and osmolarity as blood. Iodine-containing materials are currently the contrast agents of choice for cardiovascular studies, largely because iodine's 33-keV absorption edge is near the average photon energy for a typical diagnostic beam (Figure 27.9). X-ray studies of arteries and veins with contrast agents are referred to as *angiography*. Angiography confined to the study of arteries is called *arteriography*, while studies of the venous system are termed *venography*.

Atherosclerotic plaques can form, for example, in the coronary arteries, the vessels that supply blood to the heart muscle. This creates constrictions (narrowing) that impede and sometimes stop arterial blood flow. This condition, if not corrected, can cause angina and a heart attack. In *coronary angiography*, the contrast agent outlines the vessels and displays constrictions that may be present. If not too severe, the constrictions can be removed by mechanically opening the vessels, a procedure known as *angioplasty*. In more severe cases of coronary artery *stenosis*, it may be necessary to surgically install a vessel in parallel to the constricted artery, a procedure known as a *bypass graft*. Often a *stent* tube is placed inside the vessel after angioplasty to prevent it from constricting again. All these procedures are performed under continuous or pulsed fluoroscopic X-ray examination.

A momentous change in planar X-ray imaging is that a large and growing fraction of new radiographic and fluoroscopic equipment currently being installed in the United States contains image receptors that are fully digital.

27.2.7
Image Quality

The level of clinical information visible in a medical image results from a composite of four kinds of resolution: contrast, spatial, temporal, and statistical. *Contrast resolution* reflects differences in the tissue characteristics depicted in the image, and by the impact of extraneous information or structured or random noise in the receptor. *Spatial resolution* and sharpness are related to the geometry of the object being examined (e.g. sharp edges) and of the image-forming process (penumbra blurring from the finite size of a focal spot), and the inherent resolving capacity of the image receptor (blur from the diffusion of light in a fluorescent screen of finite thickness). *Temporal resolution* refers to the spatial blurring caused by the patient's voluntary or involuntary movement (cardiac motion, vascular pulsatile motion, breathing, and peristalsis) during data acquisition, or by shaking of the apparatus. *Statistical resolution* is related to the number of information carriers (X-ray or γ-ray quanta, US or MRI echoes, etc.) detected by the receptor to produce the image; random noise is inversely proportional to the square root of the number of information carriers used to form the image, and it is a common practice to improve the signal-to-noise ratio by acquiring data longer or averaging over several images, at higher dose, and so on.

In most cases, improving any one of these four resolution factors degrades one or more of the others. The necessary compromise among them represents a balance so that no single factor strongly dominates the degradation of detail in the image.

The challenge of medical imaging is to capture subtle differences in tissue composition with information carriers that probe the tissue, and to transfer the resulting patterns of contrast onto an image receptor. That is, the primary purpose of medical imaging is to transfer contrast *modulation* arising in the tissue (object) into visual modulation in the captured image. The degree to which this modulation is transferred faithfully by an imaging system, or by any independent component of it, is commonly described by a relatively simple measure of performance called the *modulation transfer function* (*MTF*). With most imaging systems, object contrast can be transferred to the image with high fidelity if the variations of physical properties within it are of relatively low frequency (i.e. the object is composed of relatively large structures that are well separated from adjacent structures). For smaller structures that are closer together, however, the modulation transfer may work less well, so that the MTF as a function of frequency, MTF(f), tends to fall off at higher frequency.

To measure the MTF of an X-ray tube focal spot, for example, one creates the image of a tiny hole (approximating a spatial delta function) in an otherwise radio-opaque thin sheet of metal. The image of the hole is scanned with a microdensitometer, and the resulting curve is described by a *point spread function* (*PSF*), the composition of which in frequency space can be determined through Fourier analysis. The result of this Fourier transform of the PSF is the MTF, expressed as a function of spatial frequency in cycles or line pairs per millimeter, just as temporal frequency may be reported in cycles per second or hertz.

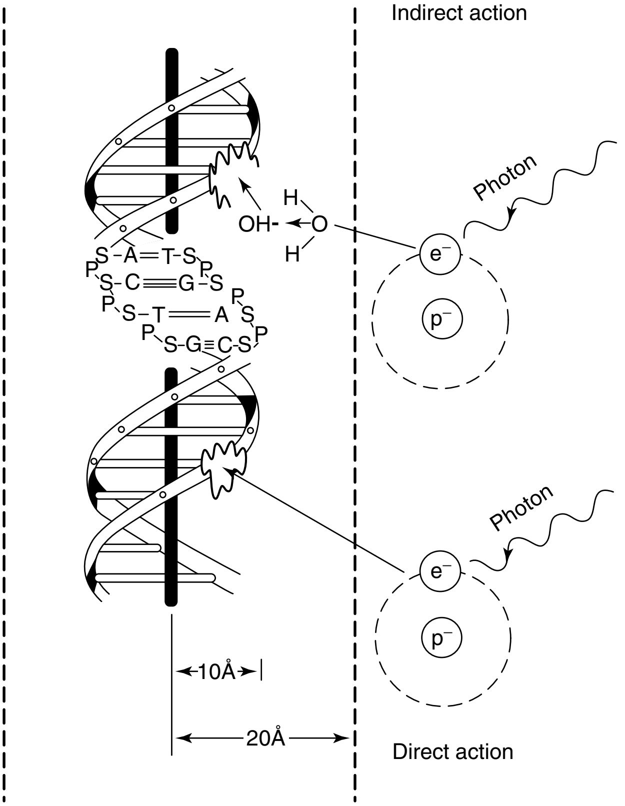

Fig. 27.10 Schematic of the direct and indirect actions of radiation on DNA. The letters S and P represent the sugar and phosphate backbone of the DNA molecule, and A, T, C, and G represent the four bases adenine, thymine, cytosine, and guanine. In direct action, an ejected electron produced by the absorption of radiation interacts directly with the DNA molecule, whereas in indirect action the ejected electron interacts with a water molecule, producing free radicals, which in turn damage the DNA molecule. (Redrawn from Hall E.J. (1988) *Radiobiology for the Radiologist*, 3rd edn, JB Lippincott, Philadelphia, p. 11, with permission.)

27.2.8

γ- and X-Ray Imaging: Radiation Dose and Health Effects

As a beam of X- or γ-rays traverses a body, it loses intensity as it transfers energy to the tissues it penetrates. This transfer of energy involves the ejection of photo- and Compton electrons from the atoms, resulting in a concentration of ions along the path of the beam. The ejection of an electron from an atom is termed an *ionizing event*, and X- and γ-rays and beams of high-energy charged particles are referred to as *ionizing radiation*.

It is the thousands of ionizations in tissue caused by the highly energetic photo- or Compton electrons that are of concern here. An ionizing event can injure or kill a cell if it occurs in an atom of a critical molecule of the cell, and in particular a DNA molecule. This effect, termed the *direct effect of radiation*, is responsible for some of the biological effects of radiation (Figure 27.10). More often, the ionizing event occurs in water, but this can still cause biological damage because the event may create *free radicals* that are highly reactive (because they contain unpaired electrons, as with the OH° or H° radicals) that can attack DNA and other important molecules *indirectly*. The indirect and direct mechanisms together are responsible for the harmful effects of ionizing radiation.

It is possible that sufficiently intense irradiation can kill so many cells and cell-precursors in an organ or tissue that it can no longer operate properly, resulting in a *deterministic health effect*. A deterministic effect typically occurs only above a tissue- and patient-specific threshold dose, but its severity increases with dose beyond that threshold. Examples are a burning of the skin (erythema), sloughing off of skin (moist desquamation), cataract generation, temporary or permanent sterilization or, in severe overexposure, *radiation sickness*, which can be fatal. Deterministic effects are caused only rarely in diagnostic imaging; a much greater worry are *stochastic effects*.

"Stochastic" is synonymous with random, or probabilistically determined, and here the word refers to the likelihood that someone exposed to ionizing radiation will experience a critical *DNA mutation* in a tissue cell (*not* a *killing* of the cell, as in deterministic effects) that leads at a later time to the induction of cancer[4] (carcinogenesis), the production of genetic consequences in offspring of exposed individuals (mutagenesis), and the development of abnormalities in persons exposed before birth (teratogenesis). With stochastic effects, it is not the severity of the disease that increases with dose, but rather the probability of its occurring at all. It is widely accepted, at least for radiation protection purposes, that the risk of stochastic injury increases nearly linearly with dose, and that there is no threshold below which effects cannot occur. The biological and epidemiological evidence for this *linear, no-threshold hypothesis* is an issue of considerable debate in the health physics profession.

---

[4] Cancer is a disease in which certain cells have been transformed so that they are dividing and multiplying at a much faster rate than normal. If these cells can be removed or destroyed without causing overly severe side-effects in the healthy tissues, the cancer patient often has a good chance of recovery. If the cells are confined to a specific region of the body and reasonably accessible, often they can be removed with the scalpel or destroyed with a beam of ionizing radiation. The latter technique is termed *radiation therapy*, and the physicians who utilize it are called *radiation oncologists*. If the cancer cells have spread (metastasized) from the initial (primary) site, the preferred treatment is usually to try to kill the cells with chemotherapy performed by a medical oncologist. A frequent approach to cancer treatment is to employ radiation to destroy the primary site of the cancer (sometimes after most of the cancer has been removed surgically), followed by chemotherapy in an effort to kill cancer cells that have spread to distant sites.

Radiogenic carcinogenesis is the health effect of greatest concern in imaging with γ- and X-rays, because at low doses its estimated rate of induction is much higher than for genetic effects or teratogenesis. It is the role of *medical and health physicists* to ensure that those who employ radiation do so in such a manner that virtually no deterministic health effects arise, and that the rate of stochastic health affects is kept below an "acceptable" level, where the meaning of "acceptable" is a social and regulatory call. The health physics literature is extensive, and several good texts provide an introduction to the field (Turner, 2007).

27.3
The Joy of Digital

First appearing in the clinic in the 1970s, computers have enabled novel computation-based imaging (CT, MRI, PET) – provided image processing and analysis tools ranging from windowing and noise reduction for all modalities to CAD or CADx for some – and allowed the instantaneous storage, retrieval, display, and transmission of images and other information with *picture archiving and communications systems* (*PACS*), electronic notepads, and so on. In so doing, they have radically changed the way that medicine is practiced. The deployment of digital imaging systems – high-bandwidth networks to transport images between acquisition, interpretation, consultation, and storage sites – and algorithms for computer recognition of image features for CADx are ushering in a whole new approach to medical imaging. The only certainty is that what we see today is just the beginning.

27.3.1
PACS, RIS, HIS, DICOM, and so on

Increasing numbers of radiology and other departments are installing PACS for both patient use and clinical research. Images from digital diagnostic devices are sent to the PACS as soon as they are acquired, where they can undergo image processing, computer-based analysis, distribution to other sites, and storage. Ideally, a PACS is integrated with the *radiology information system* (*RIS*) and the *hospital information system* (*HIS*) as part of an *integrated health care* (*IHC*) environment, so that the patient's electronic clinical record, and past and recent lab results, along with past imaging studies, can be pulled up immediately.

PACS got off to a shaky start years ago, largely because early systems were overhyped and user-unfriendly. With simpler user-PACS interfaces, better and more standardized PACS-machine connectivity such as that brought about by the *Digital Imaging and Communications in Medicine* (*DICOM*) protocol (DICOM, 2003), more effective training provided by vendors, better security, lower purchase and operational costs, and the availability of mini-PACS packages that can be upgraded as physicians choose to make fuller use of them, PACS are becoming indispensable for providing high-quality, cost-effective health care (Carrino, 2003; Huang, 2004; Smith, 2006).

In the common star network configuration, a PACS information management system receives images from any connected digital image-acquisition device, after which it can forward them and other information to any other sites (Figure 27.11). Some such sites consist of stand-alone imaging systems complete with their own image and display workstation, image archive, and image-processing computer. Others are "dumb" terminals that can receive transmitted images for viewing but lack the capacity for image modification. The latter are typically placed in clinical locations, such as critical-care units, emergency rooms, and outpatient clinics. The degree to which terminals for referring physicians can be less sophisticated (and less expensive) than those for radiologists is a highly debated issue.

Within a hospital or clinic, imaging data are usually transmitted on-line by copper or optical-fiber cable. For communication over greater distances, high transmission rates up to 2 megabits per second (Mbps) are achieved with fiber-optic cable where available, or with special "Digital Subscription Line (DSL)" and "T1" lines that can be leased from the telephone company. Also, microwave carriers can be used either directly for line-of-sight transmission or by satellite transmission for longer distances. The transmission of medical images over long distances is termed *teleradiology*. A teleradiology capability allows medical

(2000) *Physics of Radiology*, Medical Physics Publishing, Madison, WI.)

personnel to receive and respond to images on any compatible workstation, even at home; to communicate and share images effortlessly with other specialists; to obtain input from around the world on difficult cases; and to provide diagnostic expertise in remote areas. The Internet is already providing an invaluable conduit for telemedicine services, and further applications will evolve as the more powerful and versatile next-generation Internet and Internet2 become increasingly accessible.5) The medical value of next-generation Internet and Internet2 depends on there being in place agreements on a medical information (or more general) protocol to define interface uniformity, data formats, semantics, and other details.

Once in a PACS, an image may be routed to *image-processing* modules that can electronically enhance its contrast to accentuate variations in intensity among disjoint regions, smoothing out distracting random or systematic noise without excessive loss of real information, or by sharpening image resolution by emphasizing the edges of structures such as contrast-filled blood vessels. The image can then be sent to short- or long-term *storage*, and recalled almost instantly for display at any connected workstation. The image can be fetched, along with CT, nuclear medicine, or MRI studies of the patient, for comparison and correlation among the various studies. It can be examined by a *CAD* system to locate irregularities, and perhaps even a *CAD*x module that offers a statistical-based differential diagnosis. And that is just for starters!

27.3.2
Digital Display

The rapid evolution of digital technologies will continue to have a tremendous impact on imaging, and one ever-growing area of influence will undoubtedly be in systems for image display. For reasons of image quality, weight, size, required voltage, ruggedness, energy efficiency, and cost-effectiveness, flat-panel display solid-state technology (which greatly facilitated the development of the flat-panel imagers of DR) is rapidly displacing the traditional cathode-ray tube, not only in medical displays but also in computer monitors and high-definition television sets (Badano, 2004; Badano, Flynn and Kanicki, 2004; Samei, Badano, and Chakraborty, 2005). At present, liquid crystal panels, each with several million pixels, account for something like 99% of all flat-panel displays produced. However, other approaches, such as plasma, field emission, and electroluminescent panels, are also under development. Flexible, rewritable, plastic-based electronic "paper" is already available – it remains to be seen what applications arise for it in medical imaging.

True three-dimensional viewing, moreover, is now a reality. The reader may have seen stereoscopic drawings and movies years ago in which two slightly different perspectives of an object were presented in lines of blue and red; when one wore special glasses with one red and one blue lens, the spears and arrows appeared to come right out of

---

5) The next-generation Internet protocol (IPng), which is a new version of the current Internet protocol (IP), is designed to deal with the addressing and routing problems arising from the massive size and continuing expansion of the system. Internet2 is a not-for-profit consortium of universities and companies that are collaborating on these, and related, issues.

the screen! Now there are electro-optical glasses in which the lenses themselves can display slightly different electronic images for the two eyes – the images are perceived to be fully three dimensional and can be of value in virtual reality applications such as surgical planning or virtual endoscopy. Holographic displays, in which the viewer does not even need glasses, are in the early stages of development.

27.4
Digital Planar X-Ray Imaging

For many decades, the combination of intensifying screens and photographic film was the primary method for capturing and recording X-ray images. It is simple, portable, and inexpensive, and yields images with excellent anatomic detail. This approach, however, has disadvantages as well. It is limited to a narrow range of acceptable exposures, and it offers almost no flexibility for image processing. Since the same film both captures and displays the X-ray image, neither of the processes can be separately optimized. Film is bulky to store and easy to misplace, and it must be transported physically from one location to another. Replacing analog X-ray image production with digital eliminates nearly all these problems, and adds a number of clear benefits, as well.

Some clinics get a first taste of the capability of new imaging technologies by digitizing film radiographs with a scanning micro-optical densitometer. This device permits some compensation for regions of over- or underexposure, and also entry into a PACS, with all the advantages of digital technology. But to reap the full benefits of digital imaging, it is necessary to begin with a digital image receptor in the first place. While there are many variations on the theme, two general types of digital X-ray projection imaging dominate the scene at present: *computed radiography* (*CR*) and *digital radiography* (*DR*).

One great advantage of both the technologies (and of digital imaging in general) is the linearity of response of the radiation detectors over exposure ranges that are orders of magnitude broader than the latitude of any film, and the overall improvement in image quality that results from that property; there are no under- or overexposed regions of the image. Another is the separation of image acquisition from imaging processing (windowing, edge enhancement, noise reduction, etc.) and from display, so that these three steps can be independently optimized; with film, about the only processing available is the retake. And finally, there are the overall benefits of digital signal storage, communication, and analysis.

In planar X-ray imaging, new semiconductor-based digital image receptors are gaining rapid acceptance as viable replacements for screen-film combinations and for image intensifier plus television monitor or CCD optical camera (Goldman and Yester, 2004; Zhao, Andriole and Samei, 2006). Many imaging departments have gone filmless and fully digital, and are restructured around a central *PACS*. This trend is likely to continue wherever modern medical technologies are available (Thrall, 2005).

27.4.1
Computed Radiography (CR)

CR is the digital counterpart to the screen-film approach to X-ray imaging.

Appearing first in the 1970s, *photostimulable phosphor* (*PSP*) *imaging plates* (*IPs*), now composed typically of BaFBr and BaFI, are housed in an inert, light-tight cassette for exposure to X-rays. Areas exposed to higher levels of radiation will store excess charge in elevated energy states, from which they can later be dislodged with a suitable external stimulus.

Cassettes come in a range of sizes and shapes, and they are both easy to use and relatively cost effective. To convert from analog to CR, one need only exchange of a film cassette assembly with a very similar CR cassette, and the chemical film-processor for an electronic IP reader.

Inside the light-tight image processor, an exposed IP is scanned with a laser beam point of red light that, in turn, stimulates the IP to emit light of another color (blue). The emitted light is detected by a photomultiplier tube (PMT) and digitized with an 8- or 16-bit analog-to-digital converter. During scanning, the computer keeps track of the location and the light emission of each scan point, and transforms this information into a two-dimensional image. The digitized image is displayed on a video monitor and can be stored for later recall.

At present, the major limitation of the system is that, like a screen-film system, it can acquire only static images.

27.4.2
Digital Radiography (DR)

Active-matrix flat-panel imagers (*AMFPIs*) of DR and digital fluoroscopy (DF) overcome the static image limitation of CR. An AMFPI is an array of hundreds of thousands, or millions, of tiny, electrically independent semiconductor detectors that come in two general forms: they are either directly sensitive to high-energy photons (direct-detection array), or responsive to light from an overlying thin layer of fluorescent material (indirect-detection array) (Antonuk, 2004; Zhao and Zhao, 2005).

With *direct-detection arrays*, the image receptor consists of an array of several million voxel-sized photoconductive (e.g. amorphous selenium, cadmium zinc telluride, and lead iodide) tiles, each with a pair of electrodes on its face and a *thin-film transistor* (*TFT*) attached on the back side. When an incident X-ray photon undergoes a photoelectric interaction with the photoconductor layer of a volume element (voxel), there results a trail of ionizations through it. The high-voltage bias applied by the pair of electrodes sweeps the liberated electrons and holes rapidly through the photoconductor layer, and this process registers as a pulse of charge in the TFT. The set of TFTs is then read out through data lines threading throughout the detector. The data are organized by the computer and displayed as an image on the corresponding picture element (pixel) array of the display.

With *indirect conversion*, a scintillation layer such as CsI in the form of columnar (tall and thin) crystals converts the incident X-ray energy to flashes of light. An underlying matrix of amorphous-silicon photodetectors and their TFTs, one combination per voxel, converts the pattern of visible light to an electrical signal.

For most if not all X-ray applications, digital detectors yield images comparable in quality to those obtained with analog film-based techniques. Even for breast, where resolution is essential for the detection and assessment of microcalcifications, digital systems are becoming increasingly accepted (Pisano *et al.*, 2005; Fischmann *et al.*, 2005; Brateman and Karellas, 2006). A number of recent developments should significantly broaden the domain of DR. One of the more intriguing, ink-jet (rather than photographic) printing will permit fabrication of flat-panel imagers (and flat-panel displays!) on flexible plastic substrates of virtually any size and shape.

There are advocates of both CR and DR, but the two are complementary modalities and there is room for both (Monnin *et al.*, 2005). Both are likely to be around for awhile, providing quality images of teeth, chest, bone, gastrointestinal tract, extremities, and breast (Kapur *et al.*, 2004; Pisano and Yaffe, 2005). CR is considerably easier and less expensive to implement than DR, and its ruggedness makes it more suitable for mobile units. Only DR, however, can image medical events fluoroscopically in real time.

Two areas where DR has found considerable success are digital subtraction radiography and digital tomography.

27.4.3
Digital Subtraction Radiography

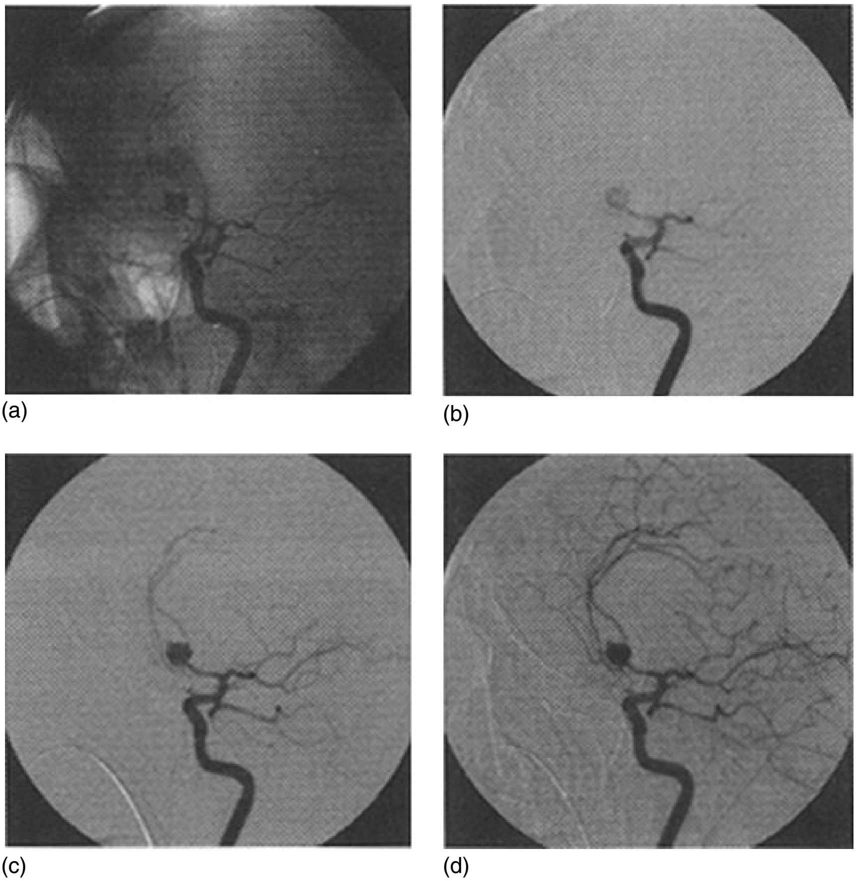
Computer subtraction of pairs of digital images taken at different times can often reveal changes, and even rates of change, that are not apparent in the separate images. In a simple example of *digital subtraction angiography* (*DSA*), an image is obtained midway during injection of an iodine-based contrast agent (Figure 27.12a). Three subsequent images (Figure 27.12b–d) are obtained at progressive times during contrast agent injection and subtracted from image (a) to yield three subtraction images that reveal only what has changed, namely the increased presence of contrast agent. Even fine blood vessels that are invisible in the prior images alone show up clearly in the *temporal subtraction* images.

Another technique, *energy subtraction*, involves the acquisition of images at two or more different kVps (Richard *et al.*, 2005).

In the resulting subtraction images, visual background noise, such as irrelevant bonelike or soft tissue structures that obscure what the clinician is looking for, is removed (Figure 27.13). A related application is dual-energy X-ray absorptiometry, which is the standard method for measurement of bone density, the major predictor of fracture from osteoporosis. Dual-energy X-ray absorptiometry is now being challenged, however, by US and other techniques (Khaw *et al.*, 2004; Wear *et al.*, 2005).

27.4.4
Digital Tomosynthesis

Digital tomosynthesis takes its analog predecessor into the modern era (Dobbins and Godfrey, 2003; Wu *et al.*, 2004). A series of DR images is acquired while the X-ray tube and beam are pivoted through a small angle. By largely blurring out the over- and underlying planes, high-quality images of each selected tomographic plane can be obtained with section thicknesses ranging from one millimeter to several centimeters (Figure 27.14). Digital tomosynthesis has been applied to chest, breast, angiography, orthopedic, dental, and other examinations. It is much less costly than CT and often produces equally useful information.



(a) (b) (c) (d)

(b–d) Subtracted DSA images obtained at three progressive time points during contrast material injections. (From Pooley, R.A., McKinney, J.M., and Miller, D.A. (2001) The AAPM/RSNA physics tutorial for residents: digital fluoroscopy. *Radiographics*, 21(2), 521–34, with permission.)

27.5
Computed Tomography

As with temporal or dual-energy digital subtraction techniques, the power of CT lies in its ability to remove irrelevant, unwanted, and interfering information.

A radiologist may be able to infer the three-dimensional shape of an object in a patient by viewing several radiographs taken from different angles. Likewise, CT involves acquisition of a large number of X-ray projection views. It then works backwards, in effect, to reconstruct the spatial distribution of materials – or, more precisely, the distribution of their X-ray photon attenuation characteristics – that gave rise

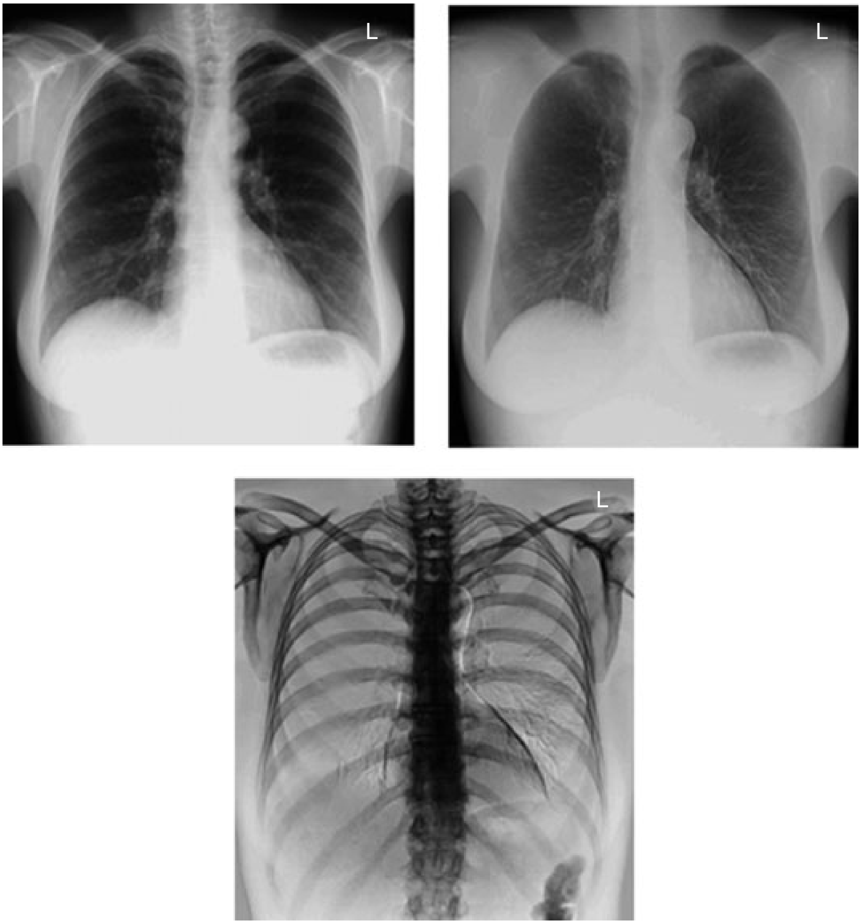


Fig. 27.13 X-ray images of the thorax in which bone (upper right) and soft tissue (lower center) have been subtracted.

to the projections (Fohr, Cody and McCollough, 2006).

In 1972 the EMI Group, a British company best known as home to the Beatles, announced the first commercially available X-ray transmission CT unit for studies of human anatomy. Seven years later, Hounsfield, the developer of this unit (Hounsfield, 1973), shared the Nobel Prize in Medicine with Cormack, a physicist (Cormack, 1963), who constructed a bench-scale prototype and did early work on CT image reconstruction from projections.

Hounsfield's device, oriented at some angle θ, scanned a narrow pencil beam of X-rays across the patient, thereby cutting out a thin slice of tissue, and moved a scintillation detector in synchrony with the X-ray beams on the opposite side of the patient (Figure 27.15). The angle was then incremented by a small amount,

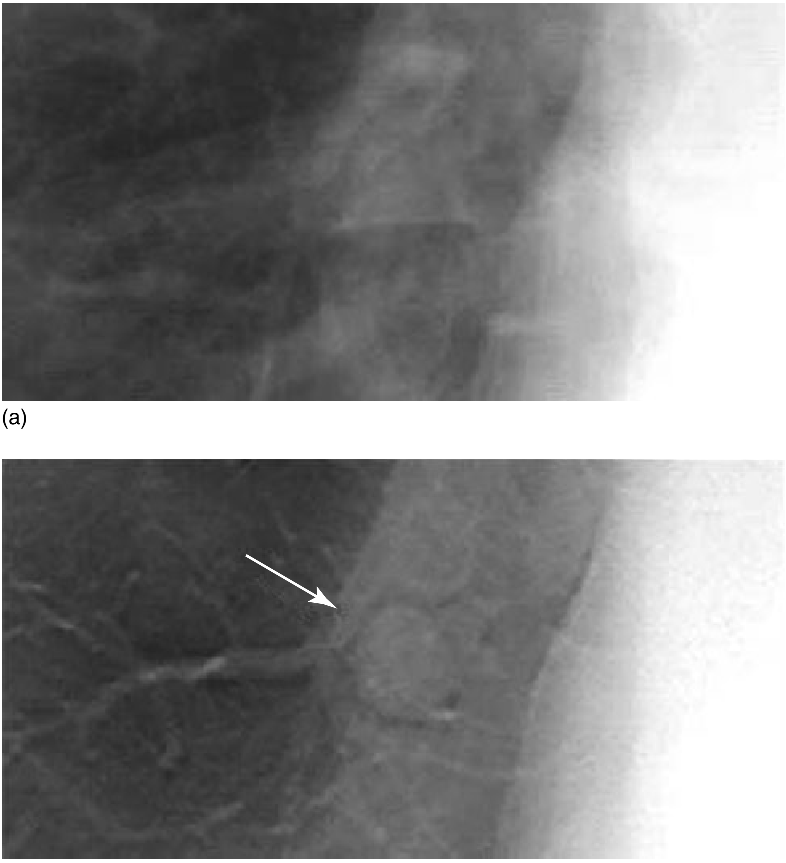

Fig. 27.14 Digital tomosynthesis of human lung. (a) Posteroanterior radiograph shows region of interest. (b) Digital tomosynthesis section demonstrates a 15-mm pulmonary nodule (arrow) that was not visualized in (a). Note also improved clarity of vascular detail in (b), which was reconstructed with a matrix inversion tomosynthesis technique that used 61 projection images acquired in 10 seconds over a total tube swing angle of 16°. Fifty-nine sections were generated with 3 mm spacing. Total subject entrance exposure was approximately the same as that for a screen-film lateral chest radiograph. (Image courtesy James T. Dobbins III, PhD, H. Page McAdams, MD, and Devon J. Godfrey, Ph.D., Duke University Medical Center.)

and the next scan begun. The intensity, $I_{\text{transmitted}}$, of X-rays that passed through the patient and were measured by the detector was, at any instant,

$$I_{\text{transmitted}}(\theta, q)/I_0 = \exp\left(-\sum \mu_i \Delta x_i\right) \quad (4)$$

where μ_i is the linear attenuation coefficient of the ith voxel lying on the beam path, q parameterizes the position of the beam as it carries out the scan, I_0 is the beam intensity in the absence of the patient, and $\sum \Delta x_i$ is the thickness of the patient for that particular pencil beam. With multiple

(a) first-generation scanner using a pencil X-ray beam and a combination of translational and rotational motion; (b) second-generation scanner with a fan X-ray beam, multiple detectors, and a combination of translational and rotational motion; (c) third-generation scanner using a fan X-ray beam and smooth rotational motion of X-ray tube and detector array; (d) fourth-generation scanner with rotational motion of the X-ray tube within a stationary circular array of 600 or more detectors. (From Hendee, W.R. and Ritenour, E.R. (2002) *Medical Imaging Physics*, 4th edn, John Wiley & Sons, New York.)

transmission measurements obtained at different orientations, the data can be *reconstructed* to reveal all the individual values of μ_i. The reconstruction yields a two-dimensional map of linear attenuation coefficients throughout the slice under examination.

The X-ray tube and scintillation detector of the EMI *first-generation* CT unit made measurements of X-ray transmission every $\Delta q = 2.5$ mm over the 40 cm linear path to yield a total of 160 transmission data points. Then the angular positions of the X-ray tube and detector were advanced by $\Delta\theta = 1^\circ$, and another scan of 160 measurements was obtained. This process was continued over 180°, providing 28 800 transmission measurements. These data were then transmitted to a computer equipped with a mathematical package for reconstructing a two-dimensional matrix of attenuation coefficients across the scanned section on a 160 × 180 pixel matrix.

It is convenient to transform this matrix into an image based on *CT numbers*, defined as

$$\text{CT number}_i = 1000\ (\mu_i - \mu_w)/\mu_w \quad (5)$$

where μ_w is the linear attenuation coefficient of water for the X-ray energy, a process that almost entirely eliminates any photon-energy dependence of the image.[6] The CT number for water is zero *Hounsfield units* (*HUs*), and that for air nearly −1000. The CT number would be about +1000 for a structure such as compact bone or colon containing barium contrast medium, because the physical density would be almost twice that of water. The CT numbers can be represented as various shades of gray to provide a visual display of the distribution of tissues. As with any other digital modality, the image appearance can be optimized by *windowing*, or shifting the relationship between CT number and voxel brightness on the display (Figure 27.16). With dual- or multienergy techniques, CT can provide information on tissue parameters beyond simple pixel HUs.

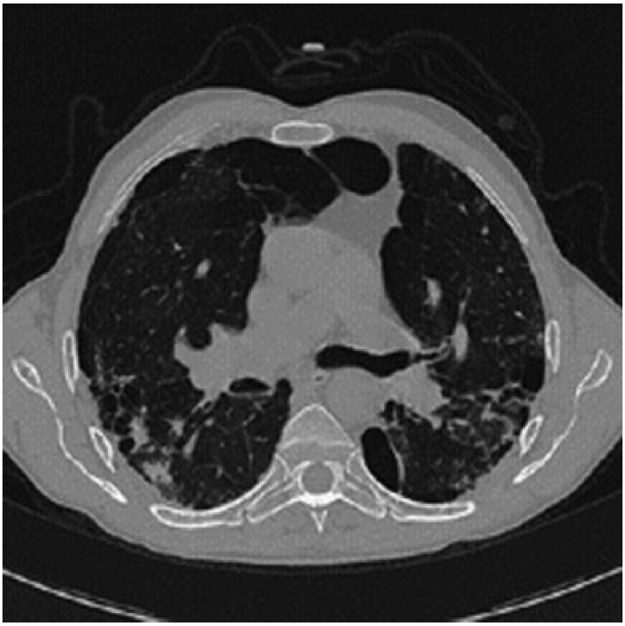

Fig. 27.16 Axial X-ray CT image of the thorax.

---

[6] The energy dependencies of the attenuation coefficients for soft tissue and water are nearly identical.

27.5.1
Reconstruction Algorithms

The general mathematical approach to CT image reconstruction was described in 1917 in a remarkable work by the Austrian mathematician Radon (Radon, 1917). The model was first used in applications of image reconstruction to radio astronomy, electron microscopy, and optics.

The process of data acquisition may be modeled by the operator equation

$$p = \hat{\mathbf{H}} f \tag{6a}$$

The function f refers to the spatial distribution of attenuation coefficient values throughout the object being examined, and $\boldsymbol{p}$ describes the set of X-ray intensity projection measurement values that it yields under the Radon operational process $\hat{\mathbf{H}}$.

For digital computations, the object space is discretized into a square (for convenience, here) matrix of $M \times M$ voxels. f may be viewed as an M^2-dimensional vector, each element of which corresponds to the attenuation coefficient value of the associated voxel. The angle θ can assume M values and, for each of them, the line parameterized by q is partitioned into M bins. There will be a total of M^2 bin values for the entire set of measurements, and it is these values that comprise the M^2-dimensional vector $\boldsymbol{p}$. An element, h_{ji}, of the *transfer* or *transition matrix*, $\hat{\mathbf{H}}$, indicates the contribution of the object's ith voxel, f_i, to the jth component of $\boldsymbol{p}$, p_j, for the corresponding values of θ and q.

The problem to be solved, the "inverse problem," is "given the set of measurements $\boldsymbol{p}$ and a model of the projection process $\hat{\mathbf{H}}$, estimate f." That is, find $\hat{\mathbf{H}}^{-1}$ such that, in effect,

$$f = \hat{\mathbf{H}}^{-1} \boldsymbol{p} \tag{6b}$$

Finding the solution exactly by way of the Radon transform is generally not feasible mathematically, and most approaches rely on various approximations. This clearly must be so when statistical noise is added to the process. Everything becomes even more complicated with complex geometries, such as 3D cone- (rather than a flat, 2D fan-) beam CT.

When the reconstruction problem is framed in this fashion, it is possible to rely on a rich body of work dedicated to solving linear systems of equations. Initially, reconstructed images were computed with *algebraic* techniques to solve the set of simultaneous linear equations of Eq. (1). As pixel matrices grew in size, however, the number of linear equations to be solved became unwieldy. Similarly, *iterative* mathematical models became too time consuming for the computers available at the time, even though they are now staging a comeback in SPECT and PET imaging. Faster algorithms designed for *filtered back-projection* (*convolution*) reconstruction have taken over the field (Kak and Slaney, 1988). These algorithms rely on a Fourier transformation of X-ray projection data into frequency space, and the use of ramp and cutoff-frequency filters to improve image quality (Barrett and Myers, 2004).

27.5.2
Generations of Scanners

The combination of translational and rotational motion employed in early CT units yielded satisfactory CT images, but required several minutes for data acquisition. This limited the method to studies of structures such as the head and extremities where voluntary and involuntary motion of the patient could be controlled. There was great interest in applying CT to thoracic and abdominal studies, of course, but the scan time had to be decreased from minutes to seconds for these areas to yield satisfactory images. Major efforts to reduce scan time led to the development of successive generations of CT scanners (Figure 27.15). *Second-generation* scanners, in which an array of detectors (rather than a single one) tracked the linear motion of the X-ray beam (Figure 27.15b) are now extinct, as are their Hounsfield-type predecessors.

Fig. 27.17 Longitudinal (a) and cross-sectional (b) view of the Imatron Ultra-Fast Computed Tomographic (UFCT) scanner. (From Gould R.G. Computed tomography overview and basics, in Vol 2, Proceedings of the American Association of Physicists in Medicine, *Specification, Acceptance Testing and Quality Control of Diagnostic X-ray Imaging Equipment*, July 1991, Santa Cruz, California, pp. 930–68, with permission.)

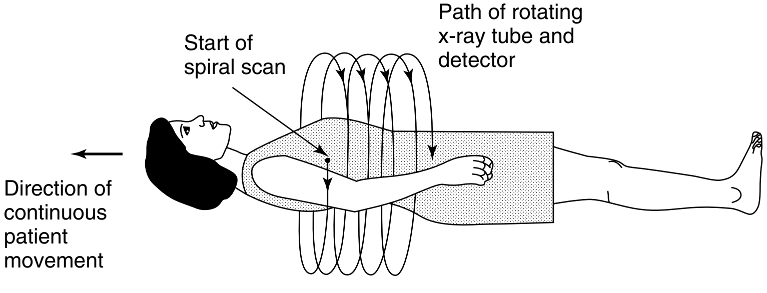
The purely rotational *third-generation* design (Figure 27.15c), and a *fourth-generation* scanner, in which an X-ray tube rotates but the ring of X-ray detectors remains stationary (Figure 27.15d), are still used in many clinics. With both types of rotational scanners, data for a single section can be acquired in just a few seconds, and there are true believers in each design.

Although newer CT scanning geometries shortened the time to acquire images, none permitted data acquisition in a time (<0.1 second) short enough to capture the heart and some other blood-perfused organs without significant degradation caused by motion. As the first significant attack on this problem, a *fifth-generation* CT machine produced X-ray projection data without mechanical motion of the scanner. The heart of the system is a very large, funnel-shaped X-ray tube in which the anode is a stationary, concave metal strip that partially circumscribes the patient (Figure 27.17). The electron beam is swung along the anode in under 50 ms, fast enough to freeze the heart in any part of its cycle. Also, its dose is low, about 1 mSv for angiography and even less for coronary calcium scoring. While revolutionary in its time, electron-beam CT images tend to be noisy, and the far more versatile multisection CT has better spatial resolution in all three directions (about 0.3 mm vs. 1.5 mm for electron-beam CT). Fifth-generation electrons-beam CT units are principally used today only for cardiac imaging, and even for those applications they are being displaced by multislice CT units.

27.5.3
Helical and Multidetector-Row CT

Two developments over the past few years have substantially increased the efficiency and speed of data acquisition in CT (Jiang, 2003).

In early *axial-mode* (nonhelical) CT systems, the X-ray tube is rotated once about an immobile table; the table is then advanced by a small amount in the *z*-axis direction, and the tube is rotated once in the opposite direction, to untangle the high-voltage cables. This procedure is repeated over and over, with each rotation producing data for a flat plane of tissue. *Helical* (*spiral*) *CT*, sometimes called *sixth generation*, allows the table to move continuously as the tube rotates in a constant direction



Path of rotating x-ray tube and detector
Start of spiral scan
Direction of continuous patient movement

Fig. 27.18 Spiral CT scanning (From Rowlands, J.A. (1999) X-ray imaging: radiography, fluoroscopy, computer tomography, in *Biomedical Uses of Radiation. Part A: Diagnostic Applications* (ed. W. Hendee), Wiley-VCH, Weinheim, Germany, with permission.)

around it. The technology is based on either third generation, with a rotating array of detectors, or fourth generation, in which a thousand or so very small detectors surround the patient and are fixed in space. *Slip ring* electrical contacts are needed to deliver power to the tube and, for third-generation machines, to retrieve signals from the detectors (Figure 27.18). Helical CT allows much faster scanning and provides images with higher resolution in the transverse plane.

The second important innovation is the ability to image multiple slices, rather than only one, for each rotation of the gantry (Cademartiri *et al.*, 2004; Saini, 2004). The single, narrow, transverse fan beam of X-rays used for axial-mode CT is broadened into a *cone beam*; each of the thousand or so detectors circling the patient is replaced with a row of 4–64 (128, 256, . . .) (or more in the future) separate detectors aligned parallel to the table axis – it is as if 4–64 thin belts, each with a row of a thousand small, closely spaced detectors, circumscribes the patient. This approach to efficiency in data acquisition makes it possible for a *multidetector computed tomography*[7] (*MDCT*) unit to acquire images of up to 64 sections of the body simultaneously at present with even more simultaneous slices predicted for the future.

MDCT (*seventh generation*) scanners use a classic third-generation scan geometry but with a cone- rather than a fan-shaped X-ray beam. For 16 or fewer sections, it is possible simply to employ well-established multiparallel-section approximate reconstruction algorithms. More sophisticated approximate and exact cone-beam algorithms have been created to yield better images, but they are computationally more complex and time consuming (Katsevich, 2004; Shechter *et al.*, 2004; Flohr *et al.*, 2005; Mori, Endo and Obata, 2005). These challenges are a target of considerable research at the present time.

CT images are displayed most commonly as cross-sectional representations of the body. By examining contiguous cross-sectional images in sequence, radiologists can intuitively integrate the imaging information into a three-dimensional model of anatomy. This integration can be accomplished also by reconfiguring the data set in three dimensions. By mathematically compiling data across planes that cut through this database in preferred directions, coronal and sagittal views, as well as those at oblique angles, can then be produced. Also, the three-dimensional database can be analyzed to yield three-dimensional images of high quality. Three-dimensional CT angiography, for example, is an increasingly important, and much less invasive and costly alternative to standard catheter-directed coronary arteriography for the demonstration of coronary artery disease, the detection and measurement of the volume of non-calcified plaques, and other applications. Similarly, virtual colonoscopy is coming to displace the real thing.

CT manufacturers continue to strive for greater scanning speed and more longitudinal anatomic coverage with each gantry rotation. Because centrifugal forces would become overwhelming, the speed of gantry rotation may not increase much beyond its present value of three cycles per second. This is good enough to examine the lung (Rietzel, Pan and Chen, 2005; Sonke *et al.*, 2005) or capture a heart at systole or diastole with little motion blurring. Shorter scan times might be achievable with multiple tubes. (Fast MRI can also support cardiac screening or image-guided intervention, and without ionizing radiation, but at significantly greater cost.) Also desirable in CT scanning is extended *z*-axis coverage that would allow functional imaging of the entire heart, lung, brain, and other structures with a single rotation. These innovations, and the development of better detector systems, will further improve resolution in all three directions so that CT will become a truly isotropic 3D imaging modality, similar to MRI. A potential difficulty with this is the increase in scatter radiation reaching the image receptors (Shikhaliev, Xu and Molloi, 2005; Siewerdsen *et al.*, 2004).

---

[7] Also known as a *multislice* and *multiring* scanner and by other names.

27.5.4
Recent Developments in Computed Tomography

Researchers have described devices in which the multiple rings of detectors have been replaced with a flat-panel imaging array (Siewerdsen *et al.*, 2004; Mahnken *et al.*, 2005). Several manufacturers have produced flat-panel prototypes, and quasi-CT C-arm devices are being marketed. However, there are daunting problems associated with the very high rates (gigabytes per second) of data transfer.

Meanwhile, a novel design of a standard X-ray tube has been introduced in which nearly everything *except* the anode, in effect, is rotated. This allows direct cooling of the anode, from its back side, that is five or so times faster than that possible with a standard rotating anode tube. This innovation permits either longer uninterrupted exposure durations or more intense (hence, briefer) pulses (Schardt *et al.*, 2004).

There is strong pressure to reverse the upward "radiation dose creep" for all X-ray technologies, and especially for CT of children and for mass screening applications. Fortunately, most operators of imaging devices are aware of the need to tailor technique factors to the dimensions of the patient, which can reduce the dose dramatically, especially to children (Kalra *et al.*, 2004; Vetter, 2005).

Finally, there is a downside to the overabundance of imaging riches: What does one do with all images it is now possible to obtain? For a single patient, it may be necessary to display hundreds, perhaps even thousands, of CT sections, and there may be a number of such patients each day. A radiologist clearly cannot examine all these images one by one, despite the possibility that a critical clinical sign may appear in any one of them – with serious medical and legal implications. Although some studies may require very high resolution, such as CT mammography or CT virtual colonoscopy (Imperiale, 2005), buying a multimillion dollar MDCT primarily to create smoother surface renderings of organs generally makes little sense. So it is essential to develop computer-based *bioinformatics* programs that can locate, and perhaps interpret, clinically essential visual items that are obscured within the reams of imaging data accumulating daily (Dodd *et al.*, 2004).

27.6
Nuclear Medicine

Many atomic nuclei are unstable because they contain combinations of neutrons and protons that cannot be held together by the combined action of nuclear and EM forces or because they possess more energy than needed to exist in their ground state. In the latter case, the nuclei can gain stability by releasing their excess energy, most commonly in the form of γ-rays. Because most γ-rays can penetrate tissue in a manner similar to X-rays, they can be detected outside the body after their emission from radioactive materials present inside the body. The procedure of administering a radioactive substance to a patient, and then using radiation detectors to measure or image the γ-rays emitted from the patient, is known as *nuclear medicine* (Cherry, Sorenson and Phelps, 2003; Chandra, 2004).

Nuclear medicine originated in the 1920s and 1930s during studies of the behavior of certain *radiopharmaceuticals* (chemical compounds containing radioactive atoms) in specific organs such as the thyroid and kidneys. A major impetus to nuclear medicine occurred after World War II (WW II) when nuclear reactors became available for the wide-scale production of *radionuclide*s (radioactive atoms) that were potentially useful in diagnostic medicine. Two inventions of the early 1960s greatly advanced nuclear medicine as a diagnostic specialty – the γ-ray scintillation imaging camera and the "molybdenum cow" for on-site generation of the particular radionuclide technetium-99m, which remains the standard workhorse of nuclear medicine. In the 1970s, the introduction of the computer permitted studies of the dynamics of physiologic processes and, in the 1980s, computers made possible the complex reconstruction computations underlying computed tomographic techniques. Today nuclear medicine, including its *SPECT* and *PET*, is one of the most sophisticated of the imaging technologies, and is essential to the detection and diagnosis of a variety of diseases and injuries.

Although a nuclear imaging study cannot compete with radiography, CT, or MRI in revealing precise anatomic detail, it may more than compensate by providing potentially invaluable information about the physiologic status of an organ or tissue.

27.6.1
Radiopharmaceuticals and Technetium-99m in Particular

A radiopharmaceutical consists of two parts: (i) an agent designed to concentrate, through chemical or other physiologic means, in a specific organ or compartment of the body and (ii) a radioisotope (most commonly by far, technetium-99m), which emits a medium-energy γ photon. The ideal radiopharmaceutical would satisfy a number of stringent requirements. First, it must be possible, usually with the aid of inexpensive commercial "kits," to combine the agent to the radionuclide quickly and easily. The radiopharmaceutical thus prepared must remain intact chemically after administration, concentrate rapidly in the organ or biochemical compartment of interest, and be eliminated rapidly from the organ after imaging. Preferably, the radioisotope (radionuclide) will emit only γ-rays (no α or β particles) and these should be energetic enough to be likely to escape the body, yet of low enough energy to interact with the detector material. And, its *half-life* (the time required for half of the atoms in a sample to undergo radioactive decay) should be long enough to allow performance of the necessary clinical chemistry and concentration in the biological compartment of interest, yet not so long that the patient continues to irradiate himself and others long after the study has been completed.

Several radiopharmaceuticals satisfy these criteria for the study of specific organs and tissues in the body (Owunwanue, Patel and Sadek, 1995; Saha, 2001). However, the nuclide employed most frequently is technetium-99m.[8] ^{99m}Tc emits 140-keV γ-rays, an almost ideal energy for escape from the body and for detection with a scintillation camera. There is little particulate radiation emitted along with the γ-rays. The half-life of technetium-99m is 6 hours, long enough to conveniently synthesize a variety of radiopharmaceuticals with desirable physiologic properties but with little hazard after a day or so.

Another major advantage of technetium is its production by decay of molybdenum-99, an easily produced radioactive nuclide with a half-life of 66 hours. The ^{99}Mo can be adsorbed to an ion-exchange column, and the ^{99m}Tc is removed daily in the clinic's laboratory by *eluting* (washing out) the column with saline solution – a routine commonly known as "milking the Mo cow." Most nuclear medicine departments receive one or more of these *technetium generators* (affectionately referred to as *technetium cows*) each week from a commercial supplier.

At least 85% of all nuclear medicine studies are performed with various technetium-based radiopharmaceuticals for studies of lung ventilation and perfusion, cardiac dynamics, liver integrity, kidney function, the presence of cancer metastases in bone and various organs, and a number of other conditions. Other radioactive nuclides that find specific applications include iodine-123 and iodine-131 for studies of the thyroid, thallium-201 for detection of impaired heart muscle, gallium-67 for identification of soft tissue tumors, and fluorine-18 for PET studies. The use of radiopharmaceuticals for medical diagnosis and evaluation is essential to the care of millions of patients each year, and the quality of their health care would be severely compromised if nuclear medicine procedures were not readily available.

27.6.2
Scintillation Gamma Camera

Almost all non-PET nuclear medicine images are obtained with the gamma camera. The action begins within the *scintillation detector*, a wide, thin single crystal typically of thallium-activated sodium iodine, NaI[Tl]. The crystal may be 0.6 cm (1/4 in.) to 1.0 cm (3/8 in.) thick, and 25 cm (10 in.) to 60 cm (24 in.) across. When struck by a γ-ray emerging from the patient's body, the scintillator emits a flash of light of intensity proportional to the photon energy. The backside of the crystal is observed by a honeycomb array of up to 91 *PMTs*. Each PMT views the flash from a different distance, and therefore sees a different intensity, and a comparison of the output voltages from all the tubes yields an estimate of where the flash occurred. This process also determines the total light emission for the flash, and hence whether it came from a primary γ-ray or a lower-energy Compton scatter photon from an interaction in the patient or elsewhere in the crystal. A pulse-height analyzer then rejects the smaller electronic signals produced by scattered γ-rays, thereby limiting the recorded interactions to only those produced by primary γ-rays.

---

[8] The nucleus left behind may still be unstable and therefore still radioactive.

Knowing where γ-ray interactions occur in the crystal must be correlated with the origin of the γ-rays in the patient. This correspondence is achieved by means of a metal *collimator* placed on the patient-side of the scintillation crystal. Most often employed is the parallel multihole collimator, and with such a device a flash detected in the crystal must have been produced by a γ-ray that originated directly below it and traveled straight along one of the collimator holes; γ-rays heading off in other directions are absorbed by the lead septa that separate the holes. In this fashion, the distribution of interactions across the crystal face reflects the distribution of radioactivity in the region of the patient being viewed by the camera. Other types of collimators that are useful in limited applications include the pinhole collimator (particularly helpful in thyroid imaging) and the converging collimator (used primarily for cardiac studies).

Planar nuclear images can reveal not only the static distribution of radioactivity in a particular organ or region but also the transient passage of radioactivity into and out of it. That is, data processing by computer permits quantitative analysis and display of the behavior of the radiopharmaceutical over time. One can partition the cardiac cycle into 25 sequential frames, for example, and, triggered by an electrocardiogram, accept counts in each for 40 ms – and repeat this enough times to acquire sufficient counts in each frame for a high-quality motion picture of the beating heart.

27.6.3
Single Photon Emission Computed Tomography (SPECT)

SPECT is the γ-ray counterpart to X-ray CT. In analogy to CT, images of the distribution of a γ-emitting radiopharmaceutical within the patient are obtained with several gamma camera heads that image for several minutes, rotate through a small angle about the patient (e.g. 6°), and then image again, and so on. A SPECT study is time consuming, but it produces three-dimensional images that can display physiology and anatomy with a high degree of sensitivity. Since the resolution is typically only 5–10 mm, SPECT (like PET) images are commonly overlaid on detailed anatomic maps of the patient obtained with CT.

Because the radiation source is inside the body, the task of image reconstruction is more difficult with SPECT than with X-ray CT. With transmission imaging, the position of the X-ray source and the intensity from it are known at all times during an imaging sequence, which is clearly not the case in nuclear medicine studies. In addition, CT directly measures the effect of main interest, photon attenuation; with SPECT, internal absorption and scatter of photons by the body are only a major complication to the primary task, which is the location of the origins of γ-rays. Prior to a SPECT examination, a CT-like transmission study is usually performed, using either an X-ray or a γ-ray beam, to acquire a relatively crude attenuation map to be used in correcting the SPECT data.

SPECT projection data are combined by computer to yield cross-sectional images of the distribution of radioactivity. Although CT normally employs filtered back-projection algorithms for reconstruction, SPECT fares better with statistical-based iterative approaches (Zimmerman and King, 2006).

SPECT has become nearly indispensable for the assessment of myocardial perfusion and other cardiac functions. Cross-sectional and 3D displays of thallium-201 and other radionuclides in the myocardium (or, more correctly, their *absence*) reveal damage to the heart muscle caused by diminished blood flow in the coronary arteries. More than half of SPECT studies are for coronary artery disease, another quarter are for bone, and the rest are for brain, prostate, thyroid, and other organs (Wernick and Aarsvold, 2004; Park, Moore and Kijewski, 2005). SPECT studies of the brain, for example, can shed light on conditions such as Alzheimer's dementia, epilepsy, and stroke.

27.6.4
Positron Emission Tomography (PET)

Radionuclei for which the proton-to-neutron number ratio is too high for nuclear stability may attempt to rectify the situation through the emission of a *positron*, the positively charged antiparticle of the electron. In positron decay, a proton in the nucleus transforms briefly into a neutron and a positron, in effect, and the positron escapes (along with an antineutrino). The emitted positron travels a few millimeters or less in tissue and collides with an atomic electron. The particles annihilate one another and create a pair of 511-keV *annihilation photons*[9] that fly off in almost exactly opposite directions.

In *PET*, a positron-emitting pharmaceutical is administered, and the pair of annihilation photons is detected with arrays of scintillation detectors surrounding, or on opposite sides of, the patient; in the latter case, the opposed array of detectors is slowly swung around by the gantry, as with SPECT. The arrays are operated in coincidence – that is, a positron-annihilation event is recorded only if two detectors on opposite sides of the patient are triggered virtually simultaneously. The origin of the pair of photons, hence the approximate site of positron emission, can be localized to the straight line between the two detectors. Coincidence events are recorded for all angles, allowing the creation of a 3D tomographic image of the radiopharmaceutical distribution. The operation of opposed detectors in coincidence improves both the spatial resolution and the signal-to-noise ratio relative to planar nuclear medicine and SPECT.

PET began with a prominent role in neurophysiological research. It made use of positron emitters such as oxygen-15 (^{15}O), nitrogen-13 (^{13}N), and carbon-11 (^{11}C), isotopes of elements that are in the small molecules of life. Most clinical and research work is now conducted with fluorine-18 (^{18}F), which has the benefit of a 1.8 hour half-life, long enough to transport it a good distance from the cyclotron in which it is produced.[10] Normally prepared in the form of the glucose analog fluorodeoxyglucose (^{18}FDG) and concentrating where glucose is being burned at an unusually high rate, ^{18}FDG is used widely

---

[9] The rest mass of either an electron or a positron, expressed in terms of energy, is 511 keV.

[10] The very short half lives of carbon-11, nitrogen-13, and oxygen-15 require a cyclotron on-site or nearby to produce the isotopes where they are to be deployed.

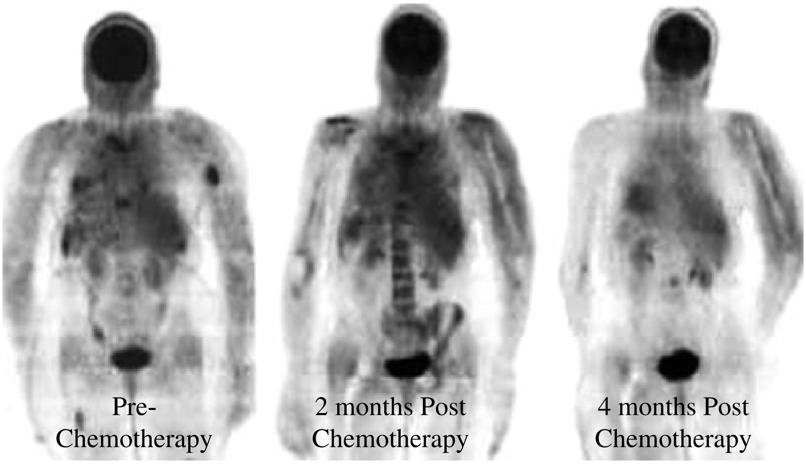


Fig. 27.19 Whole-body positron emission tomography (PET) FDG-fluorine 18 study of metastatic cancer treated by chemotherapy.

as a clinical tool for detection, localization, and staging of malignancies (Figure 27.19), and for monitoring of cancer patients after treatment (Wernick and Aarsvold, 2004; Valk *et al.*, 2003; Pevsner *et al.*, 2005; Nehmeh, Erdi and Pan, 2004).

Nearly every new PET machine now comes fused with its own dedicated CT, allowing the superpositioning of the relevant physiological information directly and precisely on a clear anatomic background. The number of clinical PET and fused PET/CT procedures in the United States has grown from about 250 000 in 2001 to more than a million in 2007. Ninety percent of the studies are performed in search of tumors; the remainder are split between cardiac and neurological studies. It is possible that, because of its better resolution, physiologically more interesting agents, and decreasing cost, PET will eventually displace SPECT and conventional nuclear medicine for many radiopharmaceutical studies.

27.6.5
Recent Developments in Nuclear Medicine

The fusion of SPECT and PET images with CT or MRI (Bacharach, 2004; Czernin, 2004) allows the projection of physiologic information on a detailed anatomic background so that tissue function can be correlated directly with tissue structure (Figure 27.19). With fusion, moreover, the CT attenuation data can be used to correct PET and SPECT images for attenuation of γ-rays within the body. In radiation treatment planning, it is proving useful to merge CT and magnetic resonance (MR) images.

Fused images can be acquired with a single, composite hybrid machine (e.g. CT/PET scanner) that acquires and integrates two separate imaging studies, one immediately after the other, with the patient in the same position. Alternatively, one can combine and register data from two independent devices with specialized software, although fusion is far more demanding in the body than in the head, and is subject to distortions due to changes in patient positioning. Common platforms for acquisition and display of fused image data from different imaging methods will undoubtedly continue to evolve as image-guided surgery and radiation therapy become increasingly desirable.

Meanwhile, advances in molecular biology are yielding receptor-specific radiopharmaceuticals and other pharmaceuticals that are opening up a new realm of opportunities for *in vivo* imaging at the molecular and cellular scale. Research in radiopharmacology and in the technologies for producing radionuclides is of growing importance, but funding of this research is becoming increasingly difficult to identify.

Production of radioactive pharmaceuticals, the creation of imaging devices and protocols, and the interpretation of nuclear images require the involvement of specialists in several disciplines, including radiopharmacology, physics, engineering, and medicine. Nuclear medicine is a true multidisciplinary specialty that represents the leading edge of high technology in medicine.

27.7
Ultrasound Imaging

Most *US* studies produce images from high-frequency sound echoes that are created at boundaries between tissues with different elastic properties or densities. With its ability to furnish images in everyone from fetuses to the elderly, and with no exposure to ionizing radiation, US is indeed a "womb-to-tomb" clinical imaging modality (Fowlkes and Wolbarst, 2006).

During WWII, echoes from high-frequency sound waves transmitted through water were used to detect and locate submarines. This technique, known as *Sound Navigation and Ranging* (*SONAR*), was developed from ideas suggested during World War I by the physicist Langevin. "Echo sounding" found additional applications during and after WWII, including the detection of flaws in welded joints and products such as steel castings. The first paper on the use of US to image human anatomy, specifically the female breast, appeared more than a half century ago (Wild and Reid, 1952). The motion- or M-mode technique for revealing the dynamics of moving structures in the heart was described 2 years later (Edler and Hertz, 1954). Since then, US has become, next to X-rays, the most widely used imaging modality. It provides clinically valuable diagnostic information, is highly adaptable, is less expensive than any other imaging technique, including projection radiography, and involves no use of ionizing radiation.

The frequencies used commonly for US imaging in medicine are between 2 and 15 MHz. This frequency range corresponds to wavelengths of a few tenths of a millimeter, which forms an upper limit to the spatial resolution achievable. Unfortunately, the absorption of US power increases rapidly with frequency, and its ability to penetrate tissue decreases, so high-resolution (short wavelength) studies are restricted to fairly superficial tissues. The 2–6 MHz region is used to examine deeper-seated organs in the abdomen and pelvis.

The velocity, v, of sound in a medium depends only on its physical density, ρ, and its adiabatic bulk elastic modulus, K,

$$v = (K/\rho)^{1/2} \tag{7a}$$

where K is, in effect, the converse of the tissue's bulk compressibility. The velocity of US in tissue, unlike its attenuation rate, depends only very weakly on its frequency, and is commonly taken to be 1540 m s^{-1} in soft tissue.

US images are produced by capturing echoes returning from reflecting surfaces in the body. Sound reflection occurs at any boundary between regions of different *acoustic impedance*, where the acoustic impedance, Z, of a tissue depends only on ρ and K:

$$Z = (\rho K)^{1/2} \tag{7b}$$

so the acoustic impedance is also seen as $Z = \rho v$.

The significance of acoustic impedance is that the *fractional reflection*, α_R, of US energy at a boundary separating two tissues with acoustic impedances Z_1 and Z_2 is

$$\alpha_R = [(Z_2 - Z_1)/(Z_2 + Z_1)]^2 \tag{7c}$$

The fractional transmission across the boundary is $(1 - \alpha_R)$. Z is much smaller for air than for tissue, for example, so US is reflected almost perfectly at the boundary of the chest wall and the lung. Consequently, little US energy is transmitted across the interface for imaging structures within the lung. Although US is not useful for examining normal lung, because of its irregular, fractal-like surface structure, it can image the heart since there is a path of solid tissue via the mediastinum. US imaging is used for imaging soft tissues in every organ system of the body other than the lung, adult brain, and bowel, where large impedance barriers impede its transmission. It is particularly helpful in identifying and characterizing cancer and cardiovascular disease.

To acquire a US image, a US transducer is placed on the skin of the patient, and air pockets are eliminated by means of a coupling gel between them. The active component in the transducer is a thin *crystal* or *piezoelectric* material that has unusual electromechanical properties: when a voltage is applied across it, it deforms and, conversely, when it is mechanically compressed or bent, a voltage appears across it. In the US system, an electronic impulse generator shocks the crystal several hundred times per second. Each time, the crystal contorts and oscillates at high frequency (MHz), thereby generating a short burst of US waves that propagate away from the crystal and into the tissue. Echoes from impedance discontinuities at tissue interfaces in the patient return to the crystal in the periods between shocks (the quiescent period). They apply pressure to the crystal, which responds by yielding a small electrical signal that is captured, amplified, processed, and displayed. An echo that returns at time t_{echo} was produced by a surface at depth

$$x_{\text{surface}} = 1/2 v t_{\text{echo}} \tag{8}$$

The earliest form of US, seldom used today, was *amplitude-mode* (*A-mode*), in which the US beam points in one, fixed direction through tissue (Figure 27.20). The display might involve sweeping a faint spot of light horizontally across a monitor in such a manner that its x position corresponds to depth within the body. For an echo created at depth x_{surface}, as determined by Eq. (9), the brightness of the spot will increase briefly with

an intensity proportional to the echo signal voltage, that is, the Z mismatch at the reflecting surface. A *time gain compensation* (*TGC*) circuit will adjust the brightness to account for natural attenuation by the tissues.

The most common method of displaying US information is known as

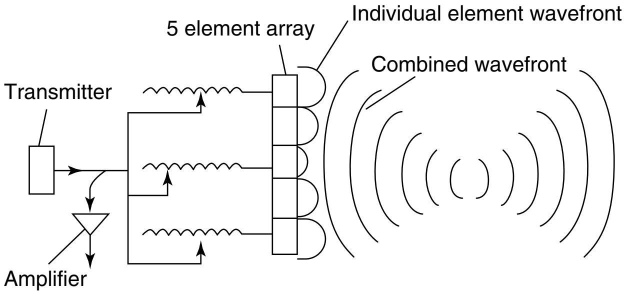

Fig. 27.21 Principle of phased-array operation, showing how a suitably phased five-element array launches a focused wave. (From Newhouse, V.L. (1993) Imaging techniques, biomedical, in *Encyclopedia of Applied Physics*, Vol. 7, VCH, New York, with permission.)

brightness mode (*B-mode*). The transducer transmits and receives US along a line through tissue, as in A-mode, and produces a line of varying brightness on the monitor depending on the strength of the returning echo. But now the US beam is swept back and forth through the tissue, perhaps 30 times per second, and the line on the display follows accordingly creating a B-mode image of the slice (Figure 27.20).

Echoes are produced not only at interfaces between organs in the body, but also from interference patterns resulting from countless reflections by microscopic structures within tissues. These echoes, often referred to as *speckle*, can be important for purposes of tissue identification and characterization.

27.7.1
Phased-Array Transducers

To acquire a B-mode image in real time, the US beam sweeps quickly through the tissue, and varies its depth of focus, as well. This is achieved with a phased array, which contains hundreds of tiny, separate, mechanically and electrically isolated piezoelectric elements (Figure 27.21) (Zagzebski, 1996). Each element is driven by an independent electronic delay circuit configured to vary the time of arrival of its own, unique voltage pulse.

The delay times depicted in Figure 27.21 cause the impulse from the transmitter to reach the top and bottom elements before it reaches those in the center of the array; US waves emitted from the top and bottom elements enter the tissue ahead of those from the center, and this timing pattern yields a curved ultrasonic wave front that converges to a focus at a particular depth in tissue. Changing the relative delays of the transducers alters the depth of focus of the US beam. A multielement array also allows us to steer the beam, as well. Increasing the delays of the top transducers relative to the bottom transducers, for example, deflects the US beam downwards. With the array transducer steering the beam back and forth while increasing the depth of focus more slowly, B-mode US can generate images that are of high resolution at all depths.

A phased array can function as a focusing mechanism not only while transmitting the US beam but also while receiving the echoes. The time it takes for the US energy created by any individual piezoelectric element in the array to reflect from a point on the tissue interface and then return to any other element depends on the relative positions of the two elements and the reflection point. The feature of *dynamic focus* corrects for this complication, which otherwise would cause significant image blur. Once a US burst has been transmitted out by the array, the delay settings can be continuously changed so that the *receive focus* is always optimized for echoes returning from specific depths. Images of Figure 27.22 were obtained with a variable depth-of-focus phased-array US transducer.

Figure 27.22 reveals an exceptionally high level of detail because the fetus is surrounded by uniform amniotic fluid, so there are no aberrations introduced by slight US velocity differences in inhomogeneous tissues in its immediate vicinity.

27.7.2
Ultrasound Flow (Doppler) Imaging

US can measure the speed of flow of blood in vessels and map flow patterns in the heart by means of the Doppler effect. The frequency of an echo reflected from a moving target is altered by the Doppler shift frequency, Δf_D, where

$$\Delta f_D / f_{\text{transmit}} = \pm 2\, v_{\text{blood}} / v \qquad (9)$$

where f_{transmit} is the frequency of the transmitted US, v_{blood} is the speed of the moving target (blood in a vessel), and v is the velocity of US in the tissue containing the blood vessel. By detecting the Doppler frequency shift, the velocity v_{blood} of the flowing blood can be determined, and by observing the polarity of the frequency shift, the direction of blood flow can be identified.

Through adoption of electronic processing techniques first used in weather radar, Doppler and B-mode have been combined to reveal the flow patterns of blood through a region (e.g. a heart chamber) in real time against a background of clearly delineated anatomy (Kasai *et al.*, 1985).

27.7.3
Ultrasound Tissue Characterization

Clinical US is used principally to obtain anatomical and blood-flow information, and it is discontinuous changes in elastic properties or the density at tissue interfaces that make this possible. The images generated, however, reveal little about tissue elasticity itself, which may nonetheless be of clinical interest. US can also discriminate between normal and diseased tissues through measurements of the frequency dependence of tissue attenuation and scattering (Greenleaf, 1986).

The hardness of tissue has been used for centuries as a method to detect abnormal conditions, usually through subjective measures such as finger pressure. A more objective approach is the use of a mechanical device to apply a known amplitude of vibration to the skin, and determination of the displacement of tissues at various depths by Doppler measurements. The resulting computations yield a measure of tissue rigidity (Krouskop, Dougherty and Vinson, 1987). More recently, *elastography*, or elastic imaging, allows direct measurement of tissue elasticity parameters.

US images are compared before and after mechanical or acoustical application of static or dynamic pressure or shear, revealing the small amounts of compression or strain that are induced (Sandrin *et al.*, 2002). With the related technique of MR elastography, the tissues of interest are stressed with small (10–100 μm amplitude) vibrations, and the induced distortions are measured with a phase-contrast pulse sequence (Weaver *et al.*, 2001).

27.7.4
Recent Developments in Ultrasound

Over recent years, the evolution of diagnostic US has been quiet spectacular

(Harvey *et al.*, 2002; Wang *et al.*, 2003; Lee, 2003). There have been major strides in the design of miniaturized piezoelectric and capacitive transducers; contrast agents (which, at present, consist of fluid suspensions of erythrocyte-sized gas bubbles that may be coated with a tissue-targeting compound) (Hohmann *et al.*, 2003; Miller and Nanda, 2004); the exploitation of harmonic information, which is associated with higher frequency components created from nonlinear propagation of sound through tissues or with nonlinear oscillations of contrast agent gas bubbles (Desser and Jeffrey, 2001); the use of coded-excitation pulse trains and matched filters; image-processing software; techniques based on the absorption or speed of US radiation, rather than just on reflection; and small size and portability. In addition, two-dimensional arrays of piezoelectric elements make possible the creation of real-time images that appear truly three dimensional and that display high spatial, contrast, and temporal resolution over a large field of view (Smith *et al.*, 2004; Duric, Littrup and Babkin, 2005).

Clinical US systems normally operate in the 2–15 MHz range. Despite technical difficulties, devices are now being designed with much higher frequencies. The shorter wavelengths allow the imaging of correspondingly smaller objects. Micromachined US transducers consisting at present of tens of separate piezoelectric or capacitive elements a few micrometers across – fine enough to fit within a narrow-gauge catheter and then into a coronary artery – are being built by microelectromechanical semiconductor manufacturing technologies (Oralkan *et al.*, 2003). Vascular imaging is currently being performed in the 10–40 MHz range; at even higher frequencies (up to several 100 MHz), there are potential applications in ophthalmology, dermatology, and perhaps cellular-level imaging.

There are also early but promising results for true four-dimensional tomographic US imaging. US tomography may require hundreds of transducer elements covering a large-angle area of the body and perhaps firing and gathering echoes separately – although it is possible that a much simpler solution to four-dimensional image acquisition may be found. Transmission US tomography has been demonstrated in relatively homogeneous tissues such as the female breast, where (as in refraction seismography, used by geophysicists in the search for oil and gas) variations in the speed and/or absorption of sound are measured and processed to create images. Reflection US tomography, with its multiplicity of omni-directional echoes, continues to pose major technical problems that remain intractable at this time.

Finally, there is active research on biological effects (AIUM, 2003), especially as US applications move to much higher frequencies. This is ongoing not only to ensure patient safety in diagnosis but also to support novel applications in therapy (Curra and Crum, 2003).

27.8
Magnetic Resonance Imaging

X-ray and US imaging are termed *transmission* technologies because they involve the transmission of penetrating radiation into a region of the body from an external source. Nuclear medicine is an *emission* imaging technique because it utilizes radiation emerging from a biological compartment inside the body following administration of a radiopharmaceutical. *MRI* is a bit of both. It involves first the transmission of pulses of RF EM radiation into the body, which is situated in a strong external magnetic field, and then the detection of subsequent RF signals generated by magnetic nuclei within.

MRI not only reveals anatomic details of the various organs and tissues, as does CT, but it also provides information on their physiological status as does nuclear medicine.[11] But unlike CT and nuclear medicine, MRI does not involve X-ray or γ-ray energy, and it is frequently hailed for using no ionizing radiation. Instead, MRI employs magnetic fields and radio waves to probe the exquisitely choreographed motions of the magnetic nuclei of hydrogen atoms (almost exclusively) occurring naturally in the water (primarily) and lipid molecules within and around tissue cells.

Nuclei act rather like a spinning positively charged ball. As with any other moving charged body, they produce their own local magnetic field. An atomic nucleus therefore behaves in some ways like a tiny compass needle – not only producing its own very weak magnetic field but also aligning in an externally applied magnetic field.[12]

When a patient lies in the strong externally applied magnetic field of an MRI device, the hydrogen nuclei (which are single protons) of the water and lipid molecules in the tissues tend to align along it. Many protons settle into a lower-energy (ground) state, like a compass needle, with its spin axis and local field aligned along that of the external field. But some protons reside in a quasi-stable, higher-energy spin state, pointing in the opposite direction to the applied magnetic field.

Under conditions of thermal equilibrium, a slight excess of spin exists in the lower-energy spin state. For the magnetic field strength most commonly encountered in MRI, 1.5 T, this excess (the difference in numbers of nuclei pointing parallel and antiparallel to the external magnetic field) amounts to a few parts per million, as described by Boltzmann statistics. The spin excess in the jth tissue voxel gives rise to a relatively weak magnetic field, known as the voxel's *equilibrium net magnetization,* and is denoted by the vector $M_{j,z0}$:

$$M_{j,z0} = 10^{-6} N_j \mu \tag{10}$$

The subscript 0 indicates thermal equilibrium, and the z is a reminder that here, the net magnetization of the voxel points along the z axis defined by the external magnetic field. μ, the *nuclear moment* of the nucleus of interest, is a direct measure of the strength of the magnetic field it produces; there are N_j protons in the jth voxel; and there is an excess of about 10^{-6} nuclei (the exact value increases with the strength of the external magnetic field) in the lower-energy spin state.

When not in thermal equilibrium, which, during MRI, is almost always, the behavior of the voxel's net magnetization over time is written as $M_j(t)$. It is by monitoring the behavior of the $M_j(t)$ for

---

[11] Expanded treatments of MRI may be found in Bushong (1996); Bushberg *et al.* (2002); Hendee and Ritenour (2002); Wolbarst (2005); Weaver, Ballon and Wolbarst (2006).

[12] The only nuclei that do not act in this manner are the few that happen to contain an even number of protons (which pair up in opposite directions, so that their fields cancel) and an even number of neutrons. For better or worse, the common isotopes of carbon, oxygen, and calcium fall into this class; hence they contribute nothing to an MRI signal.

Tab. 27.1 Magnetic resonance properties of selected nuclei.

all the voxels in a section of tissue under various conditions that MRI images are created.

27.8.1
Nuclear Magnetic Resonance (NMR)

Nuclei can be intentionally flipped from their lower- into their higher-energy spin states through the process of *nuclear magnetic resonance* (*NMR*). This is achieved by irradiating the nuclei with a pulse of RF energy of the correct frequency. This *Larmor frequency* is easily deduced for the elementary, two-state quantum picture. The energy to flip a single nuclear spin depends on the strength of the external magnetic field, B_0, and on the "magnetness" of the particular isotope, as characterized by μ or by the closely related *gyromagnetic ratio*, γ:

$$E_{\text{flip}} = \gamma(h/2\pi)B_0 \tag{11a}$$

The presence of Planck's constant, h, suggests that the spin-orientation transition is a quantum mechanical event. Meanwhile, one of the fundamental pillars of quantum physics is the Einstein relation,

$$E_{\text{photon}} = hf_{\text{photon}} \tag{11b}$$

which states that the energy of a photon is proportional to its frequency. So for a photon to cause the spin transition of a nucleus in a magnetic field, it must be of the frequency[13]

$$f_{\text{Larmor}} = \gamma/2\pi\, B_0 \tag{11c}$$

known as the *Larmor frequency* (Table 27.1). For protons, $\gamma/2\pi = 42.58$. Therefore,

$$f_{\text{Larmor}}\ (\text{MHz}) = 42.58\ B_0 \quad (\text{T}) \tag{11d}$$

the central relationship of both NMR and MRI. In a 1.5-T field, water and tissue protons resonate at 63.87 MHz, and in a 3.0 T field, it is twice that frequency.

Quite remarkably, it is possible to arrive at exactly the same Larmor equation by a purely classical argument. Consider a top or gyroscope in outer space. Its rapid rotation and the Law of Conservation of Angular Momentum act to keep its axis pointing always in the same direction. But on the surface of the earth, the pivot point holding the top or gyroscope up and gravity acting at its center of mass together exert a twisting torque on it. Its equation of motion, a simple extension of Newton's law $F = ma$

---

[13] The Larmor equation is sometimes written in terms of angular frequency, in radians per seconds, as $\omega_{\text{Larmor}} = \gamma B_0$.

for a rotating object experiencing an applied torque, reveals that it will not simply topple over, but rather will *precess* around the direction of the applied field, with its axis sweeping around the surface of a cone. Similarly, a charged object, spinning with angular momentum and sitting in a magnetic field, is subject to the Lorentz force, and its resulting motion is a steady precession about the direction of the field, with the vector $M_j(t)$ circling it and constrained to the surface of a cone. And it will be precessing at the same Larmor frequency as was seen with the quantum picture!

An individual magnetization vector, $M_j(t)$, precesses in every one of the (typically) $256 \times 256 = 65$ k voxels in a thin slice.

By determining the magnitude of each vector, it should be possible, from the corresponding values of N_j of Eq. (11), to create a *proton density-weighted* (*PD-w*) MRI image that maps out the variation in numbers of protons in each voxel. The problem, however, is that the only thing we can measure in a pickup coil outside the body is the single RF signal produced by all the voxel magnetizations acting together. This problem, while perhaps seeming hopeless at first viewing, in fact has a clever and powerful solution that involves the application of various combinations of RF pulses and magnetic field gradients, as will be discussed below.

27.8.2
T1 (Longitudinal, Spin–Lattice) Proton Spin Relaxation

A PD-w image is conceptually straightforward, and of some clinical value, but of much greater medical importance are images that reflect spatial variations in the *spin relaxation times*, T1 and T2. Their meanings may not yet be apparent, but we can address T1 relaxation readily with our simple spin-up, spin-down picture. For simplicity, moreover, we shall focus hereafter on the protons of tissue water.

Imagine a tray covered with compasses with needles aligned along the Earth's magnetic field. Now, in your mind's eye, twist each needle through 180°, so that it points south, and then release them all at the same time. They will flip back over, oscillate a few times with diminishing swings, and eventually come to rest pointing north again. The average amount of time this settling down process takes for an ensemble of identical compasses is known as its *relaxation time*. It is determined both by the strength of the magnetic field interaction and by the nature of the frictional forces present, such as those occurring at the mechanical pivot points where the needles are supported.

A similar situation applies with protons. Suppose a voxel full of tissue protons is sitting between the poles of a turned-off magnet. They will be oriented randomly in all directions. Now quickly snap the field on. The protons will undergo a kind of spontaneous relaxation analogous to (but actually quite different from) that of the tray of compass needles, in which they flip into alignment along or against (because they obey quantum mechanics) the field. The time it takes them to go 63% of the way to their thermal equilibrium[14] condition is called the *longitudinal spin* (or *spin-lattice*) *relaxation time*, and designated T1:

---

[14] The time, dose, distance, energy, whatever, it takes for a system exhibiting (near-) exponential behavior to decay, be attenuated,

$$M_{j,z}(t) = M_{j,z0}(1 - \mathrm{e}^{-t/\mathrm{T1}}) \qquad (12)$$

T1 and a second related, but different, relaxation time, T2, are invaluable in creating clinical images, and it is primarily the spatial variations in the relaxation times T1 or T2 that MRI reveals.

The atomic-level mechanism that is responsible for T1-type relaxation also involves the Larmor equation, but the physical interpretation is different. For reasons explained by quantum mechanics, not only can Larmor-frequency RF photons kick protons in the ground spin state up into the excited state, with the absorption of $\gamma(h/2\pi)B_0$ of energy, but also *any* local magnetic field (not just that of a photon) that happens to be fluctuating at the Larmor frequency can "tickle" protons in the higher-energy state back down, where the proton loses its spin-orientation energy to the local environment. Magnetic "noise" occurs naturally in tissues if the water molecules are tumbling and interacting with one another and with their surroundings in such a manner that, at least intermittently, they are rotating at the Larmor frequency. In this condition, each proton experiences the magnetic field from its partner (on the same water molecule) as varying, again at least briefly, at the Larmor frequency, which can cause a downward spin transition. Unbound ("free") water, for example, tumbles much faster than the proton Larmor frequencies for the external fields employed in MRI, so T1 is long (4000 ms at 1.5 T), as is the case with other nearly clear fluids such as cerebrospinal fluid (T1 = 2.5 seconds). For water bound to intermediate-sized biologic molecules (which themselves may happen to be tumbling at the Larmor frequency), however, T1 can be shorter by an order of magnitude or more.

The proton relaxation times of the water in and between tissue cells are highly sensitive to the detailed nature of binding, and of friction-like mechanics and other interactions, with various biomolecules and membranes. The concentrations and biophysical characteristics of these biomolecules, in turn, depend on the type and physiologic status of the cells they inhabit. MRI is therefore able to distinguish not only among histologically different tissues, but even between healthy and diseased forms of the same tissue.

What a T1-weighted (T1-w) MR image actually reveals is variation in T1 throughout the tissue slice under examination. It can produce a degree of contrast among soft tissues that is often much better than that of CT, and it can reveal subtleties in the physiology of an organ that any form of X-ray imaging would completely miss. For some kinds of examinations, a T1-w may well be fully diagnostic – while for others, a T2-weighted image is even better.

27.8.3
T2 (Transverse, Spin–Spin) Proton Spin Relaxation

It is easiest to discuss T2 with the classical picture of NMR.

Under conditions of an unchanging external magnetic field, the protons in

---

be excited, relax, and so on, to $0.37 = e^{-1}$, or to $0.63 = 1 - e^{-1}$, of the original or final value is commonly taken as a characteristic "constant" parameter.

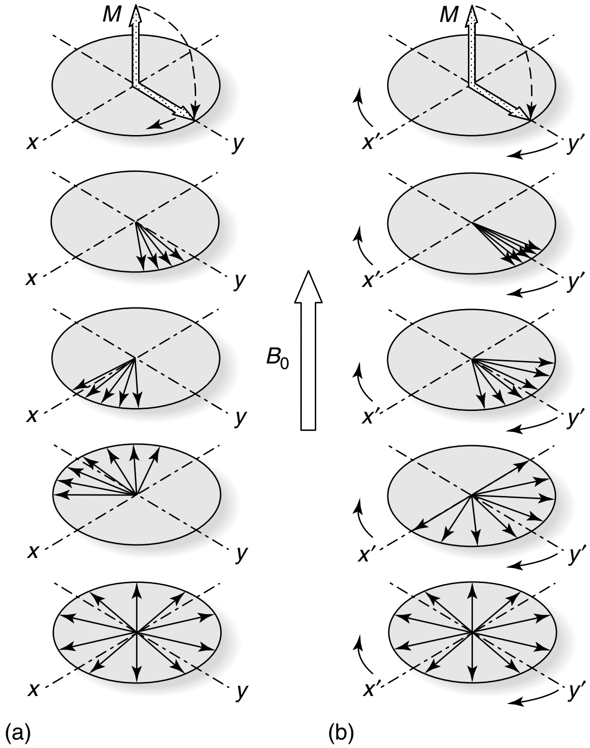

Fig. 27.23 Following a 90° pulse that drives the magnetization for a voxel, *M*, from the vertical down into the transverse plane, spin-spin interactions cause a dephasing of separate packets of protons within the voxel. This is seen (a) from the fixed frame of reference and (b) from a frame of reference rotating with *M*, at the Larmor frequency.

a voxel will be oriented in a direction close to that of the external field, yielding a magnetization $M_j(t)$ that precesses on the surface of an imaginary cone at the Larmor frequency (Figure 27.23a). If, in addition, an RF pulse with a magnetic field $B_1\cos(2\pi f_{\text{Larmor}}t)$ is applied at right angles to B_0, then the magnetization will *nutate* (rotate) away from its near-equilibrium alignment and spiral downward (Figure 27.23a) – as if the cone were slowly opening up (Figure 27.23b). This nutation, like precession, is readily explicable with a further extension of Newton's law of classical physics. For a Larmor-frequency γB_1 left on for time τ, the magnetization will spiral down through an angle of

$$\theta = \gamma B_1 \tau \qquad (13)$$

Of particular interest is the case in which $\gamma B_1 \times \tau$ yields $\theta = 90^\circ = \pi/2$, so that the magnetization of the *j*th ends up precessing in the transverse $(x - y)$ plane, and will be called $M_{j,x-y}(t)$.

With a receiver coil also located on the transverse plane, and ignoring the other voxels for the moment, $M_{j,x-y}(t)$ will induce a voltage in the coil every time the magnetization vector swings by. This process generates a Larmor-frequency signal whose voltage is proportional to the magnitude of $M_{j,x-y}(t)$. Precession of a magnetization in the transverse plane and its detection by a pickup coil, by the way, is the *only* way in which MRI data are ever obtained.

The signal produced following a 90° pulse decays exponentially with a time constant T2*:

$$M_{j,x-y}(t) = M_{j,x-y}(0)e^{-t/\mathrm{T2}^*} \qquad (14)$$

Such *free induction decay* (*FID*) corresponds to a *dephasing* of the spins over time caused primarily by two factors – random and nonrandom disturbances. The first includes the dephasing that accumulates because of slow, random magnetic interactions between a proton and its partner proton or some other spins, momentarily affecting its rate of precession in the $x - y$ plane. Another kind of random event occurs when a proton happens to lose its spin energy to its surroundings, and snaps back toward the z axis – the phenomenon of longitudinal relaxation.[15] Nonrandom, or quasi-constant disturbances arise from weak, nonchanging spatial inhomogeneities in the magnetic fields experienced even on the scale of a voxel; these are caused both by imperfections in the external magnetic field and by the presence of nearby, immobile biomolecules (the *susceptibility effect*) that have been made slightly magnetic by the external field. The random and nonrandom mechanisms act independently on the spins in any voxel, together giving rise to their dephasing over time, and causing the decline in $M_{j,x-y}(t)$ with time constant T2*.

Application of a single 90° FID pulse can provide a simple assessment of T2*, but what is usually desired are estimates of the biologically relevant *transverse* or *spin–spin relaxation time*, T2. There is nothing that can be done about the random dephasing (even if we wanted to do it, which we do not), but application of the *spin-echo* pulse sequence can actually *reverse* the dephasing effects due to the static, nonrandom magnetic field inhomogeneities. This leaves behind, in effect, only that part of the decline in $M_{j,x-y}(t)$ that is attributable to relaxation events arising from spin–spin interactions.

The decline in $M_{j,x-y}(t)$ may be understood more clearly by considering the *rates* of the several relaxation mechanisms, rather than their relaxation *times*. The overall decay of the transverse magnetization occurs at a rate proportional to 1/T2*. Contributing to it are the rates $1/\mathrm{T2}_{\mathrm{inhomo}}$ and 1/T2 corresponding, respectively, to speed-up and slow-down in precession caused by static field inhomogeneities, and to dephasing generated by random interactions among spins, as determined by the local biophysical environment:

---

[15] How can a proton precessing in the $x - y$ plane undergo a spin-up, spin-down transition? An apparent paradox arises here only because the quantum picture presented so far for a single proton is a gross over simplification for most purposes. A complete, rigorous quantum mechanical treatment reveals that the magnetization made up by the ensemble of all the spins in a voxel should be viewed as an *expectation value* that obeys the classical *Bloch equations.*

$$1/\mathrm{T2}^* = 1/\mathrm{T2} + 1/\mathrm{T2}_{\mathrm{inhomo}} \qquad (15)$$

By removing $1/\mathrm{T2}_{\mathrm{inhomo}}$ dephasing, we are left with $\mathrm{T2}^* = \mathrm{T2}$.

Now back to spin-echo, and let us ignore random, T2-type relaxation for the moment, concentrating only on the dephasing that comes from magnetic field inhomogeneities. Spin-echo begins with a 90° pulse that rotates a voxel's magnetization vector from its equilibrium configuration, $M_{j,z0}$, lying along the z axis, down into the $x - y$ plane, with virtually all the spins starting out precessing in phase (Figure 27.24a). Inhomogeneities in the external magnetic field cause some spins to precess faster than average and others slower, leading to their dephasing (Figure 27.24b). A 180° pulse, applied after the time 1/2TE[16] has passed, flips the spins through 180° within the $x - y$ plane (Figure 27.24c). This flip puts the spins that are precessing more slowly ahead of the faster ones, and vice versa (Fig. 27.24d). But because the field inhomogeneities are constant, each spin will continue to precess at the same rate

---

[16] The time TE is referred to as *the time to echo.*

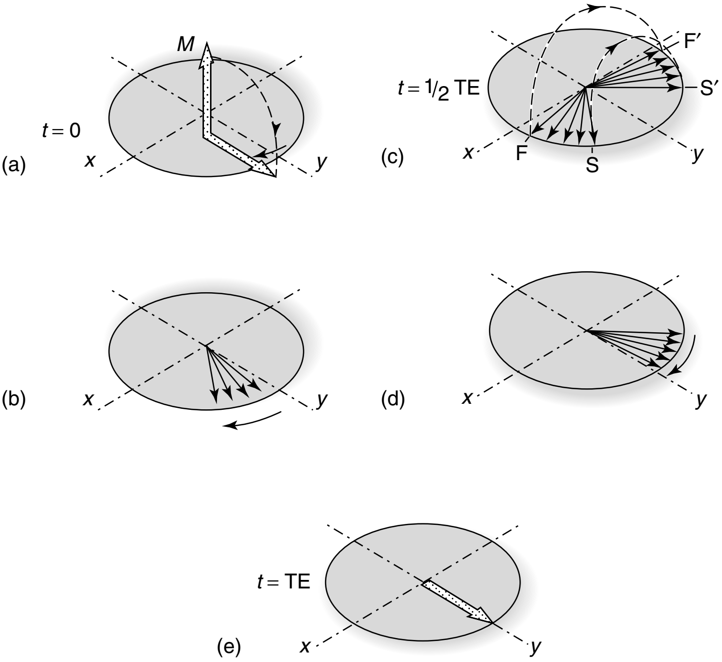

Fig. 27.24 In the spin-echo pulse sequence the 90° pulse (a) causes nutation of the bulk magnetization about the y axis. Dephasing then occurs (b) as slower components of the magnetization lag and faster components advance. A 180° rephasing pulse (c) causes nutation about the y axis and reverses the order of fast and slow components. The components then merge (d) to produce the maximum signal (e). Diagrams a–d are shown in the rotating frame of reference.

as before. So exactly at time TE, the faster spins will have caught up with the slower ones, and all will, very briefly, be back in phase again (Fig. 27.24e). As they precess at f_{Larmor} at time TE, their communal $M_{j,x-y}(\mathrm{TE})$ sweeps past the pickup coil and creates a brief but detectable ''echo'' voltage. This, in fact, is what makes signal acquisition possible – indeed, approaches other than spin-echo, such as *gradient-echo,* must find another way to create some sort of echo in order to record a signal.

In the spin-echo method, all the phase change arising during the first 1/2TE period caused by static field inhomogeneities is undone in the second 1/2TE and, in effect, these inhomogeneities are removed entirely from the picture. Now let us add T2 relaxation back in. Exactly at TE, the signal detected by the receiver coil will reflect the instantaneous value of $M_{j,x-y}(t)$ as determined by T2- (not T2*-) relaxation processes:

$$M_{j,x-y}(\mathrm{TE}) = M_{j,x-y}(0)e^{-\mathrm{TE}/\mathrm{T2}} \tag{16}$$

A sequence of measurements at TE intervals will reveal an exponential decline in $M_{j,x-y}(t)$, but one parameterized by T2, not T2*.

T2, like T1, depends on the biochemical microenvironments of resonant protons, and differences in these microenvironments among tissues strongly influence MRI image contrast. It is left as an exercise to ponder

$$\mathrm{T1} \geq \mathrm{T2} \geq \mathrm{T2}^* \tag{17a}$$

or in its perhaps more physically intuitive form

$$1/\mathrm{T1} \leq 1/\mathrm{T2} \leq 1/\mathrm{T2}^* \tag{17b}$$

and why paramagnetic *contrast agents* (most notable, gadolinium ions caged within the molecules of a chelating agent) can radically alter T1 and T2 (Allen and Meade, 2004).

27.8.4
Spin-Echo, Spin-Warp Voxel-Magnetization Localization

MRI involves manipulation of pulses of RF energy and magnetic field gradients to assess, in effect, T1 and T2 at each point in the part of the body being examined (Haake *et al.*, 1999; Liang and Lauterbur, 2000).

The signal induced in a pickup coil during resonance contains contributions from the magnetizations of all the voxels in the tissue subjected to the external magnetic field and the RF pulses. To produce an image from MR signals, the origin of each voxel-contribution must be localized to a tiny volume of tissue. With the standard *spin-echo spin-warp* approach, the voxel locations are determined by three separate processes that localize the signal origin along three orthogonal axes.

The first step is to select the transverse slice of tissue at some particular position along the z axis (the direction of the external magnetic field, B_0) for further investigation. This involves application of a *slice-select gradient* magnetic field, which points always along B_0, but whose strength varies linearly with z. This z gradient alters not only the applied magnetic field along the z axis but also the proton Larmor frequency. Thus, there is a direct and unique correspondence among z position, local field strength, and proton Larmor frequency for a slice. So with application of a narrowband 90° RF pulse, only those protons in the selected narrow (typically a few millimeter) transverse slice of tissues at the corresponding

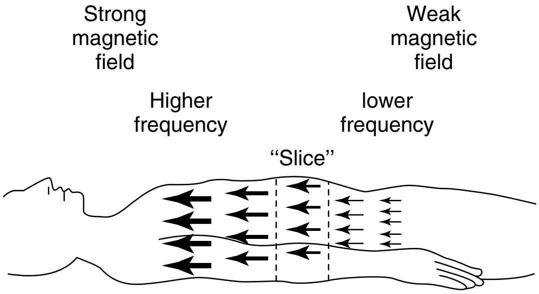

Fig. 27.25 A craniocaudal "gradient" or change in the magnetic field along the craniocaudal axis allows receiver coils to be "tuned in" to a slice.

z value will resonate and nutate down into the $x-y$ plane (Figure 27.25). Nuclei above and below the slice will be unaffected, and will not contribute to the MRI signal.

A second, *phase-encoding gradient* is now applied, also pointing along B_0 but with its field strength proportional to the y position. This gradient is applied for a brief interval before signal readout, and then removed. While it is on, the gradient alters the precessional frequencies of the nuclear spins in such a manner that those with higher y values precess faster than spins on the low field-strength end – and the amount of additional phase difference accumulated by a nuclear spin during the gradient-on interval depends on the position of the spin in the y direction. When the gradient is removed, these phase differences are locked in, and their determination during readout serves as a way to identify the location of voxels in the y direction. The amount of phase difference accumulated in a given voxel depends on the gradient amplitude, the y position, and the gradient on-time.

Locating the origin of an MRI signal component and its voxel along the x axis involves application of the *frequency-encoding* or *readout* gradient during signal readout, which spreads out the voxel-specific resonant frequencies according to their x positions. For an image matrix with 512 pixels along the patient's x axis, say, the x gradient must be strong enough for the RF receiver and frequency discriminator to be able to separate the acquired signal into components centered at 512 distinct frequencies.

A single reading, with one setting for the y gradient and one for the x gradient, does not provide anywhere near enough information to individually localize all of the voxels in the tissue slice selected along the z axis. So while the x-gradient amplitude is always set to the same value, the amplitude $G\gamma$ of the y gradient is systematically stepped upward in strength, with a readout (with the x gradient on) for each setting of the y-gradient amplitude. For a 512 × 512 matrix, for example, 512 readings are made, each with a different value for the y gradient or its on-time, and for every one of them, the signal is then separated into 512 frequency components.

Acquisition of phase- and frequency-encoded MRI signals over many cycles yields a complex set of data that is best analyzed by two-dimensional Fourier transform (2DFT) methods. This analysis constitutes the fourth and final step in the process of spatial localization of MRI signals.

The entire image creation process may be repeated several times, with the resulting images averaged to reduce image noise. Representative MRI images are shown in Figure 27.26.

27.8.5
Flow Imaging: Magnetic Resonance Angiography (MRA)

The acquisition of data for an MR image takes time, during which blood can move a considerable distance within a tissue slice. *Magnetic resonance angiography* (*MRA*), exploits this movement to produce maps of blood flow (Higgins *et al.*, 2005; Elkington, Gatehouse and Cannell, 2005; Slavin and Bluemke, 2005; Bulte, Kostura and Mackay, 2005).

Blood moving into a z-axis slice during signal acquisition will display a brightness different from that of stationary tissues present in the slice, primarily because the blood was outside the slice when the RF pulse was applied to excite the nuclear spins; blood moving within the slice will tend to "disappear" from the image, because the phase-encoding method relies on the tissues remaining stationary over multiple cycles of the signal acquisition process. Also, blood present in the tissue

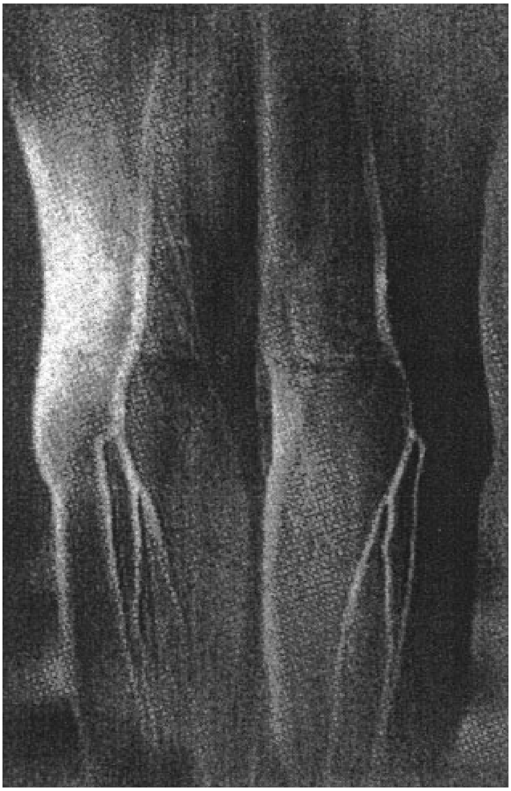

Fig. 27.27 Magnetic resonance image of blood vessels in the legs, obtained by subtraction of the systolic image from images during diastole. This is one of the earliest examples of magnetic resonance angiography. (From Newhouse, V.L. (1993) Imaging techniques, biomedical, in *Encyclopedia of Applied Physics*, Vol. 7, VCH, New York, with permission.)

slice during RF activation is "tagged," in the sense that the nuclear spins are oriented perpendicularly to the applied field; the path of this "tagged" blood can be followed in subsequent MR images.

Phase encoding can be applied in a manner that preserves the MR signal during diastole (when the heart is expanding and the blood is essentially stationary), and ablates the MR signal during systole (when the heart is contracting and the blood is moving rapidly). By subtracting the systolic image from the diastolic image, the moving blood in selected blood vessels can be revealed with excellent clarity (Figure 27.27).

At the other extreme from the rapid flow of blood through arteries and veins, *diffusion MRI*, which is becoming widely used in the assessment of acute stroke and malignancies, is able to reveal information (the diffusion tensor) about the actual directions of fluid (primarily water) diffusion in tissues (Holodny *et al.*, 2005; Yoshiura, Mihara and Tanaka, 2005).

27.8.6
Functional MRI (fMRI)

Functional magnetic resonance imaging (*fMRI*), and in particular *blood oxygen level-dependent* (*BOLD*) imaging, can determine where in the brain the instantaneous flow of oxygenated blood is unusually high and, by inference,

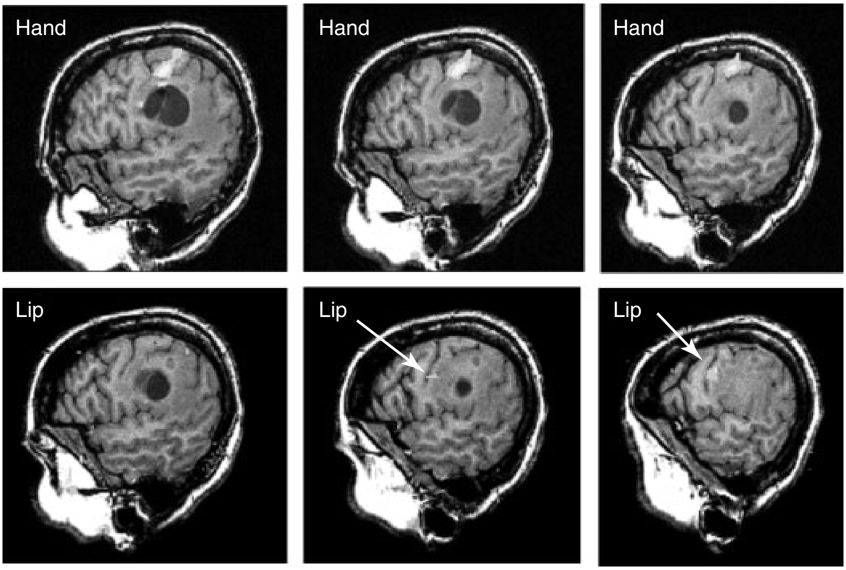

Fig. 27.28 44-year-old woman with a brain tumor. fMRI shows the location of the motor cortex that controls the hand and the lips on one side of the body. These cortical regions are important to avoid when resecting the brain tumor. (Obtained courtesy of John Ulmer, MD, Medical College of Wisconsin.)

where neurons are unusually busy (Figure 27.28).

The magnetic properties of deoxygenated blood (which is diamagnetic) differ from those of paramagnetic oxygenated blood, so in a region of tissue where deoxygenated blood is being replaced with oxygenated blood, the magnetic properties of the tissue are changing. In the brain, such a change may be triggered by increased blood flow to a region in which neuronal activity increases in response to an external stimulus (e.g. sound, light, and touch) or an internal stimulus (thinking, calculating, sending instructions to extremities, etc.). These changes can be detected and portrayed to yield a map of neuronal activity (Rosen *et al.*, 2000). The method provides information on neural activity that is complementary to contributions from PET and magnetic resonance spectroscopy (MRS) (Price *et al.*, 2002; Elas *et al.*, 2003).

As an example, in a study of potentially staggering implications, fMRI allowed researchers to determine which of several visual patterns that subjects were looking at – in effect, it allowed researchers to read the subjects' minds (Kamitani and Tong, 2005; Phan *et al.*, 2005; Faisan *et al.*, 2005).

27.8.7
MR Spectroscopy (MRS)

A proton on a molecule other than water resonates at a slightly different NMR frequency. This happens because the pattern of electron flow in its vicinity is not the same, and this leads to a slight difference in the local magnetic field that the proton experiences. This *chemical shift*,

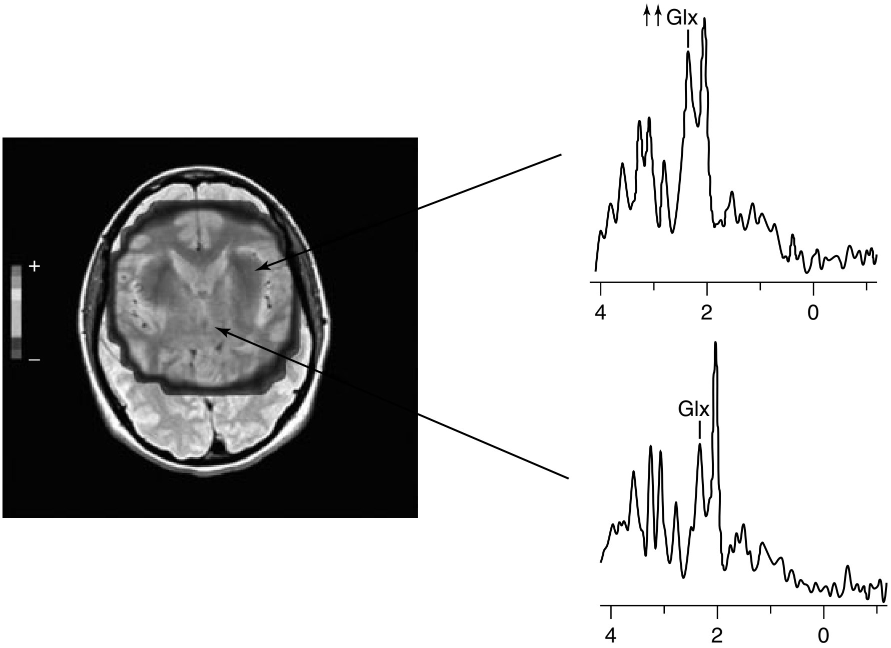

Fig. 27.29 Chemical shift/MR spectroscopic imaging (1000/18; bandwidth, 1000 Hz; 512 points acquired with two signals acquired). Transverse short echo-time chemical shift image (left) acquired at 0.5 T in a presymptomatic patient with Huntington disease shows strong elevation of glutamate (right: upper spectrum) in the head of the putamen. Unaffected thalamus (right: lower spectrum) is shown for comparison. (Image courtesy of Robert Prost, PhD, Medical College of Wisconsin, Milwaukee, WI.) (Please find a color version of this figure on the color plates.)

which is typically on the order of parts per million and increases with the strength of the external magnetic field, B_0, makes possible *MRS*. MRS can elucidate chemical processes occurring in small volumes of tissue, and is clinically proving effective in distinguishing among various forms of metastatic and benign tumors (Fayed and Modrego, 2005).

As with fusion PET/CT, MRS can be combined with high-resolution MRI to enhance sensitivity and specificity in the detection and identification of cancers and other abnormalities (Figure 27.29). And MRS of carbon-13, fluorine-19, and phosphorus-31 (rather than hydrogen-1) is also providing valuable insights into cellular metabolism and biochemistry (Stanley, 2002).

27.8.8
Higher Magnetic Fields

An area of considerable interest is the performance of MRI at higher magnetic fields ($\geq$3.0 T). As indicated by the Boltzmann factor, the magnetization in each voxel increases nearly linearly with the strength of the external magnetic field, B_0. As a result, the NMR signal strength and the signal-to-noise ratio also increase with magnetic field strength. The absolute amount of the chemical shift is also proportional to B_0, which can help to untangle messy spectra. The T1 relaxation times also may increase, and this may contribute to enhanced image contrast. The biophysical effects of operating at high magnetic fields are not well known yet, however. Also, stronger magnets are more costly.

27.8.9
Risks from MRI

MRI does not use ionizing radiation, and the absence of radiation dose to patient and staff is commonly touted as a significant plus. The effects on tissues of intense static magnetic fields, and of rapidly switched gradient fields and RF power, have been studied extensively. The Food and Drug Administration and various advisory bodies publish recommendations for limiting the principal magnetic field, the rate of switching gradient fields, RF power levels, and so on, which are thought to provide reasonable patient protection. None of these processes in and of themselves appear to pose serious risks to patients or staff under current clinical conditions when standard operational guidelines are followed.

Many new imagers use a field strength of 3 T, and a few even higher than that. The power of the pulsed RF fields is increasing, moreover, as are the strength and switching speeds of gradient fields. Studies of the long-term biologic effects of these changes continue, but meanwhile it clearly makes sense to exercise caution, especially in examining pregnant women, small infants, and patients on life support systems.

The most immediate and obvious source of danger is the principal magnetic field employed in MRI. The field is extremely strong, fills a large volume, and extends some distance beyond the bore. It can exert forces powerful enough to sling-shot a screwdriver into the magnet, or drag in an oxygen bottle or i.v. pole. Untrained personnel – housekeeping, maintenance, security, police, firemen, parents, non-MRI physicians, and other medical staff – may inadvertently bring clipboards, buckets, vacuum cleaners, scissors, car keys, or whatever into the vicinity of the magnet. If those objects have ferromagnetic parts, in an instant they can turn into lethal projectiles.

Patients or anyone else within whom there are aneurysm clips, shrapnel, or other metallic items should normally come nowhere near an MRI device until the objects are determined to be nonferromagnetic and safe. There is need for caution in examining patients with some types of surgical pins, metallic intrauterine devices, cochlear implants, and heart valves.

Another hazard is posed by the pulsed RF fields and rapidly switching gradients. Most importantly, they can disrupt the operation of cardiac pacemakers and other electronic devices.

Under some conditions, they can also induce currents that heat electrode wires or other metal objects on or within the patient, and this heating can lead to severe (albeit localized) burns. And for some pulse sequences and in tissues at certain positions within the bore, they can produce noticeable sensations even with no wires or other things present.

An MRI device can wipe out magnetic credit cards, watches, and certain medical electronic gear. It also is necessary to shield from the magnetic fields and RF noise produced by passing trucks and elevators and even flickering fluorescent lights. The RF problem can be solved through construction of a Faraday cage, a wire-mesh or solid metal panel enclosure around the patient (and RF coil) area. The MRI magnetic fields can be confined, and other fields excluded, with steel plates either in close proximity to the magnet or in the walls of the imaging room.

The objective is to prevent accidents related to magnetic or RF fields before they occur. Accomplishing this objective requires posting highly visible or audible warnings of the hazards; providing training for those who may be coming in and out of the facility or caring for patients; and, most importantly, establishing a system for scrutinizing all individuals seeking to gain entry to the device area, and enforcing appropriate restrictions on site access, even during an emergency.

27.8.10
Recent Developments in MRI

The ability of MR to provide flexible imaging parameters, and thereby images that demonstrate differences in a variety of tissue properties, surpasses that of any other imaging method. This capacity, together with the superb contrast differentiation among soft tissues, makes MRI a superb imaging modality with applications that are still evolving.

There is a wide range of variations and refinements in the general approach to signal generation, acquisition, and localization that permit MRI images to provide an ever-expanding range of information. Images can be presented for different slice thicknesses and at any desired orientations throughout the body. They can be designed to display information about hydrogen-atom (water or fat) concentrations, and about variations in T1 and T2 among tissues. A major objective of MR researchers and manufacturers has long been to reduce image-acquisition time without loss of image quality (Nitz, 2002; Jahng, Stables and Ebel, 2005). Obtaining signals from multiple RF coils simultaneously, a process known as *parallel imaging*, substantially reduces the number of phase-encoding pulses required and, therefore, the scan time (van den Brink *et al.*, 2003).

MRI is a vibrantly evolving technology, and its influence on clinical medicine and patient care continues to expand. It can be argued that the increasing flexibility, wider applications, declining costs, more subtly nuanced pulse sequences, and growing magnetic field strength (i.e. the increase from 1.5 to 3.0 T) of MRI, as well as the associated improvement in signal-to-noise ratio (Hu and Norris, 2004; Okada *et al.*, 2005), are placing the technology in a position to displace many of the applications of CT, PET, and conventional angiographic methods over the coming decade.

27.8.11
Electron Resonance Imaging

Electron-spin resonance (*ESR*) imaging, also known as *electron paramagnetic resonance* (*EPR*) imaging, is analogous to MRI, but involves stimulated and relaxation spin transitions of unpaired electrons rather than of unpaired protons (Elas *et al.*, 2003; Berliner, 2003). Since an electron is three orders of magnitude lighter than a proton, it has a correspondingly greater magnetic moment and higher Larmor frequency. At 1 T, an electron's MR occurs at 28 GHz, rather than at 42 MHz for a proton (1 GHz = 1000 MHz).

Microwave energy tends to be strongly absorbed in the process of excitation of rotational states in water – indeed, that is how microwave heating works – and at gigahertz frequencies, microwaves are absorbed in a millimeter or so of skin. At considerably lower resonance frequencies and field strengths (e.g. 0.01–0.04 T), however, the improved penetration permits imaging of free radicals *in vivo* in small animals. A variation on the theme, known as *proton–electron double resonance imaging* (*PEDRI*) involves the simultaneous performance of electron and nuclear MRI (Figure 27.30) (Liebgott *et al.*, 2003).

27.9
Laser Optical Imaging

The properties of visible and near-visible light transmitted through regions of the body have long intrigued scientists.

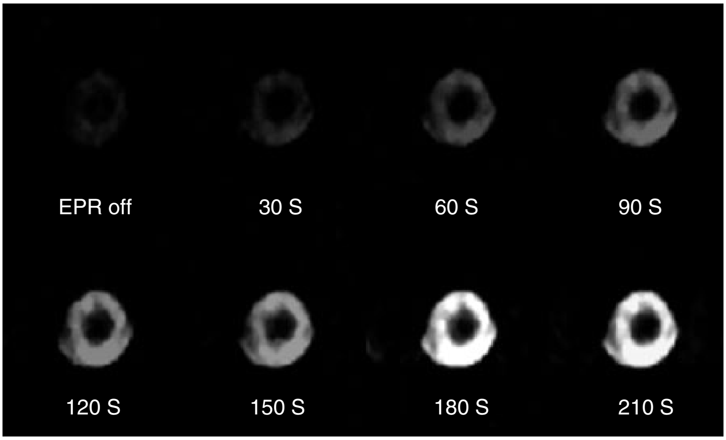
In the 1980s, interest surfaced in the use of transmitted light to image the female breast as a screening method for cancer. *Diaphanography* (*transillumination*) is the medical counterpart to shining a bright flashlight through the hand to display the bones. As with X-rays, beams of visible and near-IR light are differentially attenuated as they pass through different parts of a breast, and their shadows can be recorded as images on film or with an electronic camera. Transillumination of the breast can sometimes help distinguish benign from malignant masses – but this modality produces more false-positive and false-negative results than do conventional mammography and US, and it has not been accepted as a standard clinical tool.

The clinical utility of optical methods depends largely on the ability to extract image information about objects embedded in turbid media, so there have been serious efforts to reduce the level of scatter radiation reaching the image receptor. Improvements both in *time-resolved spectroscopy* techniques and in the theory of photon transport in tissues have contributed to advances in the field. One family of time-resolved spectroscopy methods, for example, employs gated detectors that are so fast that, following an extremely short laser pulse, only unscattered photons (which travel directly from source to detector and arrive first) are accepted. This approach can display tumors and other abnormalities by recording light transmission as a laser is stepped through a region of interest – a much more refined version of diaphanography.

Laser optical tomography or, for one particular application, tomographic laser mammography, yields cross-sectional images of tissue obtained by projecting laser beams inward from many directions. These images are useful in studies of blood perfusion, tissue oxygenation, and neovascularity in the brain, breast, and extremities.

In one interesting variation on this idea, *photographic acoustic (photoacoustic) tomography* exploits absorption differences among various tissues for laser light pulsed at megahertz frequencies. The pulses heat up and thermally expand small regions of tissue extremely rapidly, thereby producing ultrasonic waves that can be detected by sensitive piezoelectric receptors.

With a somewhat different approach, *confocal scanning laser tomography* can noninvasively acquire three-dimensional images of the posterior segment of the eye, creating a quantitative description of



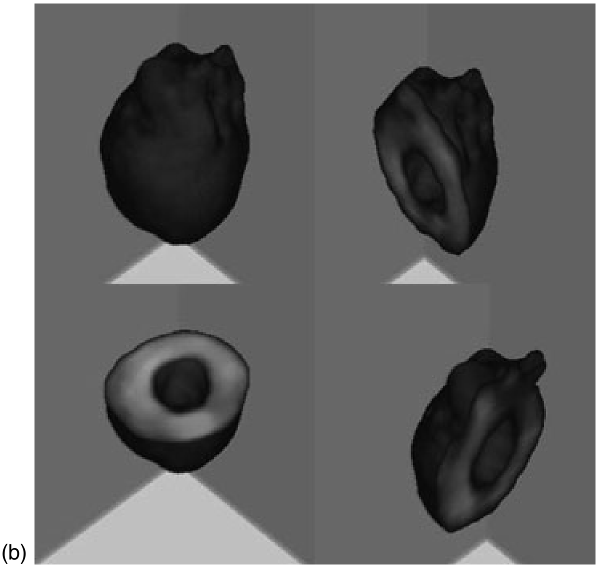


Fig. 27.30 Proton–electron double resonance imaging (PEDRI); also known as *Overhauser imaging*. (a) Time course of PEDRI study of myocardial uptake of free radical probe TEMPONE (4-oxo-2,2,6,6-tetramethylpiperidine-1-oxyl) by isolated perfused rat heart. TEMPONE as infused through a side arm proximal to the perfusion cannula at final concentration of about 3 mol l^{-1}. Two-dimensional PEDRI sections were then sequentially acquired every 30 seconds, with each scan taking 27 seconds. At low field strength of 0.02 T, the electron-spin resonance and nuclear MR frequencies are 567 MHz and 856 kHz, respectively, and an Overhauser enhancement of −13 was achieved. (b) Three-dimensional gradient-echo PEDRI images of isolated beating rat heart infused with 3 mol l^{-1} TEMPONE. Top left image shows complete three-dimensional surface-rendered image; the other images are cutaways to show internal structure. The image took 4 minutes 30 seconds to acquire at 0.02 T. (Images courtesy of Haihong Li and Jay Zweier, MD, Davis Heart and Lung Research Institute, Ohio State University, Columbus, Ohio.)

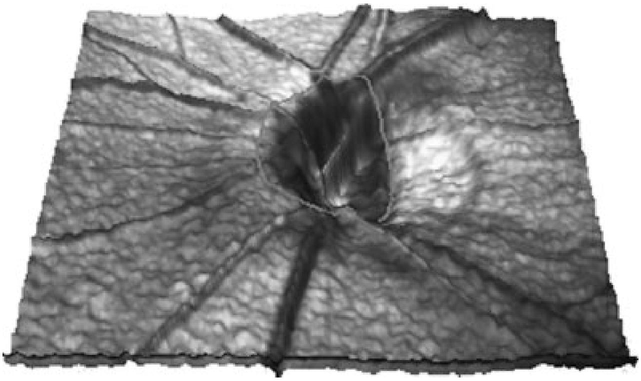

Fig. 27.31 Confocal scanning laser tomographic image of posterior segment of the eye shows topography of optic nerve head and of surrounding retinal surface in three dimensions. In less than 2 seconds, the 670-nm laser performed a sequence of 64 scans of the retina over a 15°–15° field, creating 64 386–386-pixel planar images out of light reflected from different depths. The shape of the edge of the indentation edge, emphasized by the drawn line, indicates nerve fiber layer defect at the rim of the optic nerve head. (Image courtesy of Heidelberg Engineering GmbH, Dossenheim, Germany.)

the optic nerve head and the surrounding retinal surface (Figure 27.31). A laser beam is focused to some depth within the eye and scans a two-dimensional plane. Only light from that focal plane is allowed to reach the detector. A sequence of such two-dimensional optical planar views is acquired for increasing depths of the focal plane, and the result can be displayed as a three-dimensional topographic image of the optic nerve head and peripapillary retinal nerve fiber layer. The approach is useful not only for detecting abnormalities directly but also for tracking subtle changes over time that would be difficult to detect clinically. A recent study suggests that, with expert interpretation, the power of the technique as an aid in the diagnosis and management of glaucoma is comparable to that of the accepted standard of stereofundus photography (Zangwill *et al.*, 2004).

Optical techniques such as optical coherence tomography and phase-resolved microscopy permit real-time micrometer-scale imaging and very sensitive display of cellular dynamics to depths of several millimeters in tissue. In *optical coherence tomography*, a thin beam of pulsed optical or IR laser light passes into an interferometer, one arm of which is directed at tissue through an optical fiber, which is, perhaps, part of an endoscope (Yu *et al.*, 2003). Light that scatters coherently in the top few millimeters of tissue contains information not only on the relative absorption of the radiation but also on changes in the light's phase. Scattered radiation returning from the tissue is caused to interfere with light from the reference arm, so that the phase shifts and degree of absorption can be measured. When such interference data are obtained for a 1024 × 1024-pixel matrix imposed on the tissue surface, the system can form 1-megapixel cross-sectional images in real time. Since the time of arrival of the scattered photons at the detector depends on the depth of the scatterer within the tissue, different levels in the tissue can be examined separately. Penetration is only several millimeters, but resolution can be 10 μm or better. Combination of the images with spectroscopic information can provide even more detail about the tissue for possible use as an optical biopsy.

Diffuse optical tomography provides measurements of hemodynamics and neural activation at depths of several centimeters in tissue. *Nonlinear microscopy*, which employs nonlinear optical methods such as mutiphoton molecular excitation, optical harmonic generation, and depletion of stimulated emission, can image subcellular morphology and trace molecular dynamics at subnanometer resolution at depths of up to a fraction of a millimeter in living tissue.

Tissue is nearly opaque throughout most of the IR, visible, and ultraviolet parts of the EM spectrum. One way to deal with this challenge is to use a very intense laser beam, as in diaphanography. Another is to take advantage of a narrow window of transparency in the near-IR region, with wavelengths in the 700–900 nm range. An important set of applications makes use of the fact that oxygenated and deoxygenated hemoglobin both absorb these wavelengths well but have spectra that differ enough to allow distinction between the two species. This distinction can be important in studies of blood flow and oxygen consumption. Each year, one million women undergo core-needle breast biopsy in the United States. While considerably easier on the patient than excisional biopsy, the core-needle technique suffers from a false-negative rate of up to 7%, despite needle guidance with X-ray fluoroscopy or US. But a more sophisticated probe currently under development may substantially reduce the false-negative rate (Breslin *et al.*, 2004; Lubawy and Ramanujam, 2004). After the probe has been guided to the tumor site within the breast, it transmits near-IR laser light into the breast tissue, and then senses the light coming back from it. The spectrum of the light returning from a tumor may differ from that from normal tissue because of irregularities in the degree of oxygenation, fluorescence characteristics, or other properties. In cases where no difference is detected, the tip of the probe can be repositioned to further search for disease. On finding tissue that yields a difference in returning light, the probe is used to acquire a core biopsy specimen. Unlike mammograms, the laser probe works well in dense tissue, such as in the breasts of young women, and may find applications in other organ systems as well.

27.10
Cellular and Molecular Imaging

Molecular imaging is the minimally invasive *in vivo* sensing, depiction, and characterization of spatially localized biologic processes at the cellular and molecular levels (Britz-Cunningham and Adelstein, 2003; Schultz *et al.*, 2004; Michalet, Bentolila and Weiss, 2006). Having evolved out of conventional nuclear medicine and still largely in a preclinical stage, molecular imaging now represents “the convergence of multiple image-capture techniques, basic cell/molecular biology, chemistry, medicine, pharmacology, medical physics, biomathematics, and bioinformatics into a new imaging paradigm'' (Massoud and Gambhir, 2003).

The development of molecular imaging is attributable, in part, to the synthesis of novel molecular agents that attach with high specificity to genes, proteins, and other biomolecular targets and that can then be detected with various imaging modalities (Schultz *et al.*, 2004). Among the agents are those that are activated only in response to particular changes in the local biochemical environment, such as specific gene expression or enzyme activity (Allen and Meade, 2004; Shah and Weissleder, 2005).

Molecular imaging is being driven also by the design of micro-CT, micro-MR, micro-PET, optical bioluminescence, fluorescence molecular tomography, and other methods for the study of small laboratory animals (Figure 27.32). In general, the corresponding clinical machines designed for 70-kg humans are scaled down, often with improved image quality and almost always at substantially reduced cost. The image receptor for micro-CT, for example, can be a commercially available ''off-the-shelf'' CCD (Wang, Zhao and Yu, 2005; Schelbert, Inubushi and Ross, 2003).

Molecular imaging technology – indeed, the whole field of biophotonics – is undergoing leaps in sophistication (Vo-Dinh, 2003). In addition to the new pharmaceuticals, imaging techniques, and methods for therapeutic monitoring, there are numerous recent reports on the monitoring or imaging of exogenous gene delivery and expression, protein–protein interactions, apoptosis as a predictor of therapeutic response, tumor growth, dopamine and serotonin neurotransmission, and much else. Also being studied are the dependence of absorption, scatter, and fluorescence of various wavelengths of light by tissues that may reflect the cellular integrity, matrix materials, and vasculature, all of which may depend on the patient's age, gender, state of health and other characteristics.

Fluorescent lifetime imaging microscopy, for example, exploits the dependence of the fluorescence decay time on tissue type to help identify abnormalities (Godavarty, Sevick-Muraca and Eppstein, 2005). Another approach makes use of *quantum dots* (*qdots*), which are fluorescent semiconductor nanocrystals (Gao *et al.*, 2004; Michalet *et al.*, 2005; Morgan, English and Chen, 2005). At nanometer sizes, a system begins to act somewhat like a large molecule or a set of interacting large molecules, with quantum mechanical properties quite different from those of a bulk piece of the same crystalline or amorphous material. Because of quantum confinement effects, the narrow, laser-stimulated emission spectra of quantum dots depend on their sizes, which can be precisely controlled during synthesis. When qdots emitting various colors are conjugated to antibodies, antibiotics, or other recognition molecules and are then injected intravenously, they can help detect and map out a number of specific cellular markers of diseased tissues simultaneously – a form of *in vivo* multiplexed optical biopsy. Also, MRI, PET, and CT contrast agents can be grafted onto their surface so that they, too, can provide molecular imaging diagnostics. It may even be possible to attach therapeutic agents to quantum dots, which could be activated once in proper position.

Considerable numbers and varieties of molecular imaging systems are being investigated and, as with any new

field, are undergoing rapid growth. Few are similar to one another in design. A plethora of recent publications describe these systems, including a recent issue of *Medical Physics* that contains abstracts from a major symposium on the subject (Medical Imaging Research Symposium, 2003). Topics include, in addition to the ones discussed above, diffuse optical tomography (Choe *et al.*, 2005); fluorescence resonance energy transfer, Fourier transform IR spectroscopy, autofluorescence imaging, hyperspectral imaging, video capillaroscopy, and others.

27.11
Emission Imaging

27.11.1
Electrical Source Imaging: Electrocardiography and Electroencephalography

The normal movement of ions within and between active nerve or muscle cells gives rise to weak, transient electric and magnetic fields that can extend to the surface of the body and beyond.

A general approach, *electrical source imaging* (*ESI*), has been devised to detect, and perhaps create images from, faint electrical fields with devices positioned external to the body. This method is termed *electrocardiography* (*ECG, EKG*) when applied to the heart and *EEG* for studies of the brain.

To map the surface potential on the scalp with reasonable resolution requires 20 or more electrodes, and 200 or more are needed for the torso. At present, sites of intense electrical activity in the heart and brain can be localized by image reconstruction techniques; the shapes of the voltage pulses as they change over time can also be clinically informative. Arrays of many electrodes spread over an area of the patient may eventually succeed in generating useful information in image form as well. One major problem is the rapid attenuation of electric signals in the body, so that those that do reach the electrodes are very weak and difficult to extract from background electrical noise.

ECG and EEG signals may be indicative of arrhythmias in the heart or epileptic foci in the brain. Attempts to identify more than a few sites of electrical activity are hampered by difficulties encountered with inverse computation of the origin from field measurements. Also, electrical fields are rapidly attenuated in tissue, so the fields reaching the surface are very weak.

27.11.2
Tissue Electrical Impedance Tomography

Although not exactly a form of ESI, the related discipline of tissue *electrical impedance tomography* (*EIT*) is receiving considerable research attention.

Electrons and ions in the fluids in and between cells can move about, to a greater or lesser extent, in response to an applied electric field. The standard measure of the resistance of tissue to this movement of electrons and ions is referred to as the tissue's *electrical impedance*. To assess the impedance (Z) of tissues in a region, numerous electrodes are attached to the skin, low voltages (V) are applied between pairs of electrodes, and the electrical currents (I) produced are assessed. Ohm's law ($Z = V/I$) then yields the impedance. After many such measurements have been obtained, EIT uses CT-like reconstruction calculations to generate three-dimensional maps of tissue impedance throughout the region (Poplack *et al.*, 2004; Grimnes and Martinsen, 2000; Ireland *et al.*, 2004). It is also possible to measure differences in the dielectric constant of the tissues, which is the reason why the method is referred to as impedance, rather than resistance, tomography. Spatial resolution is limited by the finite number of electrodes that can be fitted in place.

Two serious complications in impedance imaging are that only a relatively small number of electrodes can be fitted onto a given surface area, and that electric currents (unlike X-rays) do not follow straight lines. On the other hand, electric impedance tomography is safe, and can be used at the bedside, allows for long-term data acquisition, costs little, and images a new physiologic function that may turn out to be uniquely revealing for some disorders.

A*pplied potential tomography* (*APT*) is a closely related alternative for data acquisition. Voltages are applied at two points on the skin, and the resultant voltages are measured at other points on it. This process is repeated for the other pairs of electrodes. Another approach being explored is to place the region of interest in a strong magnetic field, after which passage of a high-frequency alternating current between electrodes generates a detectable US signal.

APT has been applied to the study of physiological processes such as gastric emptying, pulmonary ventilation, cardiac output, and blood flow in the thorax, head and extremities, and temperature changes during microwave hyperthermia treatments. Like MRI, tissue impedance imaging is sensitive to changes in the water content of tissues. Indeed, tissue impedance imaging is being developed by the military to monitor blood loss from wounded soldiers. Other applications include studies of gastric emptying, pulmonary ventilation, cardiac output, blood flow, and intracranial hemorrhaging in infants. Since malignant tumor tissue may be an order of magnitude or so more conductive than surrounding normal tissue, instruments have been built to facilitate the assessment of ambiguous breast masses.

27.11.3
Magnetic Source Imaging: Magnetoencephalography and Magnetocardiography

Like any other electrical currents, those within and between neurons and muscle cells generate weak magnetic fields. *Magnetoencephalography* (*MEG*) and *MCG* are similar to EEG and ECG except that they are used to detect and monitor the varying weak magnetic (rather than electric) fields produced in this fashion (Wheless *et al.*, 2004; Lesser, 2004; Barkley, 2004; Baumgartner, 2004). MEG measures the magnetic fields with detectors positioned around the head and back-calculates the locations and strengths of the neural currents that gave rise to the fields. These fields are about one billionth (10^{-9}) as strong as that of the Earth, so near-perfect magnetic shielding and highly sensitive detectors are required. Fortunately, the exquisitely sensitive *superconducting quantum interference device* (*SQUID*) fills the bill nicely: It is responsive enough to detect the movements of a refrigerator-door magnet a quarter mile away.

With millimeter and millisecond spatial and temporal resolutions, MEG demonstrates neural activity directly, as

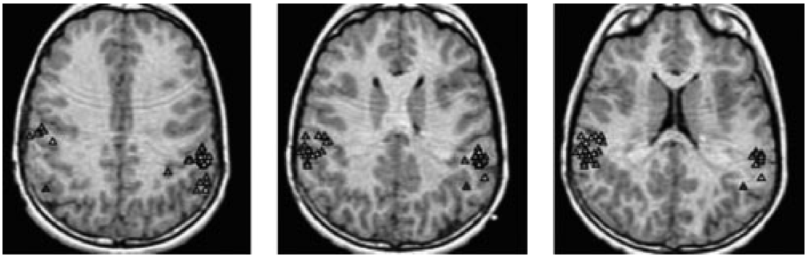

Fig. 27.33 Magnetoencephalographic spatial information superimposed on transverse T1-weighted MR sections (13/4.47). Magnetoencephalographic spike activity (*D*) in a 10-year-old patient with Landau–Kleffner syndrome. (Image courtesy of M. Funke, MD, PhD, Center for Advanced Medical Technologies, University of Utah, Salt Lake City, Utah.)

it takes place. fMRI and PET provide indirect assessments of brain function and they show only relatively slow variations, over seconds or even minutes, in metabolic activity. Unlike electrical fields, magnetic fields are transmitted through tissue with little attenuation or distortion, so magnetic source imaging (MSI) images tend to contain less noise or distortion. A major weakness of MSI, however, is that any magnetic field distribution on the surface of the body can be explained by an infinite variety of current distributions inside the body. This limitation is known as the *inverse computational problem*, and has a counterpart in ESI. Successful application of MSI (and ESI) usually requires prior knowledge of the object, such as the underlying anatomy, as obtained by MRI or X-ray CT.

MEG and MCG have already proven their clinical worth in noninvasive studies of well-localized sites of intense neuronal activity. Applications of MCG include identification of the origin of cardiac arrhythmias, and the guidance of a catheter directly to the site for treatment. MEG tracks the much weak magnetic field changes that accompany epileptic activity in the brain, migraine headache, and diabetic coma, and can detect functional areas of the brain that must be preserved during surgery (Figure 27.33). Like PET and fMRI, it can follow the brain's response to stimuli. It can be used to demonstrate subtle abnormalities in a region of the brain that appears to be structurally and physiologically normal when viewed with the aid of other modalities (Georgopoulos *et al.*, 2007).

On a different note: Under exploration as an alternative to electroshock therapy is the converse process of magnetic nerve stimulation, in which a pulse of electric current flow is generated in a well-localized region of the brain by rapidly changing the field from a powerful external magnet (Hallett and Chokoverty, 2005).

27.11.4
Infrared (IR) Thermography

The warmer something is, the more heat it emits, at a rate that is approximately proportional to the fourth power of the absolute temperature (i.e. approximately T^4). At room temperature, a body radiates EM energy that peaks in the IR region. Since IR radiation travels through soft tissues for distances only of about one wavelength (~0.01 mm), the emission rate depends on skin temperature. But skin temperature, and the local IR radiation intensity, may be influenced by disease conditions that lead to changes in superficial blood perfusion.

With one type of *radiative IR thermography* camera, a detector such as InSb (with short-wavelength IR sensitivity) or HgCdTe (long-wavelength IR) cooled to liquid-N_2 temperature scans a region of skin surface by means of a rotating prism and lens. It can operate at up to 25 frames per second, so that essentially real-time IR thermography is possible.

IR thermography has explored the angiogenesis and neovascularity that accompany breast disease, inflammatory conditions such as rheumatoid arthritis in joints, flow disturbances in blood vessels, injured muscles, diminished enervation of muscles, burns, and frostbite (Diamantopoulos, 2003).

27.11.5
Microwave Imaging

Room temperature objects also radiate energy in the microwave region, although at an intensity about 10 orders of magnitude less than that of IR radiation. Still, spontaneously emitted microwave radiation has imaging possibilities because it is more penetrating than IR, so that it can reach the skin surface from greater depths. The much longer wavelength of microwave, however, places a fundamental limitation on the spatial resolution achievable. For microwave radiation at 2 GHz, for example, the resolution and penetration depth in muscle are each about 1 cm, and the corresponding value for fat is closer to 10 cm (Newhouse, 1993). Also, because of its much lower intensity, microwave radiation data-acquisition times are considerably longer.

Microwave imaging is particularly sensitive to differences in absorption between fat and other soft tissues. The wavelength is too long to allow the degree of spatial resolution normally required for diagnostic imaging, but microwave devices may find other applications (Poplack *et al.*, 2004; Ciocan and Jiang, 2004). For example, promising preliminary clinical studies have been reported for a small device called a tissue resonance interferometer. This device generates low levels (less than that of a cell phone) of 400–1350 MHz radiation, and the returning signal may be altered by tissue irregularities, including tumors.

27.11.6
Acoustothermometry

Objects above absolute zero emit sound radiation that is described as *ultrasonic thermal noise*. The sound energy is emitted at very low intensity (e.g. 10^{-16} W cm^{-2} over a 100 kHz band at room temperature), and long data-acquisition times are required. An acoustothermometer that measures temperatures to an accuracy of 0.2 °C at depths of up to 10 cm in tissue with data-acquisition times of 30 seconds, for example, has been described (Godik and Gulyaev, 1991). Acoustothermometry has been proposed as a monitoring technique for hyperthermia treatment of tumors (Newhouse, 1993).

27.11.7
Terahertz Imaging

The terahertz portion of the EM spectrum lies between 300 and 100 mm in

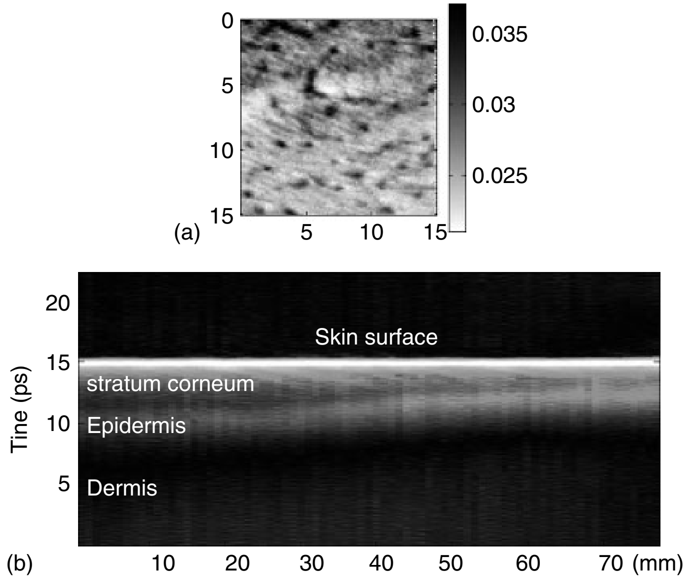

Fig. 27.34 Terahertz imaging. (a) *In vivo* terahertz image of volunteer's forearm acquired by using a handheld terahertz imaging system. The image shows a 15 × 15-mm region; a scar running from left to right can be seen in the top half of the image. The image was generated by plotting the electric field value reflected from beneath the skin surface. Dark circular regions are hair follicles of normal skin, which are not present at the scar. (b) Axial terahertz image (b scan) of edge of volunteer's hand. Gray scale indicates signal amplitude, which is plotted against optical delay (*y* axis) and position across the scanned area (*x* axis). Decrease in stratum corneum thickness across the *x* axis, from the palm-side (30 mm on *x* axis) to the backside (70 mm) of the hand, is evident. (Image courtesy of Vincent Wallace, PhD, TeraView Ltd, Cambridge, England.)

wavelength. The so-called terahertz rays, or T-rays, do not penetrate water or tissue well, so they would be of little use in examining deep-seated tissues. A substantial fraction of cancers lie in the epithelium, however, and while many of these are readily apparent to the trained eye, some that are small and flat can be overlooked or are simply not visible. Standard modalities are not adept at depicting or characterizing epithelial tumors – but *terahertz imaging,* because of the ability to recognize the spectral fingerprints of surface proteins that are markers for certain cancers, seems capable of detecting them at an early stage, when they can still be treated effectively (Figure 27.34). Terahertz rays are nonionizing and offer imaging resolution of less than a millimeter; the equipment is safe and portable. But there are major difficulties with terahertz sensing and imaging systems, including their inefficiency and high cost of production. However, recently created photonic band-gap materials may soon change that situation (Poplack *et al.*, 2004; Walker *et al.*, 2004; Wang and Mittleman, 2004).

27.12
Mini- and Nanotechnology

Small-scale technology offers exciting possibilities for medical imaging. There already exists a disposable video camera–transmitter–light source combination the size of a pill that sends color images to a receiver–recorder (strapped to the waist) as it wends its way through the bowel. Compared with endoscopy, limitations of the system are related to the inability to control the position of the camera and its direction of view and battery lifetime. These challenges, however, are surmountable.

At the smaller level, quantum dots and other nanoparticles that display specific physical or chemical characteristics, such as stimulated fluorescence or paramagnetism, or objects coated with nanoparticles, may be detected with appropriate imaging technologies (Wickline and Lanza, 2003). Ceramic, metallic, and organic nanotubes, nanowires, and other structures have been the subject of intense investigation, as have been (more recently) nanostructures such as minute sensors, motors, or other electromechanical devices (which might contain biologic components). They could enter a blood vessel and be directed to an area of interest, where they could acquire and transmit images; implement enzyme-, antibody-, or genome-based biologic tests; perform biopsies; build tissue-like materials and organs; and even carry out small-scale surgeries. While some might find this all to be a bit too Star Trek-ish, others would argue that it is already happening (Thrall, 2004; Silva, 2004). The National Cancer Institute, in particular, has recently announced a 5-year, $144 million program to develop nanotechnology in cancer detection and treatment.

27.13
Roles of Computers in Medical Imaging

Since it began playing a significant role in imaging four decades ago, the computer has made its presence felt primarily in image acquisition and processing, and through its tools to enhance contrast, sharpen edges, and reduce noise (Barrett and Myers, 2004; Bankman, 2000; Sonka and Fitzpatrick, 2000). But it appears that now and in the near future, there will be an increasing focus on faster, greater-capacity, and more reliable image communication, archiving, retrieval, and interpretation capabilities – that is, the development of ways to ‘‘tame the raging beast’’ of information overload in health care. (Berner, Detmer and Simborg, 2005; Blackmore, 2005; Morris *et al.*, 2005; Andriole, 2006). The PACS, as noted earlier, is a powerful starting point for helping all these to happen, especially as it becomes increasingly interconnected with the RIS, HIS, and the Web.

The advantages of placing all patient-related information onto Web-based interoperable data sets that link physicians, hospital medical records, and laboratories may seem self-evident. For most clinics and medical centers, however, this idea remains a distant dream. The health care industry invests only 2% of its gross revenues in information technology, compared with other information-intensive industries (e.g. finance, utilities, and communications), which typically spend about 10% (IT in the healthcare industry, 2005; Bates and Gawande, 2003). Furthermore, clinical information technology systems that exist often cannot readily connect with one another. The impact of miscommunication and misinformation on patient safety is a huge, closely related issue. The Institute of Medicine has estimated that 44 000–98 000 people die annually because of medical errors in the United States, making this the eighth leading cause of death, ahead of acquired immunodeficiency syndrome and breast cancer.

27.13.1
Medical Image Informatics

The amount of visual and other medical data being generated at the levels of molecules and cells, tissues and organs, and individuals and communities is populating huge databases at an ever-increasing and alarming rate. The relatively young discipline of biomedical informatics is beginning to provide tools to search for, identify, select, retrieve, integrate, analyze, model, display, store, communicate, and manipulate all these information (Berner, Detmer and Simborg, 2005; Blackmore 2005; Morris *et al.*, 2005; Andriole, 2006).

Biomedical informatics is perhaps best known for its successes in untangling the vast quantities of data coming from work on the genome. It may well come to play just as important a role in the clinic, such as in attempting to keep a cap on the impending CT slice-overload crisis. CT already produces hundreds of slices per patient, and that is bound to increase (256-slice machines are in the prototype stage), along with the swelling numbers of CT patients. Researchers in the field will continue to develop ways to integrate and scan effectively through the databases needed for clinical care, as they grow in size and complexity.

There are related applications, such as when there occurs a crisis on a spaceship halfway to Mars, or after detonation of a nuclear weapon in a city, where rapid access to the right essential medical information would prove to be invaluable. Here, too, effective medical informatics could make the difference between proper management of the situation and utter chaos.

27.13.2
Image Interpretation by Means of Computer-Aided Detection and Diagnosis

Interpretation of medical images is a complex process that is as much art and acquired intuition as science, and it requires years of training, much of which is provided in the "master and apprentice" style. Computers, on the other hand, excel at highly analytic jobs that involve logic and memory, such as playing chess or calculating just about anything; but even the most clever of them has great difficulty with even the most elementary tasks of everyday life that happen to require judgment or common sense, such as recognizing a face with a new beard or distinguishing a liver with a small lesion from one that is normal but just looks odd.

Still, there have been great strides in machine learning. Neural network algorithms and other species of computer program, for example, can improve their success rate at performing certain tasks by "learning" from past experiences; that is, they use feedback information from humans to build decision rules based on the successes and failures of past decisions.

Machine learning, pattern recognition, and statistical inference programs begin with the detection and characterization of a point, a straight line, or a circle on a blank background. Programs that search for irregularities in mammograms, chest CT sections, texture in US scans of the liver, and other images are greatly more complex and sophisticated, but the basic concepts are much the same. By comparing their analyses to databases compiled from a large number of normal and abnormal images, *CAD* systems can find and draw attention to questionable regions in an image. And a more highly evolved *CAD*x program can even provide a statistical-based tentative diagnosis to the interpreter for consideration.

Studies involving CAD have demonstrated a reduction of false negatives (missed identifications) and an increase in the accuracy of diagnosis of the typical radiologist (Doi *et al.*, 1993). Now that Medicare reimbursement is available, for example, CAD and CADx are being used routinely in many mammography clinics, with both digital and digitized images, as sharp-eyed and untiring second readers to pick out subtle cancers. Clinical successes here and in other applications are tantalizingly suggestive of even more wonderful things to come (Wagner *et al.*, 2002; Giger, Karssemeijer and Armato, 2001; Vyborny and Giger, 2002).

CADx is still a far step from the use of expert artificial-intelligence systems, however, to provide a primary diagnosis from general medical images without human intervention. Such systems would essentially have to mimic the thought processes of physicians interpreting images, including the incorporation of ancillary information such as the patient's history and data acquired by physical examination. These thought processes are largely intuitive, acquired through training and experience, and are almost impossible to articulate clearly. Indeed, complete replacement of the human interpreter of images with computer algorithms is a major challenge that, perhaps, we will be able to meet only partially in the foreseeable future. Fortunately, an expert system for image interpretation does not have to be perfect to be of value – but it must be able to function at least with the effectiveness of the average radiologist.

A voice record, like an electrocardiogram signal, may be viewed as a one-dimensional image. Likewise, verbal order-entry and real-time updating of patient charts by physicians with wireless tablet computers that incorporate dictation and transcription and error-prevention software is a kind of CAD. As many a secretary well knows, the ability of a computer to transcribe voice dictation of radiology reports automatically has undergone major advances. Radiologists in the United States dictate over 130 million reports annually, and computer-based technology reduces the costs associated with manual transcription considerably in a number of centers. Voice patterns are as distinctive as fingerprints, moreover, automatic dictation could enhance security, as well, and reduce unauthorized access of patient information.

It is not clear how quickly CAD and CADx will evolve, but a number of people involved in their development believe that the writing is on the wireless, flat-panel monitor on the wall.

27.13.3
Input of Computer Technologies from Other Fields

The National Aeronautics and Space Administration, the Defense Advanced

Research Projects Agency, the Central Intelligence Agency, the National Security Agency, and other government entities have developed highly sophisticated imaging technologies to assist astronomers in searching the heavens back to the beginning of time, to sharpen the capabilities of spy satellites, to select relevant messages out of billions of phone calls, to keep cruise missiles on track, to allow surveillance of individuals suspected of terrorism or criminal behavior, and to practice medicine in space (Fincke *et al.*, 2005). These agencies look for civilian applications of their nonclassified technologies, and they have already transferred numerous ideas and equipment designs to medicine.

Similarly, much of the technology that makes modern clinical imaging so vibrant and flexible was introduced first in the entertainment and communications industries for applications such as video games and special effects for movies and television. These technologies will evolve, and their spin-offs into medicine will continue to improve the quality and efficiency of patient care.

27.14
Radiation Treatment Planning

Cancer is characterized by an abnormally rapid proliferation of cells, initiated typically by the incorporation or activation of certain kinds of misinformation into some cells' DNA. Treatment normally involves some combination of surgery, chemotherapy, and radiation therapy, in which beams of high-energy photons or electrons from a *linear accelerator* (*linac*) are arranged with their cross-fire region centered on the lesion; in many circumstances, radiation treatments, usually delivered in separate daily sessions spread out over the course of weeks, are more effective at killing tumor cells than healthy tissues.

The successful treatment of a localized cancer with ionizing radiation requires that both the tumor and its microscopic extensions into normal tissue receive a lethal dose of ionizing radiation. At the same time, the dose to nearby normal tissues must be kept low enough to avoid serious complications. The art of the discipline is to find, for any patient, an optimal balance between these (and other) objectives (Figure 27.35). Suppose the probability $P_{\text{tumor}}(D)$ that the cancer will be controlled by killing tumor cells increases with D, the radiation dose. The probability $P_{\text{organ}}(D)$ that life-threatening or otherwise unacceptable radiation complications in a nearby critical organ can be avoided, on the other hand, is a decreasing function of D. The overall probability $P_{\text{patient}}(D)$ that the patient will survive both the disease

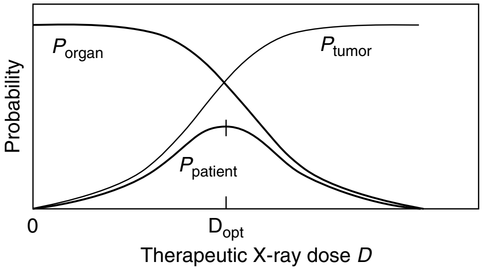

Fig. 27.35 Therapeutic outcome probabilities for cancer patients undergoing X-ray treatment, plotted schematically as functions of radiation dose D. The probability of success (P_{patient}) is the product of the probability that the tumor will be destroyed (P_{tumor}) and the probability (P_{organ}) that the treatment will not cause life-threatening damage to normal tissue.

and the treatment is (Wolbarst, Chin, and Stavrev, 2006)

$$P_{\text{patient}}(D) = P_{\text{tumor}}(D) \times P_{\text{organ}}(D) \tag{18}$$

If the tumor dose is too low, the cancer is likely to recur. At high doses, on the other hand, the therapy itself is likely to cause unacceptable complications, perhaps threatening the patient's life. Between these extremes the physician seeks to maximize the patient's survival of both the cancer and the treatment. If the radiation dose that optimizes the balance between curative treatment and complications is so high that the patient experiences extreme discomfort, or if the objective of the treatment is palliation rather than complete cure, the patient and physician may settle for a lower dose, even though the chance of surviving the cancer is reduced.

Radiation-dose optimization demands accurate delineation of the margins of the cancer and of radiosensitive organs. That, in turn, demands good medical images. Before CT and MRI, cancer localization and treatment planning depended principally upon projection radiography combined with clinical and surgical (if available) information and knowledge of the natural course of the disease. But it is frequently hard to see the cancer clearly with projection radiography, and to transcribe the essential information into a three-dimensional representation of the region of concern for designing a treatment plan, that is, for determining the orientation, relative weighting and shaping, and so on, of each of the radiation beams so as to give good coverage of the target while adequately sparing critical structures.

CT and MRI have largely overcome the problem of delineating anatomy, and PET/CT fusion machines are increasingly finding application in tumor localization; indeed, many treatment centers have a CT unit dedicated to treatment planning and monitoring. These modalities can provide a 3D picture of the patient's anatomy, which includes the site of the cancer and its immediate surroundings, the critical organs, and the body contour. The data, being in digital form, are entered immediately into the treatment-planning computer and, once an acceptable plan has been generated, it can be shipped semi-automatically to the linac controls.

Each treatment session must be carefully monitored to ensure proper setup and, in particular, correct positioning with respect to the treatment machine; when various forms of DR and flat-panel CT are used for this purpose, as is increasingly the case, the process is called *image-guided radiation therapy* (*IGRT*). Installing, managing, and monitoring are all the responsibilities of the medical physicist.

Most radiation treatments involve the use of multiple fixed radiation fields converging on the cancer from different directions. In this manner, the dose is concentrated in the cancer while much lower doses are administered to surrounding normal tissues. In some cases, a better dose distribution can be achieved by rotating the gantry of the treatment machine continually or in steps around the patient during treatment so that only the cancer is constantly in the path of the X-ray beam. One complication is that cancers are almost always asymmetrical. The size of the X-ray beam must therefore be expanded or contracted from one position of the gantry to the next, and its shape can be varied by means of *multileaf collimator*. This approach to external beam X-ray treatment is termed *conformal therapy*. The dose distribution can be improved further by simultaneously varying the dose rate. This *intensity-modulated radiation therapy* (*IMRT*) is becoming the norm at advanced centers for treatment of some forms of disease. It requires detailed three-dimensional knowledge of the anatomy of the irradiated tissue, together with exquisite computerized control of the linac.

27.15
Conclusions

Medical imaging is perhaps *the* prototypical example of "high-tech" medicine. Its successes illustrate the contributions of medical physicists and engineers working with physicians to improve the health and welfare of patients. But there is still much to be done, especially in refining the growing convergence of imaging with therapeutic techniques to cure disease and prevent the debilitating effects of injuries.

Physicists have played an instrumental role in the evolution of all branches of medical imaging. The American Association of Physicists in Medicine, a member society of the American Institute of Physics, includes over 6000 members. Graduate and postdoctoral training programs in medical physics increasingly attract bright young physicists, and among them are many of those who will bring about the advances yet to be made.

Glossary

Absorbed dose: the ionizing energy absorbed per unit mass of an irradiated material.

Active-matrix flat-panel imager (AMFPI): a solid-state semiconductor-based X-ray image receptor consisting of a matrix of hundreds of thousands or millions of separate X-ray detectors. Analogous to a CCD optical camera and used in digital radiography.

Artificial intelligence: the property of a machine capable of logical, systematic reasoning, by which it can learn functions normally associated with human intelligence.

Bremsstrahlung: the X-ray radiation (*Strahlung*) caused by the sudden "braking" (*Brems*) of electrons by a solid.

Acoustic impedance: a characteristic of a tissue, defined as $Z = (\rho/K)^{1/2}$, where ρ is its physical density and K its compressibility, a measure of its elasticity. At a boundary between two tissues, their Z values together determine the amount of reflectivity of ultrasound that will occur there.

Contrast agent: a substance placed in veins, arteries, the GI tract, and so on, that enhances the image contrast.

Characteristic X-rays: electromagnetic radiation emitted as a result of rearrangements of the electrons in the inner shells of atoms following a disruption; the spectrum consists of lines whose wavelengths depend only on the element concerned and the energy levels involved.

Charge-coupled device (CCD): a semiconductor-based electronic optical camera, comprising hundreds of thousands or millions of pixel-size photodetectors. The charges stored in the separate pixels are read out electronically row-by-row and immediately digitized.

Compton effect: scattering of a high-energy X-ray photon by an orbital electron of an atom, which is ionized in the process. A lower-energy Compton scatter photon is created, and the rest of the incident energy is transferred to the liberated electron as kinetic energy.

Computed radiography (CR): an X-ray imaging method in which a pattern of X-rays transmitted through the patient is recorded on a solid-state photostimulable phosphor (PSP) imaging plate (IP). The plate is read by a scanning laser beam that stimulates the emission of light of another color.

Computed tomography (CT): the process of producing high-contrast X-ray images of thin (usually transverse) slices of tissues within the body, with visual interference from over- and underlying tissues removed.

Digital radiography (DR): An X-ray imaging method in which a pattern of X-rays transmitted through the patient is recorded in digital form on an AMFPI, which is read in a manner similar to that of a CCD.

Doppler effect: the change in frequency of ultrasound waves reflected from a moving object.

Dynamic range: the amplitude range of signals that can be detected by an imaging system without distortion or disappearance into background noise.

Expert system: a computer system composed of algorithms that perform a specialized, usually difficult professional task at the level of (or sometimes beyond the level of) a human expert. For the basis for computer-aided detection (CAD) and computer-aided diagnosis (CADx), see *Artificial Intelligence*.

Fluoroscopy: use of an image intensifier or AMFPI to image receptor for obtaining dynamic, real-time X-ray images.

Gantry: an extended mechanical structure holding elements of an imaging system.

Image intensifier: an electronic vacuum-tube device that receives a life-sized, pale X-ray pattern from a patient and produces a bright, small-area optical image suitable for input into a TV, CCD, or other optical camera.

Intensifying screen: a luminescent panel within a screen-film cassette, in which incident X-rays cause the emission of points of light that, in turn, exposes a photographic film.

Linear attenuation coefficient: fractional rate of attenuation (by coherent scattering, the photoelectric effect, and Compton scattering events) of X-rays in an absorbing medium.

Mammography: X-ray imaging of the breast.

Modulation transfer function (MTF): a measure of the ability of an imaging system to register fine detail present in the object.

Neural network: an information-processing system that utilizes a large number of simple modules, to transmit, receive, and store digital information.

Photoelectric effect: the liberation of an inner-orbital atomic electron by a photon of electromagnetic radiation.

Pixel: the smallest area that can be displayed by a digital imaging system; a larger image is composed of many pixels.

Projection radiography: the technique of producing a common X-ray image. Transmits a uniform beam of X-rays through the body, thereby embedding an X-ray shadow in it that exposes a cassette and the photographic film within. The image results from variations in thickness, density, and chemical composition of the tissues, and depends on the effective energy of the X-ray beam.

Real-time display: a display that is able to follow changes in the object that occur at physiologic rates.

Spin–lattice relaxation: the process, parameterized by T1, by which nuclear spins (in MRI, primarily protons in tissue water molecules) that are disrupted return to their equilibrium condition lying along an external magnetic field.

Spin–spin relaxation: the process, parameterized by T2, by which nuclear spins precessing in a magnetic field exchange energy with other nuclear spins and thereby dephase.

Subtraction: temporal subtraction is a process in which the information content of two images, one obtained before and one after an intentional change (e.g. injection of contrast medium into a vein), are subtracted from one another; all that remains is the image of that which changed, with no distractions from irrelevant tissue background. Other forms of subtraction, such as with a rapid change of kVp, can serve other purposes.

Teleradiology: the transmission of digital medical images electronically over long distances.

INTRODUCTION

When a current flows through an electrical circuit, it creates a magnetic field. Inductance is the quantity that relates the energy stored in a magnetic field to the current flowing through that circuit. It defines the relationship between the voltage and current needed to add or extract energy from the magnetic field. *Inductor* is the generic name for a class of devices used for adding inductance to an electrical circuit. It covers a wide range of devices, applications, and configurations. Inductors range in size from small fractional-turn helixes having masses of several grams to devices hundreds of cubic meters in volume having masses in excess of 50 000 kg. Inductors are used as components of tuned circuits, electronic filters, magnetic energy storage devices, and measurement apparatus.

Because inductors usually comprise a number of turns or coils of conductor on a form, they are sometimes referred to as inductance coils, electric coils, or simply coils. There are other names used to describe inductors for specific applications. These include choke, choke coil, energy-storage choke, reactor, inductometer, induction coil, magnetic switch, pulsactor, and saturable reactor. A number of these will be described in detail to illustrate the distinction among different types and classes of inductors.

Inductors are classified according to their geometric configuration and whether or not a magnetic material is used to enhance the inductive effect. Inductors without magnetic materials are called air-core inductors. Those that use magnetic materials to enhance the inductive effect are referred to as iron-core inductors.

Inductors are typed according to whether or not they provide a fixed, adjustable, or variable inductance. The different classes and types are represented schematically by four different symbols as shown in Fig. 1. Combinations of these basic symbols are used to represent more complex inductor arrangements.

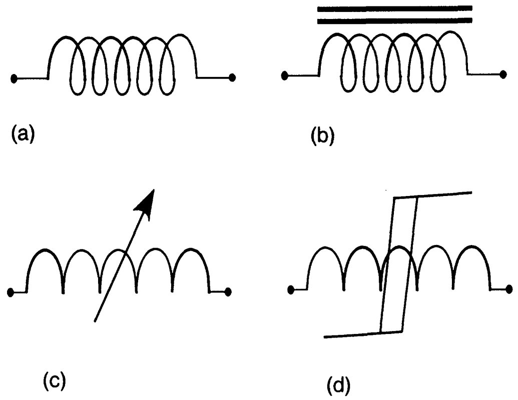

FIG. 1. Schematic symbols used to identify the different types of inductors: (a) air-core fixed inductor, (b) iron-core fixed inductor, (c) variable inductor, (d) saturating or nonlinear inductor.

The first section of this article explains the concept of inductance and the general principles and techniques used in its calculation. A historical perspective is taken to illustrate the development of different concepts and calculation procedures.

The class of air-core inductors is described and some formulas presented for the calculation of inductance. This is expanded to the more general class of linear inductors that can have iron cores but operate in the linear region. The operation of nonlinear and variable inductors is also presented.

The section on engineering aspects discusses how the electromagnetic system requirements are used in conjunction with the thermal and mechanical limitations of the available construction materials to synthesize a specific configuration. Examples of specific applications are presented in the last two sections.

1. GENERAL PRINCIPLES AND HISTORICAL PERSPECTIVE

1.1 The Concept of Inductance

In 1831 Faraday first showed that an electric current is induced in a closed circuit when the magnetic field in its vicinity is altered. This change in field could be caused by the movement of a permanent magnet in relation to the circuit or by a changing current in a neighboring electrical circuit. Lenz showed that the induced electromotive force (emf) or any current it generated in a closed circuit always acted to prevent the magnetic field linking it from changing. The amount of flux linking an electrical circuit is called the flux linkage λ. These two observations form Faraday's law:

$$\text{emf}=e=-\frac{d\lambda}{dt}. \tag{1}$$

Faraday (1839) reported that when a current flowing in a circuit was interrupted it produced an emf greater than that of the voltage source used to initiate the current. He showed that the inductive effect of a circuit on itself was part of the same phenomenon as that of a current affecting neighboring conductors. The inductive effect of a circuit on itself is called self-inductance. The inductive interaction between two or more distinct electric circuits is defined as the mutual inductance between the circuits (see TRANSFORMERS).

If the change in flux linkages is not due to a physical motion of conductors and the materials are linear, the induced emf can be related to changes in current by

$$\text{emf}=-L\frac{dI}{dt}, \tag{2a}$$

where L is the self-inductance of the circuit. For harmonic fields, Eq. (2a) becomes

$$V=j\omega LI=j(2\pi fL)I, \tag{2b}$$

where V is the magnitude of the counter emf, j is $\sqrt{(-1)}$ representing the 90° phase shift between voltage and current in phasor notation, ω is the angular frequency of the sinusoid equal to $2\pi f$, and I is the phasor current. The quantity $2\pi fL$ is known as the reactance of the inductive circuit element. The unit of inductance is a weber per ampere designated as the henry, after Joseph Henry, an American scientist and inventor. Assuming a constant inductance, Eqs. (1) and (2a) can be combined to give an equation for L in terms of λ and I:

$$L=\frac{d\lambda}{dI}, \tag{3a}$$

which, subject to linearity, is also

$$L=\lambda/I. \tag{3b}$$

The concept of flux linkages is often confusing and difficult to apply. For this reason, Maxwell (1891) preferred to explore inductance in terms of energy and geometrical functions giving an alternate definition of inductance:

$$L = 2W/I^2, \tag{4}$$

where W is the energy stored in the magnetic field as a result of the current I in the circuit. The stored magnetic energy can be related to the magnetic vector potential A. This is extremely useful in field calculations using numerical methods, such as the finite-element technique, as it allows for the direct calculation of inductance in very complicated arrangements and multicoil systems (see MAGNETOSTATICS).

Equations (2)–(4) give the same values of inductance and are useful when the surrounding media and materials are linear and there are no hysteresis, residual fluxes, or eddy-current effects. However, when these conditions are not met, using these equations interchangeably can result in serious errors. Rader and Litscher (1944) extensively treat the subject of inductance in the presence of nonlinear materials and eddy currents, giving examples showing when each formulation is appropriate.

The distinction between the formulas is illustrated in Fig. 2. Consider a nonlinear inductor operating at a current whose magnitude I is given by the length *oa* and total flux linkage is equal to length ***ab***. The linear or flux-linkage inductance L_b from Eq. (3b) is *ab/oa*. However, from Eq. (4) the inductance L_c is equal to twice the total stored energy (shaded area *obc*) divided by the square of the current. At operating point *b*, the incremental inductance L_e given by Eq. (3a) is the slope of the line *o′e′*, which is just *ae/oa*. In nonlinear circuits $L_b > L_c > L_e$, and which one is appropriate to use depends on the circuit application.

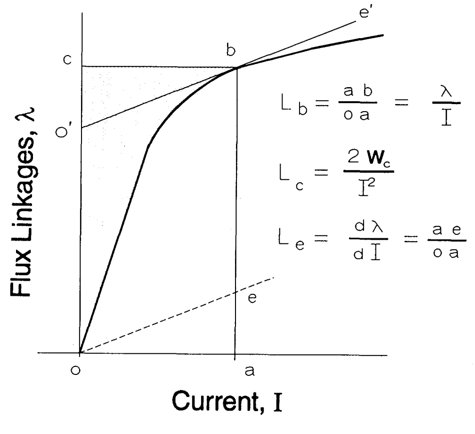

FIG. 2. Nonlinear magnetization curve illustrating how "inductance" differs depending on the selected definition and operating point.

In nonlinear devices such as saturable reactors and magnetic amplifiers the incremental inductance L_e is more appropriate. Magnetic switches are highly nonlinear, and their performance characteristics must be derived from a direct analysis of the *B-H* characteristics of the device (see related articles on MAGNETS and ENERGY CONVERSION).

1.2 Analytical Methods

The development of the concept of inductance was based on experimental observations. The defining equations are from this observational reference frame in terms of energy or voltage and current. Fundamentally, however, inductance is a measure of how an arrangement of conductors stores and exchanges electrical and magnetic energy. Therefore, it is a geometric quantity dependent on the physical arrangement of the currents and the permeability (inductive capacity) of the surrounding space.

The difficulty with magnetic materials arises because their inductive behavior is both nonlinear and hysteretic. When the surrounding space has materials that are conducting, currents are induced in them through mutual induction, and the observed inductance at the terminals is the resultant of the combined effects, making the calculation of inductance difficult.

Highly accurate formulas for inductance are available for cases where no magnetic materials, hysteresis, or eddy-current effects are present. Maxwell and his contemporaries developed exact solutions for the simple geometries comprising sheets or filaments of current. In all but the simplest cases, these formulas contained complicated inverse hyperbolic, trigonometric, and elliptic integrals. Analysis of these functions was difficult given the available tools. The approach taken was to represent the more difficult functions by rapidly converging series expansions that were then used to derive solutions for more complex geometries. Correction factors were developed to account for the fact that real inductors were made of finite-dimensioned wire with separation between turns. These complexities can best be illustrated by example.

Consider a circular loop of mean radius a, using a conductor with circular cross section of radius r. The inductance in henries with all dimensions in meters is given by

$$L=0.4\pi a[(1+r^2/8a^2)\ln(8a/r)(r^2/24a^2)$$
$$-1.75]\times 10^{-6}. \qquad (5)$$

Lorenz developed a closed formula for the inductance of a finite-length right circular cylindrical solenoid, with a current-sheet winding (infinitesimal radial thickness), in terms of elliptic integrals, given by

$$L=(3.2\pi N^2a^3/3b^2)$$
$$\times\{(2k^2-1)E/k^3$$
$$+(1-k^2)F/k^3-1\}\times 10^{-6}, \qquad (6)$$

where a is the radius of the solenoid, b is its axial length, and F and E are complete elliptic integrals of the first and second kind, respectively, and modulus $k=[4a^2/(4a^2+b^2)]^{1/2}$.

A highly accurate formula for a solenoid with a finite radial build (thickness of winding including insulation) c, length b, and mean radius a, developed by Weinstein, is given by

$$L=0.4\pi aN^2(p+s)\times 10^{-6} \qquad (7)$$

where $x=b/c$ and

$$p=\ln(8a/c)+\tfrac{1}{12}-\pi x/3+\ln(1+x^2)$$
$$\times[1/(12x^2)-\tfrac{1}{2}]+(x^2/12)\ln(1+1/x^2)$$
$$+\tfrac{2}{3}(x-1/x)\tan^{-1}(x) \qquad (8)$$

$$s=(c^2/96a^2)\{[\ln(8a/c)-0.5\ln(1+x^2)]$$
$$\times(1+3x^2)+3.45x^2+221/60-1.6\pi x^3$$
$$+3.2x^3\tan^{-1}(x)-\ln(1+x^2)/10x^2$$
$$+(x^4/2)\ln(1+1/x^2)\}. \qquad (9)$$

Equation (7) loses accuracy as the solenoid approaches a current-sheet type winding ($x>25$) or as c approaches a. Although very accurate for squarish type sections ($x<10$) and $a>c$, the terms in Eqs. (8) and (9) consist of large positive and negative numbers that nearly cancel. These equations illustrate the two major difficulties in using series expansions:

1. The equations are generally only valid over a particular range; and
2. the individual terms in the series nearly cancel, requiring a high degree of accuracy in the separate terms for even moderate accuracy in the final answer.

Rosa and Grover (1911), working for the U. S. National Bureau of Standards, made what is perhaps the most comprehensive investigation of the various formulas available at the time. Later, Grover (1946) refined this work and produced a book of working formulas and tables that can be used to calculate the inductances for the important geometric arrangements. Grover's formulas employing only one or two terms give accuracies to greater than one part in 1000 over extremely wide ranges of geometric variation. Corrections for winding space and insulation are readily incorporated into the formulations for all of the important geometries.

From a geometric perspective, inductance is just N^2 times the permeance $\mathscr{P}$ of the magnetic path. If the magnetic path can be clearly defined, it is possible to derive reasonable approximations for inductance. In general, defining the magnetic path is difficult, and the magnetic-circuit approach offers no calculational advantage. Iron-core inductors are an exception, since one of the purposes of using a magnetic material is to provide a clearly defined magnetic path. Therefore, the magnetic-circuit approach provides a reasonably simple and accurate approximation for the inductance in many iron-core inductor problems.

Today numerical methods and high-speed computers make it possible to calculate inductances accurately for complex conductor arrangements including the effects of eddy currents, nonlinear magnetic materials, and hysteresis.

1.3 Types of Inductors

The three main parts of an inductor are the winding, the winding form, and the core. The winding usually comprises a number of turns of conductor wound about some axis of symmetry. The winding form is the structure used to support the winding. The region enclosed

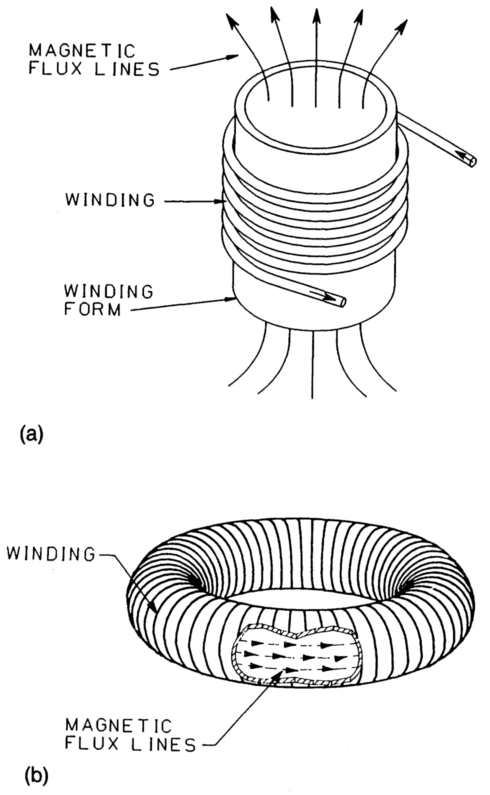

FIG. 3. The two most common types of air-core inductor configuration: (a) solenoid and (b) toroid.

by the winding in which the magnetic field is formed is called the core. Inductors with nonmagnetic core materials (wood, ceramic, plastic, air, oil, etc.) are called air-core inductors. If a magnetic material is used in the core to augment the inductive effect, the inductor is referred to as an iron-core inductor. The most common materials used in iron-core inductors are alloys of silicon steel. However, many different magnetic materials are used in the construction of inductors, especially at high frequencies, such as ferrites, powdered iron, cobalt-iron and nickel-iron alloys, and amorphous metals.

The two most common geometric forms of air-core inductors are solenoidal and toroidal. An inductor is solenoidal if the direction of the magnetic field is primarily straight within the body of the inductor and flux closure is external to the winding. Figure 3(a) shows a short solenoidal inductor of circular form. The winding form for a solenoid is generated by taking a closed planar figure (circle, rectangle, polygon) and extruding it along a straight line normal to its plane. If the length of the solenoid is short relative to its diameter, it is referred to as a pancake coil.

A toroidal inductor is one in which the direction of the magnetic field is predominantly a closed (generally circular) path so that flux closure is within the body of the winding. A toroidal winding form is generated by taking a closed planar surface and rotating it about a straight line in the same plane but external to the closed surface, as illustrated in Fig. 3(b). Because the winding closes on itself, toroidal inductors have a relatively small external magnetic field. In general, toroids have continuous smooth windings that approximate a current sheet over the surface of the winding form. It is not always possible or desirable to have a continuous winding over the surface of the form. An alternative to the smooth toroidal construction is to use discrete short solenoidal sections arranged in a generally circular pattern as illustrated by Fig. 4. This type of arrangement is known as a caged toroid and is used primarily in large energy-storage inductors and confining magnets used for fusion experiments.

In toroidal windings there are two components of electromagnetic forces acting on the windings. The first acts on the local cross section (minor radius) to expand the coil, as with any loop of wire. The second force acts to

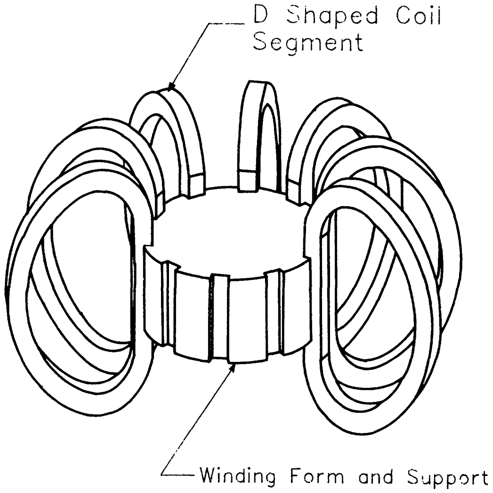

FIG. 4. Cage-type toroidal inductor with a 10-segment winding. The "D"-shaped coils provide a constant-tension winding that improves the inductor's ability to withstand electromagnetic forces.

compress the entire toroid inwardly toward the major axis. File *et al.* (1971) reported that a constant mechanical tension in the winding could be maintained by using a D-shaped cross section for the winding form. Shafranov (1973) later reported that this was also the optimum cross section for maximizing the inductance per given length of conductor for a toroidal arrangement. The D-shaped cross section is the shape taken by a sausage or water balloon resting on a flat surface. The internal expansive forces are like the local Lorentz forces in the coil, and the gravitational action flattening the bottom is analogous to the Lorentz forces acting to compress the toroid about the major axis.

The windings on iron-core inductors are generally either solenoidal or toroidal in form although alternative concepts are sometimes used. In addition to enhancing the inductive effect, the magnetic core also serves to contain the magnetic field within a controlled volume, limiting the "leakage flux." These inductors are generally named according to the shape of the magnetic core rather than winding type. A partial list of the more popular core configurations includes C-core, E-core, picture-frame, gapped-core, two-legged, three-legged, and racetrack.

Electrically conducting cores are sometimes used in variable-inductor high-frequency applications. Their operation is based upon a transformer action established between the main winding and eddy currents in the core, which act like a short-circuited secondary winding. As the core is inserted further into the winding, the magnetic coupling between winding and core increases and the inductance decreases, reaching a minimum when the core is fully inserted.

2. PRINCIPLES OF OPERATION

2.1 Fixed Inductors

These inductors provide a constant inductance over some range. There are many different configurations, but the essential feature is that the winding, core, and any air gaps remain fixed in position with respect to one another. Fixed inductors can be of the iron-core type, provided that their operating range is within the linear range of the core material. Many of these inductors use ferrites as the core material because of the high frequency (kHz to MHz) of operation.

2.1.1 Resonant Circuits. These are an important part of many electrical circuits and are the most common application for inductors. In these circuits, inductors and capacitors are selected to operate at a resonant frequency f_r given by

$$f_r = 1/2\pi\sqrt{(LC)}. \tag{10}$$

2.1.2 Chokes. These are inductors designed to isolate low-frequency from high-frequency signals in mixed-frequency electrical circuits. They are designed to "choke off" the flow of ac from one portion of a circuit and allow dc or relatively low-frequency ac power to flow to some other portion of the circuit. The inductance needed to achieve a desired level of isolation is derived from Faraday's law as

$$L = V/2\pi f_c I \tag{11}$$

where V is the voltage applied to the inductor and I is the maximum current that is to be allowed through the choke at the "cutoff" frequency f_c. Choke inductors come in a variety of geometric arrangements, but they are almost always of the iron-core type to maximize the inductance for minimum material and volume.

2.1.3 Energy-Storage Inductors. These inductors are designed to store energy in their magnetic fields (see STORAGE OF ENERGY). They are generally associated with power supplies of significant rating (several kVA to 1000 MVA) and are sometimes called inductive reactors or simply reactors. In the lower end of the energy ratings these devices are generally simple air-core solenoids. If stray fields are a problem, then an iron shield may be placed around the solenoid, or a toroidal arrangement may be selected having either a uniformly distributed or a cage-type winding construction (see Fig. 4).

In power systems these reactors are used

1. to supply energy for line charging in long transmission lines;
2. to limit fault currents through either series or neutral grounding;
3. to stabilize nonlinear loads in furnaces, welding, or other applications where arcs and nonlinear loads are present; and

4. to balance the current distribution between different parallel circuit branches.

They are also used in resonant power supplies for particle accelerator magnets (see Sec. 4.3), electromagnetic launchers, and some pulse-compression systems (see Accelerators, Linear; Cyclotrons; Synchrotrons).

These inductors are generally air-cored because of the high energy density achievable in nonmagnetic materials, equal to $B^2/2\mu$. Magnetic materials are often used for a portion of the magnetic flux path to concentrate the energy storage into small volumes of nonmagnetic material at a high flux density and to control the leakage flux. These reactors generally have solenoidal windings surrounded by an iron frame and are referred to as "solenoids in a box," or "picture frame" inductors as shown in Fig. 5(a). This type of inductor can still be classified as an air-core inductor as the volume surrounded by the winding is nonmagnetic. The air-core versus iron-core classification often becomes clouded as is the case with the inductor shown in Fig. 5(b). In this case, the volume surrounded by the winding as well as the outer legs consist of alternating magnetic and nonmagnetic regions. This arrangement is used to provide a linear inductance with high energy-storage capability and a well-defined magnetic path. The inductor in Fig. 5(c) uses two windings wound about the legs of a magnetic core and is clearly an iron-core-type inductor.

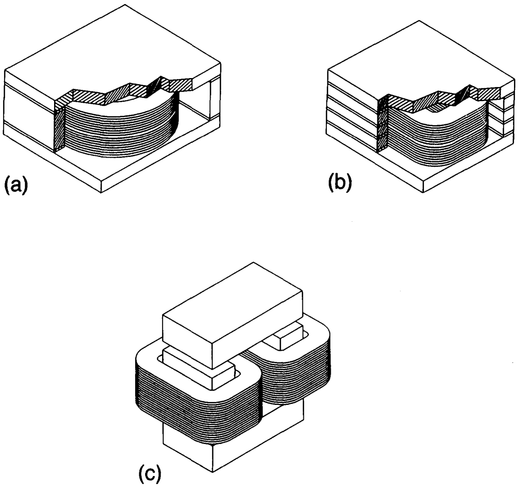

FIG. 5. Different construction methods used for large air-core and iron-core inductors. (a) Picture-frame construction with one large air gap in center of coil. (b) Picture-frame with continuous central leg and air gaps in the external legs. (c) Double-winding distributed air-gap construction.

The inductance required for a particular level of energy storage is found from Eq. (4). If the energy is to be stored in a region of constant permeability μ at a uniform flux density B, then the volume $\mathscr{V}$ needed is given by

$$\mathscr{V}=2\mu W/B^2. \qquad (12)$$

Equations (4) and (12) are used in combination with the characteristics of the power supply to define the optimum physical configuration for a particular application.

2.2 Adjustable Inductors

Adjustable inductors provide a variation in inductance through physical changes in the configuration of the winding arrangement. These inductors have either taps or sliding contacts that are used to alter the number of turns forming the inductor. They may also consist of several fixed inductors that are switched into various series or parallel combinations to provide a variation in inductance. In these inductors the variation in inductance is in discrete steps rather than a continuous variation.

2.3 Variable Inductors

Variable inductors provide an inductance that varies in a continuous manner over some range. This variation is achieved by

1. moving either all or part of the magnetic core with respect to the winding;
2. altering the permeability of the core material; or
3. moving one or more sections of the winding with respect to one another, thereby altering the mutual inductance between these sections and changing the inductance.

2.3.1 Moving Core. In this type of variable inductor a core is moved into or out of the center of a solenoidal coil. These devices are used in electronics applications where fine tuning of a resonant circuit is important. Typically the core is a low-loss ferrite material of cylindrical shape that moves on a threaded shaft. As the magnetic core is inserted further into the winding, the inductance increases over some range. In conducting-core inductors the inductance of the circuit decreases as the core is inserted further into the winding because of the eddy current generated in the conducting core material.

Moving-core inductors were formerly used to control the power flow to certain loads such as theater lights, where they operated in much the same manner as a rheostat without the attendant power loss. Solid-state devices have replaced variable inductors in most power delivery applications, but they are still widely used in communications circuits, using both magnetic- and conducting-core materials.

2.3.2 Saturable Reactors. These are devices that achieve a variable inductance by shifting the point on the magnetic saturation curve at which the inductor operates. This is accomplished by having an iron-core inductor with a control and load winding. The load winding is always divided into two separate windings as illustrated in Fig. 6. With this arrangement there is no ac voltage induced in the control winding; yet the control winding, shown on the central leg of the reactor, still functions to saturate the core. This can also be accomplished by using two separate magnetic cores, but the principle is the same.

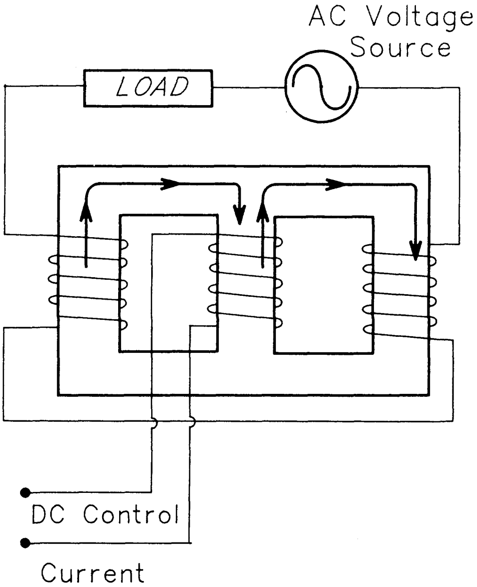

FIG. 6. Saturable reactor illustrating load and control winding arrangements. Note that the core and load windings are arranged so as to keep ac voltages from being induced in the dc control winding.

The inductance of the load winding is the incremental inductance determined by its operating point on the saturation curve (refer to Fig. 2). Shifting the operating point of the circuit is accomplished by varying a dc current through the control winding to cause either more or less saturation in the core. Saturable reactors were first introduced in the early 1900s, and their development proceeded along with that of vacuum tubes. Although saturable reactors tended to be heavy and bulky, they had many advantages over vacuum tubes. They are very simple, rugged, highly reliable devices capable of controlling large amounts of power. Saturable reactors can be designed to have essentially the same operating characteristics as silicon-controlled rectifiers (SCRs) and Triacs.

2.3.3 Magnetic Switches. These switches are saturable inductors capable of withstanding large voltages for short periods of time before saturating. Upon saturation the inductance of these devices decreases by two or three orders of magnitude. Magnetic switches are similar in operation to saturable reactors in that both depend on a large change in inductance caused by the saturation of a magnetic core material. Magnetic switches differ from saturable reactors in that they have a far greater swing in inductance, and it is the load circuit that drives the core to saturation, not a separate control winding. Schematically these devices are represented by the nonlinear inductor element shown in Fig. 1(d).

Melville (1951) first described the use of saturating reactors in pulse generators for radar modulators, nuclear particle acceleration, impulse testing in electrical apparatus, and auxiliary circuits in other power modulator applications. He coined the term "pulsactor" for these new devices that have since become known as magnetic switches. The principal advantages of these devices over electronic, spark-gap, or ignitron switching are that they have an indefinitely long and reliable life and can achieve high repetition rates, passive operation, and high efficiency. Their main disadvantage is that they are relatively heavy and difficult to operate in parallel because of triggering and timing problems.

Magnetic switches fell into relative obscurity until the 1980s, when the need developed for high-voltage (megavolt), high-power ($>10^{10}$ W), high-repetition-rate devices. Birx (1980) revisited the magnetic switch from the standpoint of these different application requirements taking advantage of new geometric configurations and better materials (amorphous metals; see METALLIC GLASSES).

A basic single-module magnetic switch circuit along with a magnetization curve and the voltage at several locations as functions of time are shown in Fig. 7. Operation of the switch is as follows: At time $t=0$ switch S_1 is closed and current begins to flow. Initially, the core is unmagnetized or is magnetized in the negative sense with respect to the applied voltage, and the inductance of the magnetic switch L_P is very large. As current begins to flow the flux in the magnetic core increases to the saturation flux density (B_s), and the impedance of the saturable reactor decreases rapidly. The inductance during the pulse is determined by the differential inductance as described in Sec. 1.1 and illustrated in Fig. 2. The initial inductance is the unsaturated value determined by the linear slope of the magnetization curve. The switch is driven so far into saturation that its saturated inductance can be calculated as if no iron core were present. The saturated inductance is typically 2000–3000 times less than the unsaturated inductance.

The time it takes for the switch to change from its "open" state to "closed" is given by

$$\int_0^{\tau_s} V_L(t)\,dt=NA\Delta B=NA[B_S-(-B_R)], \tag{13}$$

where V_L is the voltage across the magnetic switch, N is the number of turns on the core, A is the cross-sectional area of the core, ΔB is the change in flux density, and τ_s is the time to saturation. If the core is unpolarized, the flux swing will be from 0 to B_S. In general, however, magnetic switches are polarized so that the flux swing is from $-B_R$ to $+B_S$.

By using multiple stages in conjunction with capacitor storage, it is possible to get much higher changes in inductance as well as significant pulse compression compared to a single stage.

The Melville line is the classic example of a pulse-forming network using multiple magnetic switch modules, as shown in Fig. 8. Capacitor C_1 in Fig. 8 is charged through inductor L_0 at a rate roughly proportional to $\pi\sqrt{L_0C_1/2}$ for an ideal source. The charging continues until L_{P1} saturates. At this time C_1 will begin to discharge through L_{P1} and charge C_2. C_2 will charge much faster than C_1 because the saturated inductance of L_{P1} is designed to be much less than L_0. C_2 will then discharge into the load R once L_{P2} saturates. The saturated inductance of L_{P2} must be much less than that of L_{P1}. Figures 8(b) and 8(c) illustrate the voltage and current profiles at various points in the circuit. The voltage pulse is compressed in time but remains relatively constant in magnitude. The current pulse, on the other hand, is compressed in time but its amplitude is continually increasing from stage to stage. In an ideal system the energy transferred down the successive stages will remain constant with the magnitude of the current pulse increasing in direct proportion to the time compression it experiences. The energy

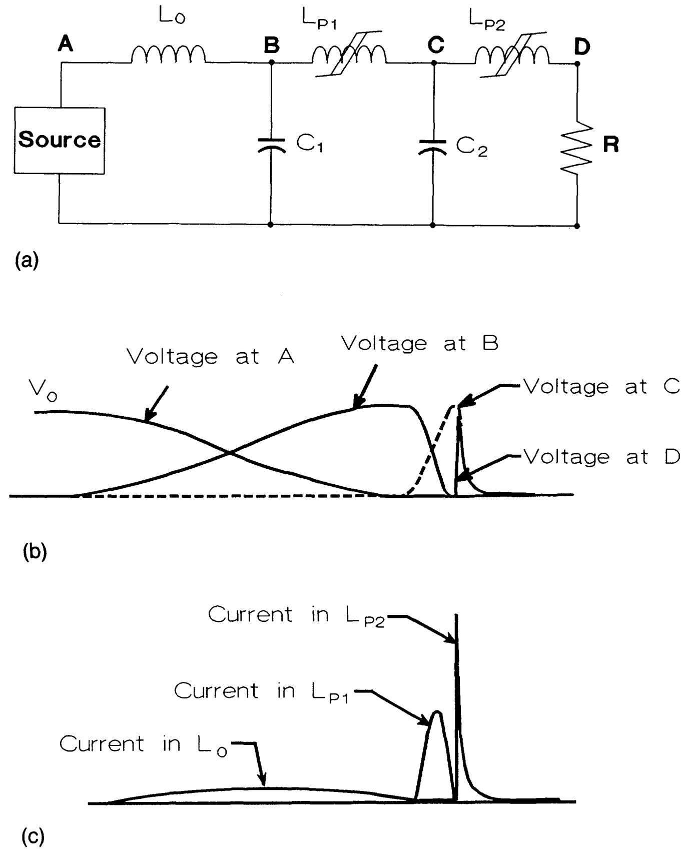

FIG. 8. Classic Melville line two-stage magnetic pulse compression circuit. (a) Schematic of compression line. (b) Voltage compression at selected points as a function of time. (c) Current through selected components illustrating compression of pulse width and increasing pulse magnitude.

lost per stage is typically less than 1% of the input energy.

The circuit described has only two magnetic switch/capacitor modules. In practice this arrangement can be extended to k elements where each C_n and L_{Pn} form a switching module. The gain g of an individual module is defined as the ratio of the capacitor's charge time to its discharge time. This is also equal to the square root of the ratio of the saturated inductance of module $n-1$ to that of module n. The overall gain G is equal to the product of the gains of each individual module.

For a given energy to be transferred, the minimum core volume is given by

$$\text{Minimum core volume} = (\pi/2)^2 \mu_{\text{sat}} W (g/\Delta B)^2 (1/sf). \qquad (14)$$

It depends on the gain, flux swing ΔB, energy W to be transferred, saturation permeability μ_{sat}, and the ratio of magnetic material to total core volume, called the core-space factor, sf.

3. ENGINEERING ASPECTS

The first task in any design problem is to establish the performance requirements and constraints for the particular application. For inductors, these requirements include the inductance, operating voltage, frequency, duty cycle (continuous, intermittent, pulsed), allowable energy loss, and tolerances on each parameter. The constraints define the environment in which the inductor will operate. These include maximum operating temperature, ambient temperature, available and acceptable sources of cooling, limitations on stray magnetic fields, size, weight, and the thermophysical properties of the construction materials. Economic factors such as the relative cost of materials and labor as well as the operating costs act to constrain the design further.

The objective is to produce a design that utilizes the minimum amount of resources while meeting the performance specifications within the constraints. This requires input from a broad spectrum of engineering disciplines including electromagnetics, dielectrics, thermodynamics, and mechanics. The specific functional requirements determine the relative importance of the different disciplines, but each must be addressed to some degree. Making tradeoffs between the operating requirements and environmental constraints constitutes the bulk of the design effort as described in the following sections.

3.1 Electromagnetics

The electromagnetic analysis defines the inductor configuration best suited to the specific set of specifications. Tradeoffs of different configurations establish the best configuration for an application. The electromagnetic analysis determines the main field profile, leakage field, losses, and forces within the device and its surroundings. The analysis may be relatively simple or may involve sophisticated three-dimensional nonlinear magnetic-field analysis techniques.

3.2 Dielectrics

The insulation system is a critical part of the overall design. The spacings between conductors and structural members, winding form selection, and insulating materials are important design parameters. The requirements of the insulation system also influence the inductance and electromagnetic performance, in particular the leakage fields. The insulation designer must ensure that the insulating materials are compatible with the environment and perform over the life of the inductor. Transient performance must be carefully evaluated as inductors, by their very nature, can generate voltages far in excess of the normal operating levels when subjected to transients.

3.3 Thermodynamics

Losses of one type or another are generated in every inductor and must be managed. The thermodynamic analysis ensures that temperatures will not exceed the allowable operating values for the materials in the inductor or surrounding components. All aspects of cooling, loss management, and the thermodynamic properties of the various components must be addressed. The general progression of cooling schemes in order of increasing cost and effectiveness is from free convection to forced air to forced liquid and then to cryogenic methods.

The components in electronic circuits are generally thought of as having low loss. However, the loss density in these small devices is often quite high. For instance, some inductors in a household television set reach temperatures in excess of 100 °C. The coatings on the wire and the form itself must be designed to withstand these temperatures.

Thermal management plays a key role in the design of cryogenic inductors. In cryogenically cooled designs the thermal analysis is primarily directed toward heat leak from the outside into the cryostat. Internal losses are primarily due to movements of the conductors or structural components. Although these losses are small, even the slightest amount of heat can cause significant increases in temperature that can cause the inductor to become unstable, especially if it is superconducting.

3.4 Mechanics

Currents flowing through conductors generate forces and stresses that must be analyzed and supported. This requires an accurate knowledge of the magnetic-field profile and current distribution. In ac devices the forces are oscillatory and can cause unacceptable noise and/or mechanical fatigue after some period. Inductors have been designed that carry currents of several million amperes. Although transient in nature, the forces generated are huge, requiring massive structural supports. The mechanical analysis and design must ensure that the inductor will be self-supporting and structurally sound.

4. INDUCTOR APPLICATIONS

The diversity of names by which inductors are known only suggests the wide range of size, shape, and function to which these devices are applied. Some of the more novel

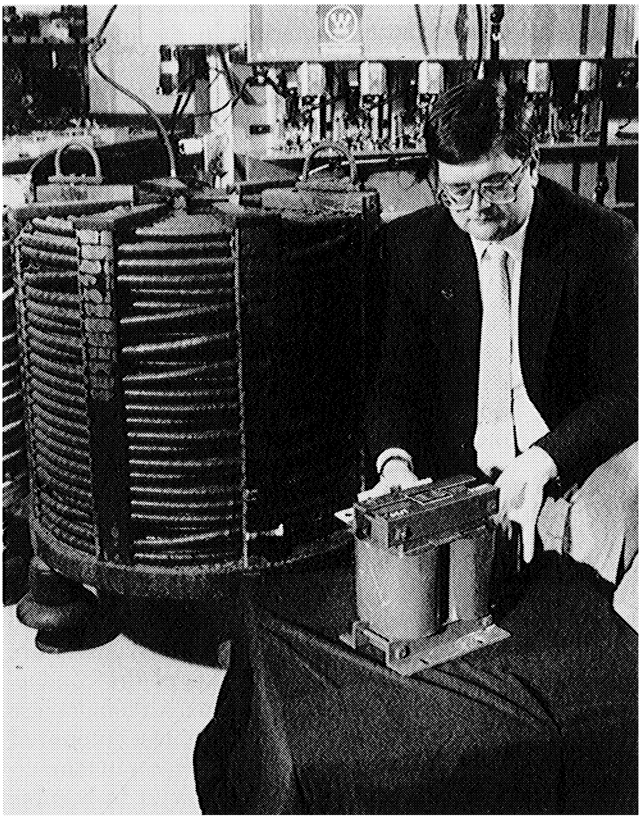

FIG. 9. An air-core power reactor used to provide a constant current for 100 μs during a switching operation is in the background, and an iron-core choke inductor used to limit ac current flow through a circuit is in the foreground.

aspects of inductor technology are presented to illustrate this diversity further.

4.1 Power Reactors

The loosely wrapped solenoidal air-core inductors shown in the background of Fig. 9 are typical of energy-storage reactors. These inductors have 94 turns in two parallel windings in a solenoidal arrangement 0.66 m long with a 0.7874-m outside diameter and 0.330-m inside diameter. If the current were uniformly distributed over the winding area, the inductance based on Eq. (7) would be 7.5 mH. However, the actual inductance, because of the looseness of the winding, is only 1.88 mH. This large variation between a theoretical uniformly distributed current assumption and reality illustrates the need for care in inductance calculations and why the correction factors for winding spacing must be considered in inductor design. These particular inductors are being used to provide a relatively flat current for a short period of time for a solid-state switching application. As the switch is opened, magnetic energy from the series-connected inductor is returned to the circuit. For time periods on the order of the switching time, 100 μs, the current remains essentially constant.

The relationship between the physical size of an inductor and its inductance can be misleading. For instance, the small iron-core inductor in the foreground of Fig. 9 is a 30-mH inductive choke, whose inductance is 15 times greater than that of the larger air-core reactors shown in the same figure. The volume of this inductor is 0.028 m^3 as compared to the 1.28 m^3 of the air-core reactors. This inductor is designed to limit the flow of ac current in a circuit.

4.2 Energy-Transfer Inductors

Inductors function as intermediate energy-storage and low-voltage to high-voltage load-matching devices in many pulsed-power applications. One such application is the hypervelocity electromagnetic macroparticle accelerator (or electromagnetic launcher). In

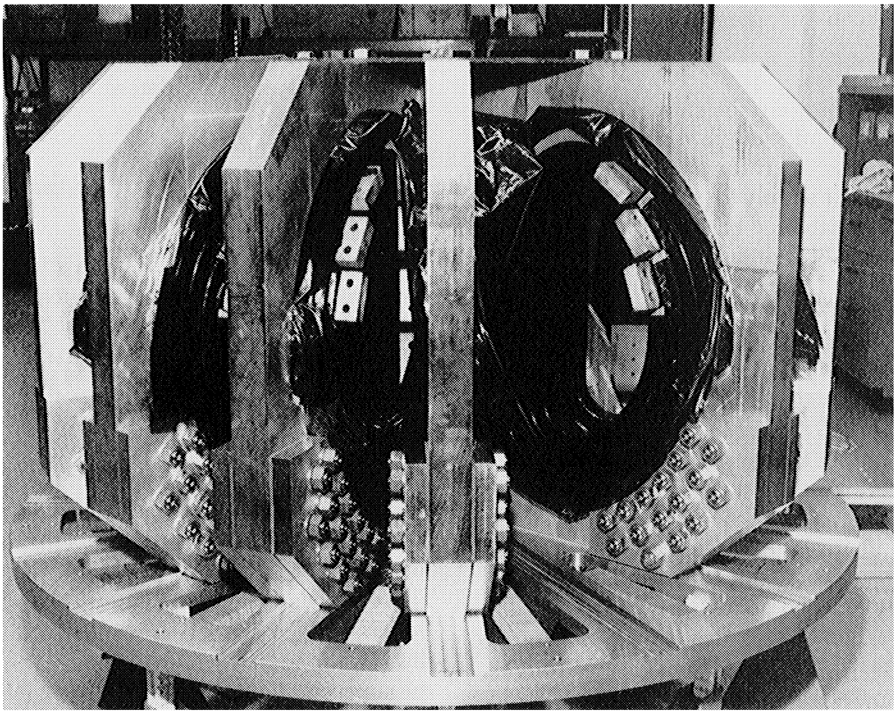

FIG. 10. Liquid-nitrogen–cooled, eight-segment caged-toroid energy-storage inductor used in a Westinghouse electromagnetic launcher power supply. The inductor will store 10 MJ of energy at 2 MA. Note the bracing structure needed to withstand the huge electromagnetically induced forces during operation.

this application, a low-voltage power supply is used to energize an inductor with high current over some relatively long period. At the appropriate time in the charging cycle, a commutating switch in series with the inductor and in parallel with the launcher is opened forcing current to flow into the high-voltage electromagnetic launcher. From Eq. (1) a sufficient voltage will develop across the inductor to keep the current flowing at its initial value. As the energy is extracted from the inductor the current will decay.

An inductor built for a 10-MJ particle-launcher system is shown in Fig. 10. It is a liquid-nitrogen–cooled toroidal cage-type inductor capable of storing 10 MJ of energy at 2 MA. Each of the eight coil segments measures 1.5 m high by 0.5 m across and is wound in the shape of a D to provide a constant-tension winding to maximize its energy-storage density. The Lorentz ($\mathbf{J}\times\mathbf{B}$) forces during operation are extremely high, which is the reason for the massive coil-support structure. The eight-section cage toroidal construction is a sufficiently close approximation to a pure toroid that the stray magnetic field is negligible.

4.3 Resonant Charging for Particle Accelerators

Synchrotron-type particle accelerators use powerful uniform-field electromagnets spaced periodically along the beam path to guide the particles along their equilibrium orbit. The field strength of these bending magnets must increase as the particles gain energy, and hence momentum, if they are to stay within their orbit. The field magnitude and rate of variation must be precisely controlled and balanced among all of the magnets for proper operation of the synchrotron.

White *et al.* (1956) introduced a resonant charging scheme that

1. reduced the cost and complexity of the magnet power supplies,
2. minimized the reactive power require-

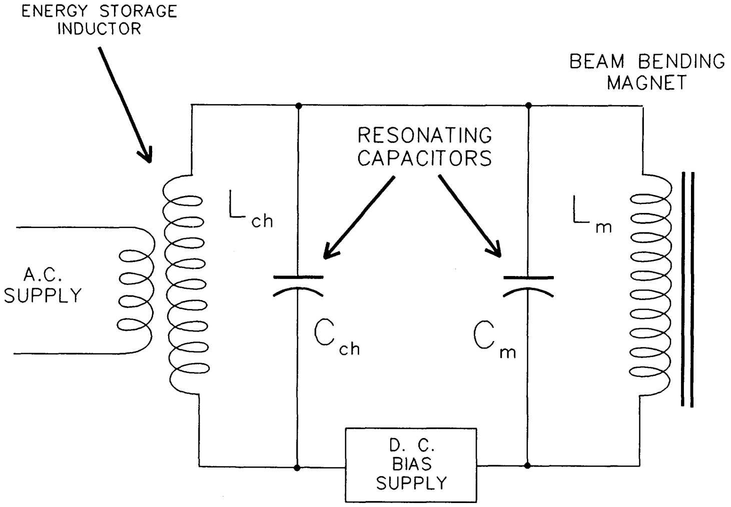
ments from the electrical grid and,
3. could keep the magnets in synchronization.

The basic White circuit shown in Fig. 11 is designed with an inductor and capacitor resonant at the accelerator operating frequency and a dc power supply to pass the bias current. Energy is transferred back and forth between the magnet and inductor in precise synchronization with the particle acceleration. An ac source feeds power to the system via a secondary winding on the inductor to make up for losses. These resonant cells are connected in series to provide the synchronization among magnets. It is desirable to have all of the magnets connected in series; however, some accelerators require such a large number of magnets that this is not feasible.

The inductor is designed to store the energy of the magnets during the nonacceleration period and return it to the magnets as the particle accelerates. It also is used to provide makeup energy due to system losses through a secondary winding. Sasaki *et al.* (1989) designed a dual resonant power supply for the National Laboratory for High Energy Physics (KEK) in Japan that utilized a water-cooled air-core inductor comprising two pancake solenoidal coils enclosed in a picture-frame iron core as shown in Fig. 12. The secondary winding is directly interleaved with each primary turn to provide high magnetic coupling in this air-core inductor. Electrical losses are minimized by using a stranded cable transposed about a hollow conductor through which the cooling water circulates.

4.4 Superconducting Magnetic Energy Storage

Storage of large quantities of electrical power in a superconducting inductor for later recovery has been proposed by Boom and Peterson (1972) of the University of Wisconsin. In the superconducting magnetic energy storage (SMES) concept, electrical power from the ac grid is converted to dc, which is then used to energize a superconducting inductor. Since the inductor is superconducting, there are no losses and the current will circulate until extracted and converted back to ac power. There are significant refrigeration cost penalties associated with keeping the inductor at the low temperatures necessary to maintain the superconducting state. Studies have shown that efficiencies as great as 90% can be achieved by this method of energy storage as compared to 67% typical of hydroelectric pumped energy-storage systems. The greater efficiency is attributed to the ability of the inductor to store the electrical energy directly without intermediate energy conversion steps, as is the case with the pumped-storage concept.



15p

FIG. 11. Circuit schematic of a single-module White circuit used for resonant charging of an accelerator magnet. Typically, these modules are connected in series to ensure that the same current flows in each magnet. Energy is shifted between magnet and inductor in precise synchronization with the beam acceleration profile.

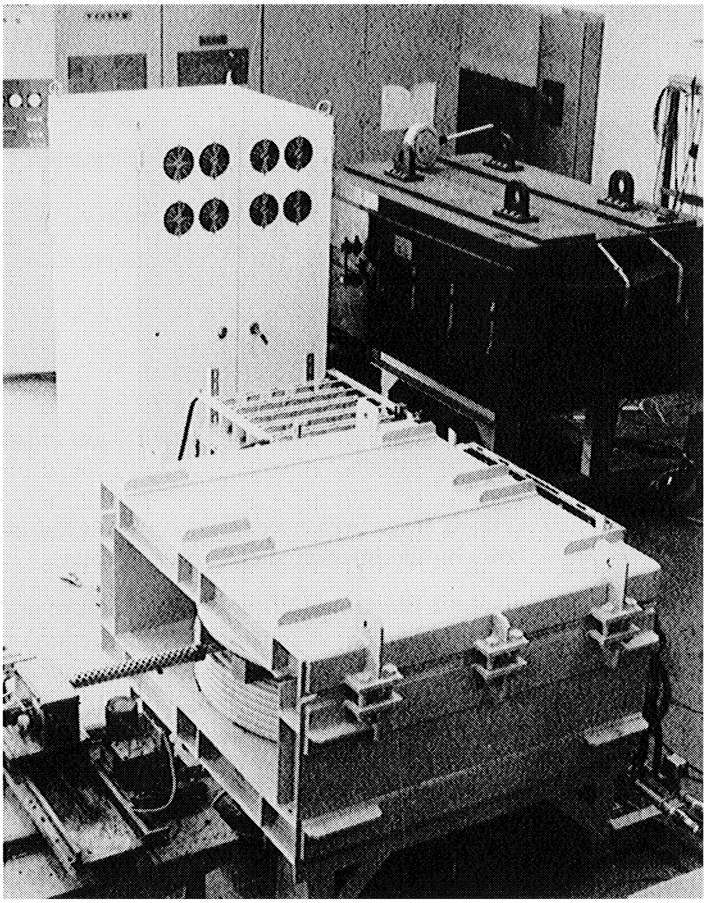


FIG. 12. Energy-storage inductor used in the Japanese National Laboratory for High Energy Physics (KEK) rapid-cycling proton synchrotron. The inductor is of picture-frame construction with two water-cooled pancake coils enclosed by an iron core. It is 11.8 mH with a peak current of 2150 A.

A 19.8-TJ (5500 MW h) full-scale SMES is currently being considered. An artist's conception of the concept being proposed by a team headed by Ebasco Services, Chicago Bridge & Iron, Westinghouse Electric, and the University of Wisconsin is shown in Fig. 13. This solenoidal inductor is 872 m (2864 ft) in diameter with a winding height of over 27 m (89 ft). The entire structure is enclosed in a cryostat filled with liquid helium designed to keep the heat leak to a minimum and to contain the tremendous tensile stresses on the winding. The entire structure is buried in a trench to provide additional support and stability.

4.5 Magnetic Switches

Magnetic switches have a wide range of applications in all types of pulse-forming networks including radar modulators, pulse compression lines for free-electron lasers, particle-beam accelerators, and solid-state switching circuits. The best performance is achieved in high–repetition-rate, high-voltage, continuous-duty applications. They have been used extensively in neutral-particle beam experiments such as PBFA and Comet.

With a core mass in excess of 2000 kg, the magnetic switch employed in the Comet experiment at the Sandia National Laboratories is perhaps the largest magnetic switch built to date. It is a single-shot device that has been tested to 2.7 MV, and 270 kJ per pulse at a peak current of 900 kA. The switch was a single-turn coaxial arrangement which formed an integral part of the transmission line. Figure 14 shows the switch in various stages of construction.

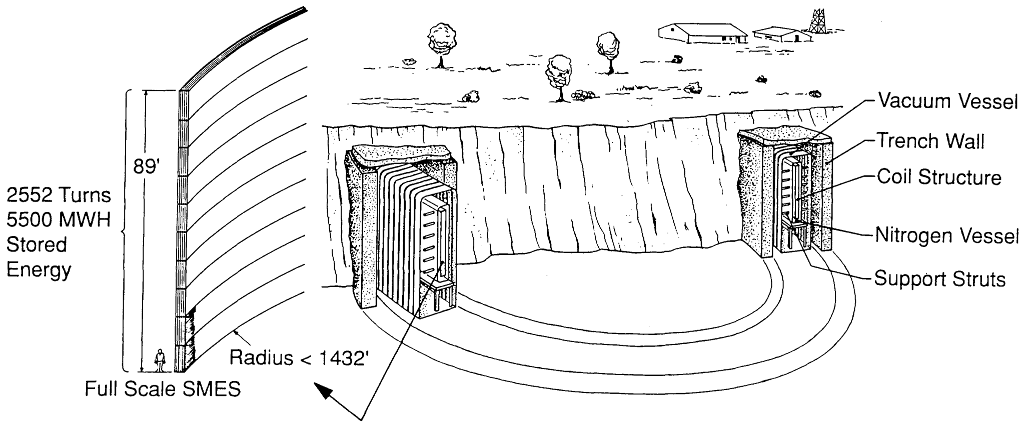

FIG. 13. Artist's conception of a full-scale superconducting magnetic energy-storage coil. The coil is over 870 m in diameter and stores 19.8×10^{12} J for later recovery by the power system.

4.6 Electronic Circuit Applications

Inductors in one form or another can be found in virtually every electronic circuit. Their uses in electronic circuits can be divided into three distinct functional categories: resonant tuning, filters, and current-source reactors.

4.6.1 Resonant Tuning. This type of tuning makes use of inductor-capacitor (*LC*) combinations to form a network selected to operate at a particular frequency as given by Eq. (10). These resonant networks provide regenerative feedback to an amplifier having nonlinear power characteristics to form a harmonic oscillator. Oscillator circuits are used in the generation, modulation, and demodulation of electromagnetic signals generally found in communications systems. Tuning to different frequencies is achieved by varying either the capacitance or inductance of the resonant combination. Variable inductors are used in circuits that may be susceptible to moisture or other contaminants because they are easier to seal against environmental factors than are variable capacitors.

In many applications, *LC* resonant elements have been replaced by circuits using piezoelectric crystals as the resonant elements because they are orders of magnitude more stable than inductor-capacitor combinations. Some integrated circuits have inductive elements built into them by the formation of a spiral conducting path. This arrangement, however, is generally avoided because of the relatively large area needed to construct inductors on the integrated circuit's substrate.

4.6.2 Electronic Filters. These make use of the variation in reactance as a function of frequency exhibited by inductors and capacitors to control which harmonics are either passed through or eliminated from a particular harmonic signal (see ELECTRONIC CIRCUITS). They are classified as either high-pass, low-pass, band-pass, or band-elimination depending on their function in the circuit. High-pass filters allow high-frequency signals through the system for further processing while rejecting frequencies below a particular value. The low-pass filter serves the opposite function. Band-pass filters select a band of frequencies for further processing, while band-elimination filters are used to reject a range of frequencies from the signal stream.

For inductors, the opposition to current flow, or inductive reactance, varies in direct proportion to the product of the inductance and frequency of the signal, as illustrated by Eq. (2b). In capacitors, the capacitive reactance varies inversely to the product of the capacitance and frequency. An inductor connected electrically in series with a load resistance represents a first-order low-pass filter because it presents a low series impedance to the lower frequencies of an applied harmonic signal. A second-order low-pass filter could use an inductor connected in series with the parallel combination of a capacitor and load. If the capacitor is placed in series with the parallel combination of an inductor and the

(a) Magnetic core being wound from alternate layers of insulation and amorphous metal strip. (b) Finished magnetic switch ready for installation in the pulse compression line.

load, then a high-pass filter is obtained. Bandpass filters place an inductor and capacitor in series with the load, while band-elimination filters use a parallel combination of a capacitor and inductor in series with the load.

4.6.3 Current-Source Reactors. These reactors are used to control the magnitudes and rates of rise of current in electrical and electronic circuits. They are particularly useful in solid-state switching circuits used for power applications. Once triggered, solid-state devices can turn on in a relatively short space of time, generally 50 μs or less. If the current increases too rapidly, hot spots can be created that will thermally degrade the device. An inductor of appropriate size placed in series with the solid-state device will control the rate of rise of current through it to acceptable levels. Nonlinear inductors are often used for this application so that the series inductance decreases by several orders of magnitude after the solid-state device has been turned on. Many applications require that several solid-state devices operate in parallel. No matter how good the control system, not all devices will turn on at the same time. If this happens, all of the current will be flowing through only a few of the devices, resulting in an overload and premature failure of those devices. Eventually, the entire parallel combination will fail. By placing inductors in series with each device, the distribution of current can be controlled to ensure that the devices share the current load on an even basis.

GLOSSARY

Flux Linkage: The flux passing through a simple one-turn loop of wire. In a coil, the summation of the flux through each turn.

Henry: The unit of inductance. A circuit has 1 H of inductance if an emf of 1 V is induced when the current is changing at a rate of 1 A/s. Equivalent to a weber per ampere.

Hysteresis: The tendency for the field to persist in a magnetic material after the exciting field has been modified.

Permeability: A measure of the inductive capacity of a material given in units of henries per meter.

Phase Shift: The difference in phase angle between two sinusoidal waveforms.

Phasor notation: The technique of representing variables such as voltage, current, impedance, and resistance as complex numbers in the analysis of harmonic problems, having a magnitude and phase angle with respect to some reference.

Reactance: A complex constant of proportionality relating voltage to current, similar to resistance in Ohm's law. It is a function of frequency as well as inductance and capacitance.

Further Reading

Information on design details and new applications and designs for inductors can generally be found in conference proceedings for applications to specific technology areas. The IEEE Pulsed Power Conference, the IEEE Power Modulator Symposium, the Symposium on Engineering Problems in Fusion Research, the *IEEE Transactions on Magnetics*, and the *IEEE Transactions on Nuclear Science* are good sources of related material for large inductor designs. The *Proceedings of the Institution of Electrical Engineers* (IEE) is also a good source of information. For accelerator applications there are numerous conferences sponsored by host laboratories throughout the world that can be good sources of information. For communications applications both the IEEE and IEE have societies that publish articles that may be of interest.

Carter (1967) provides a good physical insight into the electromagnetic field and treats the concept of inductance especially well. For anyone calculating inductances of standard geometries the Grover (1946) book is essential. Both Smith (1985) and McLyman (1978) do a thorough job of inductor design details for one wishing to build devices.

INTRODUCTION

Information science is a relatively new discipline, so new that the name is not widely known nor is there broad agreement as to what it means. Generally, it has grown out of studies of the design, use, and measurement of collections of information and of information systems, and, although rarely part of any

made that the systems studied are primarily computer systems. Computer science tends to concentrate on computer internals: design of hardware and algorithms, engineering of computer software, and the performance of the hardware or software components. Information science, on the other hand, tends to deal with systems as a whole, the interrelation of the systems with their users (indeed, even to

Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

effect of information systems on their environment, and the extent to which they accomplish their objectives.

As a formal discipline, one branch of information science grew out of library science when, in the early 1960s, library science began to turn its attention increasingly to new methods of organizing and retrieving information, at least partly by the application of new technology to these problems. Other aspects are found in the disciplines of computer science, linguistics, communication (the social science), and telecommunications engineering. In Europe, the expression *information science* is rare; *informatics* is more likely to be used. Today, there are several respected scholarly societies and journals in the field, listed in Sec. 9.

After World War II there was a large amount of scientific documentation that had been created on the Allied side and more captured from other countries. In the 1950s the new "cold war" began, which had an accelerating effect on the growth of science and technology. Government agencies that supported scientific work believed that a vast amount of information was not being used because it was not accessible, and they invested heavily in developing systems to handle this information. *Handle* meant to organize it—classify and index it—and to develop means to search, retrieve, and disseminate it.

Technologically, information science evolved along with several streams of developments in other disciplines. These were

1. computers, primarily the evolution of time-shared large computers or, latterly, networked small ones;
2. telecommunications, especially packet-switched data communications networks;
3. large databases that became necessary for many disciplines, for example, in recording information about publications in science, and that demanded the use of computer–computer communications for remote searching;
4. new concepts in the organization and representation of information for more effective retrieval;
5. algorithms for interpreting and searching natural language and for measuring the relationships among words or texts; and
6. a movement toward more direct use of computers by end users, requiring new appreciation of user behavior.

This article is organized as follows: Section 1 discusses the nature of information as a mathematical concept and as a commodity, and the representation of information and coping with its ambiguities. Section 2 discusses databases, the logical configurations in which information is stored, and their structure; maintaining quality of the content of a database; and knowledge bases that record information about how to process or interpret data. Section 3 contains an overview of modern information systems; the components and flow of information; and some examples. Section 4 presents an overview of information retrieval, which today means mostly retrieval of text or coded representations of text. Section 5 discusses informetrics, or the measurement of information phenomena. Section 6 discusses information networks, which have made access to information systems not only physically easier but economically attractive. Section 7 considers users of information systems, and characteristics of importance and how they are studied. Section 8 explores the impact of information systems on society as a whole and some of the social issues of current concern. Section 9 discusses societies and journals in information science.

1. GENERAL ASPECTS

1.1 Nature of Information

Information is ubiquitous, so much so that it is difficult to define it in a way that satisfies both scientific rigor and popular conceptions. In the context of transmitting messages composed of strings of characters, Shannon (Shannon and Weaver, 1959) defined the information content of a communication system as

$$H = -\sum p_i \log_2 p_i , \qquad (1)$$

where p_i is the probability of symbol i being selected for transmission, and summation is over the number of possible symbols. The units of H are *bits*. Shannon was a communications theorist, concerned with such problems as computation of channel capacity. He emphasized that his work was not intended to apply to semantic aspects of information or to the meaning of messages transmitted. He also intended that H measure the amount of information in a *system* that generates symbols with the given probabilities, *not* the information content of a *single message*. The probabilities refer to the choice of a letter or a word, not of a message. The frequency distributions of letters in English are fairly uniform over a variety of writings, as are the frequencies of the most commonly used words. But no one knows or can predict the probability of a given message if the source is free to send any combination of English words.

The popular meanings of information (there are many) center around the related concepts of novelty, dispelling of uncertainty, and the probability of occurrence of a message. A message contains information if its contents were not already known to the recipient (novelty). A message contains information if it clarifies an issue (dispels uncertainty). An unexpected message contains more information than an expected one. That a heavy favorite wins a race is not much information, but that a long shot won *is* very informative. It is, of course, impossible to know the *a priori* probability of occurrence of a news item, which is one reason why Shannon warned against computing H for semantic information.

Yet another set of definitions shows the influence of cybernetics. Here, information is a message that changes the state of a system receiving it. Or, information is what enables decisions to be made, i.e., a choice among alternatives. Making a choice changes the state of a system; hence these definitions are compatible with each other. For more information on the formal information theory as applied to coding and transmission of information, see TELECOMMUNICATIONS.

1.2 Related Concepts

Terms closely related to *information* include *data, knowledge, meaning, intelligence,* and *wisdom.* As may be expected, there are no universally accepted definitions for these terms. *Data,* in common usage, tends to mean a set of symbols whose meanings or values are not necessarily known or accepted, but whose structure is known. Hence, it is possible to read data or operate upon it with a program, but without some form of interpretation or evaluation we cannot gauge its significance. The structural aspect is important. If we have simply a set of numbers with no known internal structure, it hardly even qualifies as data. What is data to one person may be highly significant information to another. The subjective nature of the distinction between data and information is becoming widely accepted.

Information is data that has been understood and evaluated, or is meaningful. Thinking, interpreting, or processing converts data into information. *Knowledge,* in general usage, is a higher form of information. The term tends to be applied to bodies of information rather than individual messages. When we use this word, we often mean to imply information possessed or accepted by an authority or an authoritative community. The sentence "We have knowledge of the laws of bankruptcy" is, in common usage, a far stronger statement than "We have information about bankruptcy law." Information acquires the status of knowledge by virtue of general acceptance or acceptance by respected authority, such as by a dictionary or encyclopedia or the *Handbook of Physics and Chemistry.* In Sec. 2.6 we discuss a particular form of knowledge called a *knowledge base.*

Intelligence has a number of meanings, one of which is approximately what we have called *information. Wisdom* is a term not routinely used in scientific work but often used colloquially. It tends to have much the same connotation as knowledge, but now knowledge held or promulgated by a person or community of special distinction.

1.3 Representing Information

An aspect common to all the various definitions is that information is *not* the ink and paper or magnetic disks with which it is represented. It is not something tangible. Information is a consequence of the receipt of a message or sequence of messages that may be recorded in any medium, using any symbol set mutually understood by sender and receiver. The symbolic representation of information consumes space, matter, and time to transmit, but the information itself does not. However, the material and time requirements for storage and transmission of symbols are of critical importance in information-system design.

In scientific work, information is often represented by numbers or codes made up of letters and numbers. There is little of the concept of syntax associated with such representations, but there is some. Given a vector or array, we know that each element is normally the same kind of entity (temperatures, weights, distances, etc., all represented as integers, decimal numbers, or floating-point numbers). Computer programs can easily be written to "understand" such data structures. However, if information is represented in natural language, the syntax is highly complex and often ambiguous. There is no complete definition of the syntax of a natural language nor of the composition of a picture. It is relatively easy to search a numeric array for occurrence of a stored value or a function of a stored value, such as the point where a second difference changes sign. However, it is a far more uncertain procedure to search a body of natural language text to determine whether the concept of the effect of global warming is discussed therein, or to search a picture to see if it portrays a cow. Clearly, there are many ways to describe global warming or to express concern about it, and certainly many ways to picture a cow. The ambiguity or uncertainty that accompanies this kind of searching in collections of information, called *databases*, makes up a large part of the domain of interest of information science. As Sir Walter Scott (1828?) put it, "The end of uncertainty is the death of interest." For example, does "She read her paper on time" refer to the subject matter of the paper or "her" adherence to a schedule? Only context can determine the answer. The sentence "I really liked that" can mean what the words seem literally to say or the exact opposite, depending on tone of voice, if spoken, or the general sense of a written text—is sarcasm used elsewhere? How do we program a computer to recognize sarcasm?

To find information in a large collection of text requires that users understand the vagaries of the text and seek alternative ways of expressing concepts. They must anticipate how authors have represented concepts, not just how they, themselves, would represent them. This, in turn, may require training of users, classification or indexing of the text, and computer programs that can not only search for what the user has requested but help the user decide what to request. See Sec. 7 for a summary of human considerations in the design and use of databases.

Because it is often too expensive or even impossible to store a complete text, graphic, or audio recording, we must often make do with classification codes or other descriptors to convey information about content. In bibliographic work selection of such terms is called cataloguing and indexing. It is crucially important if the original cannot be stored and searched. Today, we are less dependent on indexing for text, still very much so for graphics and sound images.

1.4 Information as a Commodity

Information has been bought and sold, surely for as long as *information* has existed, probably beginning with tips on good hunting and fishing locations and practices. Economists and information scientists have long been fascinated with the fact that, since it is not really the information, but its representation, that is sold, the information remains with the seller after the sale, unlike any other commodity. Hence, scarcity resulting from depletion of stock is not a basic element in determining price. The kinds of information packages that bring the highest prices seem to be those for which interest or demand is high, but access is limited. It is often to the benefit of the purchaser to maintain the access limitation. Thus market research reports, stock market newsletters, and spy reports cost much. Purchasers do not necessarily want their competitors to have equal access. Textbooks and newspapers cost relatively little, partially because a purchaser normally does not object to others owning a copy of the work.

A trial was held in Ontario (Potter, 1988) in which an agent of a labor union was charged with conspiracy to steal a copy of the name and address list of employees of a hotel the union wanted to organize. The judge ruled that no theft could have occurred because the hotel would still have had the information for its own use. What the hotel was potentially deprived of was not information but *exclusivity of access* to that information. Essentially the same logic applies to cases such as the infamous Pentagon Papers episode (Sheehan, 1971), in which classified U.S. government documents were copied. The government was not deprived of the information but of exclusive control of it.

In the context of the cost of access to databases, when such services first became available to the public, in 1972, the basis for charging was almost always *connect time*, the amount of time the user's computer or communications terminal was connected to the database service's computer. Computers had limited numbers of communication ports, and when one of these was in use, it was denied to others. Then, gradually, charges were placed on records or portions of records retrieved, which of course means *copied*. The trend is to charge for a combination of work done and information transferred.

2. DATABASES AND KNOWLEDGE BASES

2.1 General Aspects

Databases are collections of data, with some commonality of content, capable of being searched or processed, and usually but not necessarily containing large amounts of data. A knowledge base is similar, but the implication is that it is used to guide some process, such as searching or interpreting a database. A database may be the set of news articles appearing in the *Washington Post* over a span of 10 years. A knowledge base may be the set of information and rules used to edit a news article from the point of view of English grammatical usage as interpreted by that paper's editors. The difference in concept may not be apparent to a casual observer.

2.2 Record Structure and Content

A *record*, as the term is used here, is a collection of data elements that concern a common *entity*. An entity is the subject of an element of information, such as a laboratory animal or a bank depositor. Information about an entity is represented as a set of *values* of *attributes* or *variables*. Examples of attributes are the *name* of a person, *time* of an event, and *amount* of a bank deposit.

Attribute values are represented as numbers, words, or arbitrary strings of any characters. Attributes also have names, and they have relationships to the entity described. Sometimes, the name adequately describes the relationship. If the entity is a person and the attribute is *date of birth*, that is reasonably self-explanatory. If, however, an attribute is called *pay*, it is not clear whether this is an hourly rate of pay or the amount of a forthcoming check. Therefore, the design of a record should include the list of attributes represented, the manner of representation (integer, character string, etc.) and the relationship of attribute to entity. The record itself then consists of a set of values of the attributes. The name of the attribute, its relationship, and nature of representation could be a part of the record, but they normally are not.

All attribute values for an entity can be stored together or stored separately and brought together when and as needed. In manual systems, those based on paper or other non-computer-readable records, all information related to a given entity is normally stored together, on a single sheet of paper or in a single file folder. In early data-processing systems records took the form of punched cards or were sequences of bits recorded contiguously on a magnetic tape. Today, the information about an entity may be physically distributed over several files on different computers, possibly located in different cities.

One subclass of records is *surrogate records*. A common example is the library catalog card. The card is not itself the book it describes, and it contains virtually none of the content of the book. However, it is descriptive of the book and it represents it in user searches. Search decisions are made using the surrogate, not necessarily the actual document. Gradually, surrogate records, once of vital importance, are becoming less so because it is becoming feasible in many cases to store the entire entity in the record, obviating the need for a surrogate.

2.3 Representation of Attribute Values

We have defined three levels of information representation in a database: the entities about which there is information, the attributes or aspects of an entity about which there will be information, and the representation of the attribute values. Database designers must decide what attributes to represent—whether, for example, a medical bibliographic database should contain only records about research and medical practice or also tutorials and articles for the layperson. Researchers will consider the latter to be clutter, and laypersons will not understand the former. Given a decision about entities, it must be determined what information should be recorded about them. Bibliographic records are fairly standard but typically do *not* contain information about the type of article (research, review, opinion, tutorial, *etc.*), nor do they contain citations used in the article. Finally, the representation of attributes can vary considerably. For example, the subject of an article can be described by a hierarchical classification code, subject headings, or a set of key words extracted from the text. Which is best, which best fits the needs and knowledge of users, must be determined by the designer.

2.4 Storage Structures and Indexes

Users often have no idea how records or individual attributes are stored in computer memory. This condition is called *transparency*: the users see through the physical organization to a *logical organization* or a way of envisioning data that may actually differ from the physical organization but be easier to work with. As an example, text created by a word processor is typically stored in segments of about one line in length, but the segments are not necessarily physically stored in the order in which they appear in the text. Each is likely to be stored in the next space available at the time of storage, wherever on a disk that happens to be. But the users are not required to be concerned about this aspect of storage. They visualize and work with the text as a series of lines in the order of their appearance on the printed page.

Physical organization of data has important effects on the speed, hence cost, of any operation using a database. To explain briefly, there must be some order to records or sets of attributes when stored in memory. Records are put in order on the basis of the value of an attribute, called a *sort key*. If records are so ordered, then it is possible to determine the approximate location of a record, given its key, and thereby to limit search time. Or, if records are stored wherever space is available, then each record will have a *pointer* to the location in memory of the next record in logical (sort key) order. The alternative to ordering is to require a search of every record in a database in order to find just one attribute value.

Suppose a file of employee information is ordered on *name* or *employee number*, but a search is to be done for a physicist who speaks French. Records in this file would be randomly ordered with respect to *job title* and *language spoken*. To avoid an exhaustive search through all employee records, indexes can be created for any attributes likely to be used for searching. An index is created for one attribute. Each index entry consists of the value of the attribute and a pointer to the location of a record containing that value. Then, to find a physicist, the value PHYSICIST is looked up in the job-title index and the set of pointers to records containing that value is retrieved. A similar search for the value FRENCH in an index for languages is then done. Then, the two sets of pointers are combined, retaining only those from both lists, the Boolean algebra AND operation. The user is unaware of the pointer set retrieval and processing—it is transparent. The user is told how many records are represented in the final set and may retrieve any of the indicated records from the employee database.

There are other organizational methods such as the increasingly popular *relational model*. This permits users to use a database as if it contained whatever subset of attributes and in whatever order is convenient for the user at the time of use. The user need not be concerned with whether indexes exist or in what actual order records are stored in the original database. A database management program creates or appears to create the desired structure as needed. This method vastly simplifies computer programming for users of the database, or the composition of search requests, but does add to the operational cost. The economics of modern computer systems tend to encourage this approach, which saves human costs, which continue to rise, at the expense of hardware costs, which continue to decline in terms of unit cost of memory or computational performance. For more information on data structures see COMPUTER DATABASES.

2.5 Database Maintenance and Quality Control

In any information-producing endeavor, aspects such as timeliness, accuracy, reliability and completeness of the corpus of information, or database, are important. It is rare that a database can simply be created and then remain in a constant state. Far more likely, new information will continue to be presented for inclusion, information in the database will change or must be deleted, and errors in existing records will be detected. This means that the managers or operators of any information system must create policies on how to select new information for inclusion, when to delete outdated records, and when and on what basis to make changes. It should be readily appreciated that if a spurious signal causes an error in computing the track of an aircraft in an air-traffic-control system, it must be quickly corrected. By contrast, an error in a bibliographic record would probably not be corrected until a subsequent update cycle, which might occur anywhere from a month to half a year after discovery of the error. This can put users at a disadvantage but the cost of faster change may be prohibitive.

Thus there are some very practical questions: How much error can a database or its users tolerate? What is it worth to users to have a database maintained free of error or, since that is often impossible, to keep them below some threshold? How can error rate or content be measured and monitored in any but the most simple situations? Information science does not have theoretical answers for such questions.

Another aspect of database maintenance is the logic, time, and cost of making changes. The logic is bound up with the physical storage structure (Korth and Silbershatz, 1986). The key elements to consider are two:

1. There is usually a trade-off between optimizing a file structure for speed of search and retrieval versus speed of making changes. A database search service will normally lean toward optimizing search time because that is the dominant operation and the major source of revenue.
2. There is a difference between item-by-item database changes and complete replacement of one version with a new database. The latter is called *reloading* and is costly but sometimes necessary. If the amount of change is great enough, reloading becomes necessary. Either item-by-item change or reloading require the database or a portion of it to be kept out of use for a time, which may vary from fractions of a second to hours.

2.6 Knowledge Bases

In the new field of *artificial intelligence,* or AI, (see ARTIFICIAL INTELLIGENCE), one branch is concerned with *expert systems.* Variously defined, expert systems tend to be information systems that perform tasks traditionally considered performable only by a human intelligence. Of course, there is no strict definition of such tasks and the question of how much human intelligence was required depends on the sophistication of both the performer of the task and the observer. Nonetheless, such systems exist and their number and capabilities increase steadily.

An expert system has to have knowledge in its field, or *domain,* of application approximately equal to that of a human expert. The range of expertise is quite limited. While expert systems have been built or postulated to play chess, diagnose a medical complaint, or search a database and select the best five records meeting the user's needs, no single present-day expert system could conceivably do all these tasks. Indeed, even within the domain of information retrieval, the expert systems tend to be restricted to a single subject area.

The information an expert system uses to perform its task is, in a structural sense, just another database. The difference is that the program using it must be able to interpret the information well enough to base its action thereon. In this case, the database is called a *knowledge base,* which generally consists of a set of data, or facts, and a set of rules (Davis and Lenat, 1982). The facts are used in interpreting the rules. A fact states, for example, that a pawn may move only one or two squares forward and two squares on its first move only, excluding capture situations. A rule tells which piece to move at a given stage in a game and where to move it. A discipline called *knowledge engineering* is developing that is devoted to interrogating human experts to extract from them the information needed for a knowledge base, and then putting this into a meaningful and useful form (Hart, 1992).

The field of expert systems is still quite new and its future uncertain. Some programs have been brilliantly successful—those that can play chess, for example. But there are computer scientists and others who feel there are limits to what can be done, partially on the basis of the fact that while a computer program can interpret information in a knowledge base, it cannot have had the full range of human experience that is often required for difficult decision-making tasks (Weizenbaum, 1976).

3. INFORMATION SYSTEMS

3.1 General Aspects

In a sense, almost anything we might call a *system* can be called an *information system*. A system of equations stores information about the variables represented. A lever might be considered a system that senses the force applied to it and the position of application and transmits information about a resultant force to be applied to a mass. But the more general meaning of *information system* is a set of components capable of acquiring, processing, storing, and transmitting information. The sources from which information is acquired or the destinations to which it is transmitted may be other information systems, people, or even animals. The components usually are assembled for a defined purpose and are interconnected according to a plan. An information system also includes the data or information stored within it. Take two identical computers, loaded with identical programs, but with different sets of data, and we might have quite different information systems.

In the sections to follow, we will consider the major components of typical information systems, how information flows among them, and how that flow is controlled. First, there is a question of the boundaries of a system. For example, are sources part of the system? Are destinations? Are operators (those humans who control the system)? If all these questions are answered in the negative, then the system is a collection of mechanical parts and of information. We often find that, for purposes of evaluation, this definition is too restrictive. To assess an air-traffic-control system as if its human controllers were not an integral part would yield only a moot evaluation. Unfortunately, published descriptions and evaluations of systems are not always clear on specifying what is and is not included.

3.2 Major Components

3.2.1 Sources and Acquisition Subsystems. *Sources* provide information and may control a system's content, reliability, timeliness, etc. The procedure or basis for selecting sources and for deciding what information to ask of or accept from them may also be a part of the system. For a library, sources are publishers, wholesalers, and used-book dealers. The selection decisions are not trivial, because they involve considerations of user needs, discounts offered, reliability in delivery, and the library's desire to spread its custom to assure good service in case of future need. For a newspaper, direct sources are its own reporters or press associations, but *their* sources are varied and cannot be completely controlled by a central office. Questions of reliability arise frequently and cannot be fully answered in most cases. A seismographic information system uses instruments that are part of the system, and hence whose reliability can be periodically verified. It receives information from other systems whose reliability may or may not be open to question.

3.2.2 Processing Subsystems. *Processing* can mean almost any form of transformation of data: conversion of codes, formatting for display, performing mathematical or statistical calculations, or simply changing the order of records (sorting). Information science is typically more concerned with the selection than the processing of data but there is no sharply defined boundary between these functions. Almost any information system performs some form of both.

3.2.3 Communication and Dissemination Subsystems. Modern computer-based information systems typically consist of one or more central computers, or servers, connected with remote users' personal computers. The nature of the connection can be a relatively permanent connection, as in *local-area networks* (LANs), or dial-up connections typical of *wide-area networks* (see NETWORKS, COMPUTER; TELECOMMUNICATIONS). A voice-telephone connection is an example of a dial-up connection—the link to the destination is established on demand and is maintained as long, but only as long, as the user wants it to be.

In information retrieval, *dissemination* has a special meaning not directly related to telecommunication. It is the process by which an information system decides to whom to send records and then performs the physical distribution. This has been an important part of science information systems. It requires the user, or potential recipient, to provide a *profile* or statement of the kind of information that the user would like to receive. Then new records are compared with this statement and those that match are marked for distribution to the person who submitted the profile. Many scientific organizations and individual scientists maintain profiles with the large scientific bibliographic database distribution services. This process is sometimes called *selective dissemination of information* or SDI (Meadow, 1992, pp. 145–146). It is analogous to the older practice of preparing a routing sheet and distributing a copy of a newly arrived journal within an office or laboratory to those who requested it.

3.3 Control of Information Flow

The essence of information science lies in the study of how to control, or what governs the control of, the flow of information from its origin to its final destination. While we can use the phrase *final destination,* it is not final in the sense of reaching a terminal point and going no further. Information generation and use tend to form a giant feedback loop. The recipient of information may be a decision maker who, or which, will then use this information for decision-making purposes over a long period of time. Thus the incoming information serves as a control signal governing outgoing information, possibly in a continuous feedback cycle. Or, information published in a scholarly journal, then retrieved through a retrieval service, may flow to an author and be used in that author's *new* paper, which enters the published literature and is, itself, available to be retrieved in an indefinite cycle.

3.3.1 Control of Input. Information or data can be said to be created when an event occurs and some form of record of the event is made in symbolic form. An event will concern one or more entities. The "event" need not be instantaneous; it could well be a condition of long duration. Colloquially, we say we record the *event,* but we do not and cannot actually do this. We record *information about the event,* that is, we transform a set of perceptions about the event into a set of symbols, and these symbols must be perceived by someone or something. The classical Berkeley question about whether a tree falling unobserved makes a noise may be restated to ask whether a set of symbols constitutes information if it is never perceived. By most modern technical definitions, the answer is *no,* unperceived symbols are not information. Hence the record of the event depends on the perception as well as on the event itself.

Examples of events are a political campaign reported by a journalist into a newspaper or television news system, and the automatic recording of temperatures in a laboratory by a programmed device. In order for either of these reports to be sent, there must previously have been

1. *a policy decision on what kind of events to report*—which, of all possible ones, are wanted in the database;
2. *a design for the record*—the determination of what attributes of an entity are to be recorded and in what manner the values are to be represented;
3. *a selection of events to report*—the determination of what actual events or entities to include. Given the policy, the reality may be different. A newspaper does *not* record all the news; a laboratory sampling procedure may miss a key event.

3.3.2 Selection of Output. Information is selected from a store, not only in information retrieval, but in management information systems and numeric data systems as well. When selection is to be done, there must be some form of language for expressing selection criteria. Most frequently, the manner of selecting is to define a subset of the database in terms of the values of attributes, of the form ATTRIBUTE **RELATION** VALUE, where ATTRIBUTE is the name of an attribute, and **RELATION** is an equivalence relation such as =, >, or CONTAINS (the character string BCD *contains* the string BC). Then Boolean algebraic expressions can be formed from these basic set-defining expressions, producing a final statement such as AUTHOR CONTAINS 'ITH' AND DATE > 1991. Almost any high-order computer-programming language can interpret such expressions (except for CONTAINS, which is relatively rare except in database systems).

3.3.3 Delivery of Output to Users. Computer software must, in any case, interpret such statements as directives for how to examine a record and to determine whether or not it matches selection criteria. The system must then present its information as electronic displays, printed output, or electronic messages to other computers or devices.

3.4 Examples of Information Systems

Here are brief descriptions of three kinds of information systems: a remote-access database search system, a typical accounting system, and a professional organization acting as an information service.

3.4.1 Database Search. Dialog Information Services, Inc., is an example of a service that acquires databases under license from other organizations, called *database producers*, who are analogous to publishers of books or journals. The producers acquire the raw information, put it into usable and standard form, possibly publish it in paper form, and then also distribute it to organizations such as Dialog that will redistribute it electronically to the ultimate user. Dialog provides the computer system, telecommunications for user access, computer software to maintain and search the databases, documentation, training, and user assistance.

The service is highly diversified, offering over 400 databases whose subject matter ranges from *Peterson's College Database*, a directory of educational institutions, to *Standard & Poor's Corporate Descriptions*, providing information about officers, subsidiaries, income, bond ratings, and the like on publicly held corporations, to *Searchable Physics Information Notices (SPIN)*, a bibliographic database describing publications in physics. Users pay for the service based on a combination of time connected to the central computer, the number and form of records retrieved, and in some cases the number of search terms used.

3.4.2 A Typical Accounting System. Every company and institution and almost every family has some kind of accounting system, however primitive, whose basic purpose is to inform management of the financial state of the organization. Clearly, a laboratory with many projects, supported by different sources under different terms, needs a much different system than does a family deriving almost all its income from a single salary and having no unusual expenditures. But the purposes are similar: to account for all monies handled, for tax and other official purposes, and to enable management to make financial plans and adjust them to changing conditions.

An accounting system normally requires the creation of a record for every transaction involving an expense or a commitment, or the receipt of funds. Contrary to the database search system model, all the data are generated internally to the using organization, not acquired *in toto* from an outside source. Controlling input, both assuring that every item is reported and that input values are correct, is a critical responsibility of the system or its managers.

Most accounting systems generate a series of standard reports: a listing of all income and expense items (so that they can be checked for accuracy and so that managers can see where the money is spent), a comparison of each subdivision's expenses compared with spending plans (budget), and a tally of the status of the bank account. But there is also a need for *ad hoc* reports, enabling any manager to request data suited to a particular problem, such as all expenses connected with a particular project, independent of organization, or a time series of expenses in some category to see what changes are taking place.

3.4.3 The American Institute of Physics—An Organization as an Information System. Many organizations, such as professional societies, travel agencies, and stock brokerages, are today recognized primarily as information agencies. They not only operate information systems, they *are* information systems. The American Institute of Physics (AIP) is a federation of professional societies concerned with physics. It is a primary publisher of physics literature, a secondary publisher (indexes and abstracts), a database distributor, and the provider of an online, interactive information service. It is an organization that observes the needs of its users for information; acquires information; selects, processes, and edits it; and distributes it to its users.

As a primary publisher AIP publishes scholarly journals of research, monographs, reference books, conference proceedings, and a newsletter reporting on Washington news of interest to physicists. As a secondary publisher it publishes *General Physics Advance Abstracts* and *Current Physics Index*. As a database producer AIP publishes *Searchable Physics Information Notices* (SPIN), a database derived from *Current Physics Index* that contains bibliographic information and abstracts of articles and other published items. SPIN is then distributed to several database distributors, including Dialog. As a provider of an electronic information service, AIP operates the Physics Information Network (PINET) whose services include electronic mail, society notices of various types, and access to bibliographic databases, including the abstracts of articles in this Encyclopedia. See PHYSICS LITERATURE AND PUBLICATIONS for more detail on publications.

4. INFORMATION RETRIEVAL

4.1 General Aspects and Models

A large part of information science is concerned with *information retrieval*. The purpose of an information storage and retrieval system, or information retrieval system (IRS), is to organize and store information in such a way that it can be retrieved and to perform the retrieval. Retrieval implies selecting a subset of records from the database, according to a specification provided by a user or inquirer. An IRS is an information system that provides

1. a physical storage facility for data or information;
2. an organizational scheme for the information, manifesting both the internal composition of records and the ordering of records and indexes to them; and
3. computer software that interprets queries presented in one or more of a variety of languages, natural or artifical, and carries out the search for records conforming to specifications provided in a formal statement of information need.

There may also be

4. an intermediary function whose purpose is to convert a user's informal statement of information need into the formal version that can be processed by the IRS. The intermediary may be a person trained for this type of task or a computer program or a combination of the two.

There may be

5. assistance in analyzing and evaluating retrieved information,

and there is almost always

6. a subsystem that compiles indexes to records and that gives some indication of content or location.

4.2 Information Needs of Users

Questions to an IRS originate with a user's awareness of a lack of information. Awareness of a lack does not mean that the need is clearly defined. Belkin (1980) called this an *anomalous state of knowledge*, or ASK. A user needing information would approach an information service, perhaps a library or a computer-based IRS, where, in one form or another, it is necessary to explain the *information need*. We distinguish between the ASK and the statement of information need in that the latter is a translation or mapping of the former. This mapping may not be accurate, for a variety of reasons to be discussed in Sec. 4.4.

The user's information need must then be expressed as a *query* or question phrased in the usually formal language of the IRS (see Sec. 4.3). Barring error in the use of language or in the spelling of terms, users usually manage to retrieve *some* records. Then it becomes necessary to evaluate these, or a sample of them, decide whether they are relevant or useful, change the query if necessary, and iterate. The evaluation of record content by the user is presumably based on that person's understanding of the extent to which the record satisfies the ASK. If the needs statement from which the query is derived does not represent the ASK well, then it is unlikely the records will be of great value. Misunderstandings occur easily if the user cannot or does not express his or her actual need. Then there is dissatisfaction with the outcome of the retrieval operation, which could only work from the *expressed* need, not the unexpressed need.

4.3 Query Languages

A query language is the set of symbols and rules for their use by which a user conveys to an information retrieval system what information is wanted and other specifications such as format and order of presentation. It is a form of special-purpose computer-programming language. (See COMPUTER PROGRAMMING LANGUAGES). Most query languages are artificial, using a limited vocabulary and syntax. Many users and system designers feel that, at least for inexperienced users, natural language would be preferable, but this would require that the computer be able to translate natural-language expressions into terms it could use to direct a search. This is being done to a limited extent. Systems that employ this approach do not require full natural-language understanding; they often treat the query as a set of individual words, without consideration of syntax (Salton and McGill, 1983; Croft and Thompson, 1987).

Most programming and query languages are *procedural.* They specify a procedure to be carried out by the issuance of commands, which consist of imperative verbs, objects of verbs, and sometimes prepositional phrases and adverbs. For example, SELECT TITLE FOR AUTHOR=BOHR? might specify that the user wants to see only titles of works represented in a database that were written by an author whose last name (in last-name-first style) begins with the letters B-O-H-R. The "?" asks for retrieval of any author name with these first four letters, followed by any number of others, whether a continuation of the last name or initials. The alternative to procedural language is nonprocedural language, in which the user specifies the characteristics of output, rather than how to produce it. A specification of the format of output would show what information is to appear on a page, and where placed on the page, rather than providing the computer program that formats the display.

The conventional method of entering commands into the computer is to type them on the keyboard. *Menus* and sets of *icons* have become popular recently as a fast means of entering a command. Their use is not an alternative to commands but is a means of entering them. The language in use and the manner in which the computer system interacts with the user in presenting options, receiving commands, and responding to them are major parts of a collection of input–output programs, languages, and display designs called the *user interface,* which is increasingly being recognized as a vital factor in the success of computer usage.

4.4 Intermediation—Assisting the User

The reasons why information retrieval is iterative are that

1. natural-language text is inherently ambiguous and
2. users are uncertain of what they really want.

One reason for the latter uncertainty is that the user has an incomplete mental image of the problem at hand. A second reason is uncertainty about how best to explain or represent the information need. A third is that, to some extent, what information is seen as needed depends upon what is available, and hence a complete and satisfactory query cannot be stated until the database has been explored relative to this user's need.

Given this triple uncertainty, we generally look to a combination of help from an *intermediary* and *feedback* from the system to achieve a desirable outcome. The intermediary converses with the user, the person having the information need, with the objective of learning the user's needs, priorities, evaluation criteria, and even budget so that a query can be formulated. The intermediary then helps the user interpret output and, if necessary, revises the query. The discourse between the two is not unlike that between physician and patient or lawyer and client—the layperson's expression must be translated into the technical terms of a profession. In recent years there have been attempts, with varying degrees of success, to have some aspects of the intermediary role performed by computer software (Marcus, 1991; Marchionini, 1992; Meadow, 1992, pp. 253–269). While progress has been made, it cannot be said that the human role has been replaced.

Feedback is typically provided in several ways. One form is for the system to tell the user what the results of a search were—for example, how many records were retrieved or that a proffered input has a value out of acceptable range. A second is provided by reading the set of records or data retrieved. This, in its raw state, requires that the user who requested the information examine the output, decide whether or not it meets the objective, and decide how to revise the request or commands to the system to improve the outcome. A modern variation of this is to have the system analyze the retrieved data and either help the user to decide what changes may be needed, or directly initiate the next iteration itself. This is an example of the application of artificial intelligence to information retrieval.

4.5 Automatic Processing

One of the areas of greatest accomplishment in information retrieval research has been in the assistance the system can provide to the user—for example, in helping select the search terms that will lead to satisfactory results. Users cannot generally anticipate all the ways authors have chosen to describe a subject. In chemistry, for example, there can be dozens of different ways of representing a compound: as a chemical name, a molecular formula, a ring structure, a popular name, or a trade name, with some of these having many variations. Thesauri can be manually compiled, and word association matrices can be automatically compiled. These show the frequency with which certain words co-occur with others, and this can be done at the level of a sentence, a paragraph, or the entire document. Thus, if a user is interested in the term DISK STORAGE, a word co-occurrence table might suggest other terms that frequently co-occur with either word or both, resulting in an expanded query that might include MAGNETIC DISK, CD-ROM, HARD DISK, FLOPPY DISK, DISK DRIVE, COMPUTER MEMORY etc. Often, even experts in a field will not take the trouble to anticipate all these synonyms, near synonyms, or synonyms in limited contexts.

A second class of assistance techniques is concerned with relationships between records or texts. If a user, by whatever means, has been able to find a few good records, then a useful next step is to ask the system to find any other records that are closely related to these. "Closely related" is taken to mean related in terms of the vocabulary used. A typical function for computing a relationship is the cosine coefficient (Salton and McGill, 1983, p. 121), defined as

$$\cos(R_j,R_k)=\frac{\Sigma\, t_{ij}t_{ik}}{\sqrt{\Sigma\, t_{ij}^2\, \Sigma\, t_{ik}^2}}, \tag{2}$$

where R_j and R_k represent records, whether part of the database or a query, and t_{ij} is the frequency with which term i occurs in record j. The summations range from $i=1$ to n, the number of different terms in the combined documents. Using this measure a user can find a set of records, then ask for the subset most closely related to any given one.

In *relevance feedback* (Salton and McGill, 1983, pp. 140–145), a user retrieves some records and evaluates them. Then, these ratings are used as weights in performing a computation similar to $\cos(R_j,R_k)$, based not only on word co-occurrence but on the importance the particular user attached to a subset of the retrieved records. Other methods for computing relationships or making use of user judgements can be found in Salton and McGill (1983), pp. 199–256.

4.6 Measurement and Evaluation of Retrieval Systems

There is no measure of retrieval system performance that is at once well defined, used in research, and, perhaps the ultimate for a standard, accepted and used in trade. Evaluation is usually based on *relevance*, which can be a measure of *relatedness* between a query and a database record, or of *value* to the requestor. Unfortunately, users often do not have a clear objective in mind when using a retrieval system, leaving us with no clear measure of the degree of accomplishment. The measures most frequently used are *recall* and *precision*. Recall is the fraction of records of a database that are relevant to a query and that are retrieved by it. The difficulty of arriving at a value for recall is that, for a database of thousands to millions of records, it is virtually impossible to know which ones may be relevant but not retrieved. Precision measures the fraction of retrieved records that are relevant. This is a more practical measure, since a user or intermediary can be asked to make the necessary judgments. The difficulty is that a high value of precision is not necessarily the user's goal, although it is often assumed to be.

In practical use, for example, among commercial firms offering retrieval services, user surveys asking overall reaction to the service are more likely to be used and acted upon than measures of outcome or performance.

5. INFORMETRICS

5.1 General Aspects

Informetrics is a branch of information science that is "the study of the quantitative aspects of information in any form." (Tague-Sutcliffe, 1992). It includes patterns of language use, publication, and use of publications. It is related to, but broader than, *bibliometrics,* concerned with the measurement of various "aspects of the production, dissemination and use of recorded information" (Tague-Sutcliffe, 1992) and *scientometrics,* "the study of the quantitative aspects of science as a discipline or economic activity" (Tague-Sutcliffe, 1992). While these phenomena may seem, on the surface, to be almost random, they tend in fact to obey quite regular laws. This is a broad subject. We shall present only a few examples of the types of measures and their applications.

5.2 Language Use

The relationship of the frequency of occurrence of words in a text to the rank, by frequency, tends to follow a very smooth and mathematically simple curve. The relationship was first formalized by Condon (1928) but is commonly attributed to Zipf (1949). It states that $f=kr^{-1}$, where r is the rank, in descending order of word frequency f, and k is a constant, dependent on the sample size. This hyperbolic function is represented by a straight line, with slope -1, on a log-log scale. Most early studies of the phenomenon used "standard" English or French, but Whitehorn and Zipf (1943) also published some samples showing regular deviation from this geometric form, based upon Germanic language texts or English texts written by schizophrenic patients or by children. Mandelbrot (1953) modified it to

$$f=k(r+m)^B, \tag{3}$$

which fits most distributions better. The parameters k, m, and B are attributes of the language sampled or the sample selected. So far, there is little practical application of this relationship in information science, but it may be possible to use the Mandelbrot parameters to characterize languages, including artificial ones, and their users.

Some more traditional measures are the *type-token ratio* and Yule's *characteristic* (Yule 1944). A word *type* is a generic word appearing in a text. A *token* is one specific instance of its appearance. THE is a type, usually the most frequent word in an English text. Any one occurrence of it is a token. The ratio of types to tokens is broadly characteristic of the language or its use by an author. It is the inverse of the mean word frequency. Yule's characteristic is defined as

$$K=(\sigma^2-M)/M^2\,, \tag{4}$$

where σ^2 is the variance and M the mean of the word frequency distribution. Both these measures have been used in authorship studies to help determine the author of an anonymous text or to contest or verify that one person wrote several works attributed to a single person. Other authorship studies have used *discriminant analysis,* which involves finding relatively common words used with different frequencies by different authors (Mosteller and Wallace, 1963).

5.3 Publication Measures

A pressing problem for almost any library is to determine what scientific journals it should have in its collection to meet the demand of its users for maximum coverage of a discipline, while limiting its spending to meet budget limitations. Bradford's law (Kraft and Boyce, 1991) states that if journals in a discipline are ranked according to the number of articles on the subject in question, then organized into zones such that the journals in each zone contribute the same number of papers, then

$$N_k=N_1b^{k-1}, \tag{5}$$

where N_k is the number of journals in the kth zone, N_1 the number in the first zone, and b a *scattering factor* descriptive of and specific to the subject field of the journals. Once some basic investigation has been done in a field, then Bradford's Law can predict the number of journals required for complete coverage or, given an actual list of journals on hand, can predict the cost of an additional increment of coverage or the saving by giving up an increment.

5.4 Usage Measures

We shall illustrate one form of usage measure, *citation* of one publication or work by another, indicating that one author has made use of another's work. A citation is an assertion by an author that the *citing* and *cited* works are related. If two works are cited in the same work, then the two are *co-cited.* If the one work is cited by two others, then we have an instance of ***bibliographic coupling.*** If the two were often co-cited, then the relationship is strong. A person doing a search of bibliographic files and recovering one title might want also to recover all works that are strongly coupled to the first. This information is not contained in conventional bibliographic files or library catalogs. There are *citation indexes* published in science, social science, arts and humanities, and law that provide such information. More information can be found in Kessler (1963), Small (1973), Garfield (1979), and White and McCain (1989).

6. INFORMATION NETWORKS

A network, in the most general sense, is a set of nodes connected by links. The nodes are entities capable of sending or receiving a message, or both. The links are communication channels. The nodes may be computers or people and the links may be telephone lines or a postal delivery system.

From the point of view of information science, information networks can be classified by content and by structure. In terms of content, one major type of network is primarily devoted to sending mail or messages or even complete databases. Generally, these are characterized by *not* having the data permanently stored in the system. Messages are created and sent as needed. They tend to be specifically addressed to recipients, although group addresses are allowed, and they are deleted from the system when delivery is complete. *Electronic-mail* systems are the prime example of these. These "e-mail" systems are the modern version of a telegraph service. Individual users enter their messages and address them. A network relays a message from one node to another until the destination is reached. There are many different methods of controlling the routing. A message is ultimately delivered to a local computer to which the recipient has access and is held there until read. Then the user can delete or retain the message, reply to it, or forward to another node. Bulletin boards and electronic conferencing systems are exceptions to the storage procedure. In these applications, messages may be entered into the system and then stored for viewing by anyone authorized to have access, but reading is generally done after the fashion of reading mail, i.e., by browsing to see what is available and asking for what seems interesting. There is not necessarily a separate copy provided to each reader. Deletion is done by a person responsible for maintaining the files. An extension of this concept allows a user at one node to operate a computer program at another node, obviating the need for transmitting the program or its input data from one machine to another.

The other major content type contains typically large databases, stored relatively permanently in the system, and not for specific users, but for anyone authorized to use the system (See Sec. 3.4.1). Because there are so many records, there must be some kind of content-based search or retrieval process. Permanence of storage is a relative term; records need not stay forever, but until superseded or deleted by an editor. They are not deleted solely because they are read. Again, they have no specific addressee.

Classification by structure or control is typified by two subtypes: *local-area networks* (LAN) and *wide-area networks* (WAN). A LAN consists of a set of computers, printers, and similar equipment, linked together by cable and usually existing within a relatively short distance of each other, limited to a few hundred meters. Wide-area networks may have the components cabled together but typically make extensive use of dial-up telephone links. For more information on networks see COMPUTER NETWORKS and TELECOMMUNICATIONS.

7. THE USERS OF INFORMATION SYSTEMS

Information scientists have come to realize that to study an information system that involves humans as users or operators requires that these human "components" be included in the study. Indeed, it might be said that the domain of information science is those systems that involve human behavior as well as mechanical operation.

Some of the earliest research involving the activity of retrieving information was concerned with how people search in a library (Taylor, 1968) and how cataloguers or indexers perceive the materials they work with, in particular, how consistent they are in their decisions (Lancaster, 1991). Clearly, in any searching situation principally dependent upon surrogate records, the consistency, even more than accuracy, of indexing is critical. How to achieve consistency among indexers or catalogers remains a problem in any discipline.

Searchers using an IRS may be broadly classified into three groups:

1. *professional searchers*, whose function is performing searches on behalf of others, an activity that requires skill in eliciting the information needs of others;
2. *professional users of information*, who are members of a profession or specialized discipline and need information for their professional work; they are also able to judge the value of retrieved information; and
3. *others*, which includes students typically below the graduate level who need information but generally lack the professional's skill at evaluating it.

In general, the second and third groups do not have skill or experience in the use of computer-based information systems, but that statement is gradually becoming less true as home and routine office use of computers spreads. In characterizing users, these three types are not enough. Users vary on knowledge of the mechanical aspects of the system they are using, the language or set of commands available, the content and structure of the database, and the subject matter of the field encompassing the database. Their purpose in searching also affects performance: is it on behalf of another person (implying that the searcher may not know the subject as well as, or the exact information goal of, the end user); is it to find a few good items, or a comprehensive set?

Research has found that these three groups perform differently when doing searches (Marchionini *et al.*, 1991; Cherry and Clinton, 1991), as is to be expected. But, since most information systems do not have significantly different modes of searching to offer users of different levels, the fit between user skill and system design is important. Systems do have differences in user language or methods of providing specifications to the computer. Research suggests that performance differences are at the level of understanding what needs to be done rather than the mechanics of how.

There is not an established set of measures of the performance of information systems or of user performance. This lack hampers research because it is difficult to compare one user group with another. We recognize that there are *performance* measures and *outcome* measures. The former include such variables as time required to perform a task, number of errors (invalid commands issued, for example), or number of commands required to perform a task as meaningful measures.

Studies have investigated relative speeds of work, errors made, commands used, and sequences of commands used. As one would expect, experienced users work faster and make fewer errors. They tend to use more of the commands available to them, analogous to an experienced writer using a larger vocabulary than a novice. Usage studies have tried to identify those commands or output displays that seem to be ambiguous or give trouble to users, and to see how different classes of users respond to an error or ambiguity. They try to determine which types of users prefer to issue commands to systems, and which may prefer to select functions from a menu.

Outcome measures are concerned with results obtained, not with the manner of obtaining them. Outcome measures usually are based on relevance (see Sec. 4.6), essentially measuring the extent to which a system retrieved information useful to or subject-related to that requested. Here is where user skill in evaluating information is involved. Again, as a broad generality, the professional intermediary is not able to judge the value of a record to a user and will instead concentrate on relatedness. The professional user is more likely to judge value, and users in the third category may simply take anything offerred as acceptable.

Some research has focused on *mental models*, essentially the mental image a user has of the system being used. If two users have different perceptions of how a system operates, they will use it differently. Research is becoming more intensive on how to record and compare mental models (Gentner and Stevens, 1983). Continuing research is needed to refine the measures and the laboratory procedures for taking them and to identify the characteristics of users that are of importance. Other aspects of the role of users in information systems have been discussed in Secs. 1.3, 2.2, 3.3, 4.2, and 4.4.

8. SOCIAL AND COMMERICAL ASPECTS

In science, education, and law, and to a lesser extent in business, we have reached the point where users of information have the expectation that all published information can be accessed by anyone who can use the appropriate information networks. If information is not published, which implies lack of an intent to make it public, then it is normally protected by special access restrictions, requiring not only a password, but also membership in some select group, such as those holding a military security clearance. We have not yet reached the long-predicted point where every family and office has a computer tied into the various information networks, but we move closer every year. Here are some current social issues.

8.1 Use of Information Systems

If all published information in a field is available, then teachers, supervisors, and clients expect their students, employees, and consultants to find and use it. Not knowing how is no excuse. This, in turn, creates a need for education and training in how to find and evaluate information, which is not yet covered in the educational programs of most fields. Law is a rare discipline in which knowledge of how to search the literature of the field is a part of professional education. Conceivably, we shall see the day when failure to find information becomes grounds for a charge of professional malpractice. One subfield of information science, overlapping with sociology, studies the patterns of adoption and use of new technology by individuals and groups: who takes the lead and why, who lags and why (Rogers, 1971).

The ease of transmission and copying of files creates concern over copyright protection, not only of the electronic files but also of their printed counterparts. Will readers buy a printed journal or a computer program if a copy can be made electronically at a fraction of the retail cost? The store of information is not depleted by a sale. Should this affect the price? How can the value of information be assessed? For a general review of information economics see Hall (1981).

Privacy and freedom of access to information and media are concepts that existed before electronic media, but have become of more intense interest because of the speed of computers and large amounts of information potentially available. The prospect of virtually all information about each of us being available to anyone—faceless agents of government, insurance or credit companies, prospective employers, or the like—can be daunting. It raises the spectre of "Big Brother," popularized by Orwell (1949). That these fears have not been realized may be partially due to the vigor with which privacy legislation was supported to prevent it (Rosenberg, 1986, Williams, 1988).

Access to media has three aspects:

1. the right to see information about one's self,
2. the right to see information in the hands of government if there is no current reason for maintaining secrecy, and
3. the right to get information *into* a medium.

Rights of access to stored information are now secured by law in many countries. Less well known is the issue of access to media, typified by the right of a political party to free television air time for its candidate in an election. Broadcast frequencies are universally allotted under government control and many governments have rules requiring equal treatment of political viewpoints. The issue is highly sensitive. A similar issue arises in science publishing, when proponents of certain unpopular views claim to be barred from presenting them in major professional publications.

8.2 Growth of the Information Economy

Bell (1976) has pointed out that employment in the primary sectors of the United States' economy, agriculture and extraction, has decreased sharply since about 1900, and "industry" decreased slightly, as a percent of U.S. gross national product. But services and information-related industries have filled the gap. This has led to the terms "post-industrial society" and "the information society." In about 1970 there was virtually no industry devoted to selling databases in electronic or magnetic form. Today, this is a thriving industry. Revenues have grown from about $300 million in 1977 to over $10 billion in 1990 (Information Hotline, 1992). These figures should be treated as approximate, as the definitions of the products vary considerably. Clearly, though, information as a commodity has established itself in world markets. Science information, directly exchanged among scientists, and also science information used in business decision making play a major role in this.

9. SOCIETIES AND JOURNALS IN INFORMATION SCIENCE

The principal professional societies in information science are the American Society for Information Science, the Canadian Association for Information Science, and the Institute of Information Scientists (U.K.). Closely related are the Special Interest Group on Information Retrieval of the Association for Computing Machinery and the Division of Chemical Information of the American Chemical Society. Each holds at least an annual conference.

The major journals are *Journal of the American Society for Information Science* (U.S.), *Information Processing and Management* (U.S.), *Canadian Journal of Information Science, Journal of Information Science* (U.K.), and *Acta Informatica* and *Informatik: Theorie und Praxis der Wissenschaftlich-Technischen Information* (Germany). Some journals closely akin include *Forum of the Association for Computing Machinery Special Interest Group on Research in Information Retrieval* and *Journal of Chemical Information and Computer Sciences* (U.S.), and *Journal of Documentation* and *International Journal of Man-Machine Communication* (U.K.).

GLOSSARY

Anomalous State of Knowledge (ASK): An anomaly in one's state of knowledge, or lack of knowledge, with respect to a problem faced. The start of the information retrieval process.

Attribute: An element of information about or a variable descriptive of an entity.

Data: A *datum* is a value of an attribute. A set of data implies not only a collection of such values but that there is a known organiztion to elements of the set.

Database: A collection of sets of data about entities; or a collection of records, where each is concerned with an entity; or a set of related files, all concerned with a common set of entities.

Entity: The individual about which information is or may be gathered, such as a person, a sensor, or a philosophical concept.

Expert System: An information system capable of, or intended to perform, tasks otherwise considered to be demanding of human intelligence for performance.

Information: (1) Data that is understood or deemed meaningful or valuable by a recipient. (2) $H=-\Sigma p_i \log_2 = p_i$, the sum of the product of the probability of a symbol's occurrence times the logarithm to the base 2 of the probability, over the set of possible symbols.

Information Retrieval: The process of organizing and storing information such that it can be retrieved, and performing the retrieval by selecting a subset of records from the database, according to a specification provided by a user or inquirer.

Informetrics: The study of the quantitative aspects of information in any form; including patterns of language use, the production, dissemination and use of recorded information, and the quantitative aspects of science as a discipline or economic activity.

Knowledge: In general usage, similar in meaning to *information*, but tending to be applied to bodies of information rather than individual messages. Often meant to imply information possessed or accepted by an authority or an authoritative community.

Query: A statement of a user's information need, expressed in the usually formal language of an information retrieval system.

Query Language: The set of symbols and rules for their use by which a user conveys to an information retrieval system what information is wanted, and other specifications such as format and order of presentation. It may be a special-purpose computer programming language.

Relevance: A measure used in the evaluation of information retrieval systems, which can be of the subject *relatedness* between a query and a database record, or of *value* of a retrieved record to the requestor.

INTRODUCTION

An ideal insulator would be one that does not conduct electricity, i.e., carries no current when a voltage is applied across it. In practice, all materials provide a measurable amount of electrical conduction. The effect of a voltage is to set up an electric field **E** that exerts a force on the electrons and ions within the material. In this article we will consider only electronic conduction. Ionic conduction is taken up in the article IONIC CONDUCTION AND DIFFUSION IN IONIC SOLIDS. Electronic conduction in a semiconductor or insulator differs from that in the usual metal in various ways, one being that current may be carried simultaneously by two types of carrier. One of these has the charge $-e$ (1.6×10^{-19} C) expected for an electron, while the other, called the hole, behaves as though it had a charge $+e$. The origin of the holes will be discussed in Sec. 2 when we take up band theory. If the carriers are free to move, the force due to the field results in a net motion, specifically a drift velocity $\mathbf{v}_d$, in the direction of the force. We define the resulting current density **j** as the amount of charge crossing a unit area (perpendicular to the flow) in unit time. Thus if only electrons were conducting we would have

$$\mathbf{j}=ne\mathbf{v}_d, \tag{1}$$

where n is the number of free electrons per unit volume. If there were also hole conduction, that would add a similar term to Eq. (1) for the hole contribution. The drift velocity is a function of the size of the electric field. At low fields $\mathbf{v}_d$ increases linearly with **E** and we may write

$$\mathbf{v}_d=\mu\mathbf{E}, \tag{2}$$

where μ, the mobility, defined by Eq. (2), is a measure of how well the carriers in a particular material respond to the electric field. The mobility becomes a function of **E** at high fields, as will be discussed in later sections. Defining the conductivity κ and resistivity ρ of a material by $\kappa=j/E=1/\rho$, we deduce from Eqs. (1) and (2) that

$$\kappa=ne\mu=1/\rho\ . \tag{3}$$

If there were also hole conduction, κ would have an additional term. The statement that κ and ρ are constants, independent of E, which is generally true at low enough fields, is Ohm's law. What determines the carrier concentration and μ, and how they vary with temperature, electric field intensity, etc., are the major subjects of this article.

Rather arbitrarily, we term a material an *insulator* if its conductivity is of the order of or less than 10^{-8} S m^{-1} ($10^{-10}\,\Omega^{-1}$ cm^{-1}). As shown in Table 1, with this definition the conductivity of insulators covers a range of some 8 orders of magnitude. Good metals, such as silver and copper, have conductivities 16 or more orders of magnitude higher. It is seen from Table 1 that the class of insulators includes a wide variety of materials, mostly organic. Semiconductors also have a wide range of conductivities; these lie between the extremes of metals and insulators just cited. It

is characteristic of semiconductors and insulators that the conductivity is quite dependent on impurities and defects, and varies strongly with temperature. The values given in Table 1 are those for nominally pure specimens at room temperature. As shown in Table 1, the class of semiconductors also includes a wide variety of materials. Important elemental semiconductors are silicon (see SILICON, CRYSTALLINE; SILICON, AMORPHOUS; SILICON, POLYCRYSTALLINE), extensively used for semiconductor electronic devices (see MICROELECTRONICS), and germanium (*q.v.*). Also important for applications are the compound semiconductors made up by combining an element from column III of the periodic chart [particularly aluminum (Al), gallium (Ga), or indium (In)] with one from column V [particularly phosphorus (P), arsenic (As), or antimony (Sb)]. Of these the most important is gallium arsenide (GaAs), used for electronic devices, light-emitting diodes (*q.v.*), and semiconductor lasers (see LASERS, SEMICONDUCTOR). Compound semiconductors made up by combining an element from column II of the periodic chart [particularly zinc (Zn), cadmium (Cd), or mercury (Hg)] with one from column VI [particularly sulfur (S), selenium (Se), or tellurium (Te)] are also of importance commercially for electroluminescence (*q.v.*), photodetectors (see PHOTODETECTOR DEVICES), and photoconductors. There are numerous other semiconductors—elemental, binary and ternary compounds, etc.

The sensitivity of properties of semiconducting materials to impurities has been taken advantage of by deliberate addition of chosen impurities, the process called doping, to modify conductivity values or to achieve spatial variation of properties. The effects of doping will be discussed extensively in what follows. Another property that significantly affects κ is the structure of the semiconductor sample. The sample may be crystalline, i.e., having a regular structure in which a pattern involving a small number of atoms is repeated identically throughout (see CRYSTALLINE STATE). More typically, the regular structure may occur over large regions of the sample but with the orientation, i.e., the axis, of the structure varying in a random way from one such region to another; such a sample is called polycrystalline. Alternatively, the sample may be amorphous; in the neighborhood of any particular atom the structure may be fairly close to what it is in the crystalline case (short-range order) but this pattern is not repeated, i.e., long-range order does not exist (see Sec. 9 and AMORPHOUS MATERIALS, STRUCTURE OF).

In what follows we first describe how conductivity is measured, emphasizing the role of contacts. What makes a material an insulator or semiconductor rather than a metal was understood early in the century; the explanation is taken up in the section on band structure. That section includes also descriptions of the conduction and valence bands of typical semiconductors. The structure of these bands underlies many features of the conduction process. It is followed by discussions of what determines carrier concentration and mobility in low and high electric fields in typical semiconductors. A major part of the article deals with conduction in column-IV and III-V semiconductors, on which a great deal of work has been done. This is followed by a section on amorphous semiconductors and one on conduction in cases where the carrier motion is restricted to a thin layer (two dimensional) or to a thin strip within the layer (one dimensional). Conduction through layers of different materials, or heterostructures, is taken up in HETEROSTRUCTURES AND SUPERLATTICES, SEMICONDUCTOR, and in the various articles on semiconductor devices.

1. MEASUREMENTS

1.1 Equilibrium Conductivity

Measurements of electrical conductivity are usually carried out by attaching contacts to the sample to connect it to a dc voltage source, as indicated in Fig. 1(a). To measure the conductivity, one first measures the conductance G, defined as the ratio of the current I through the sample to the voltage drop V across it. Conductance is the reciprocal of the resistance R. For a sample of simple geometry, as indicated in Fig. 1, from the definition of j we find $I=jA$, where A is the cross-sectional area. Also, $V=EL$, where L is the length of the sample. Thus the measured conductance yields the value of κ through

$$G=\frac{I}{V}=\frac{jA}{EL}=\kappa\frac{A}{L}=\frac{1}{\rho}\frac{A}{L}, \tag{4}$$

from the definitions of κ and ρ given earlier.

For the measurements just described to yield a meaningful value of κ or ρ it is apparent that

1. the carrier concentration that exists in the sample in the absence of contacts, and of an applied field, must be retained under the conditions of the measurement, and
2. a uniform electric field must be sustained throughout the sample (with the possible exception of a very thin screening region at the contact–sample interface).

These conditions place severe requirements on the ability of the contacts to supply, or inject, charge, as well as on the sample. They are nevertheless satisfied with relative ease for metallic and high-conductivity semiconductor samples. For low-conductivity semiconductor samples and insulators they are much less likely to be satisfied. In those cases the current that flows in response to a voltage is mainly determined by the nature of the contacts.

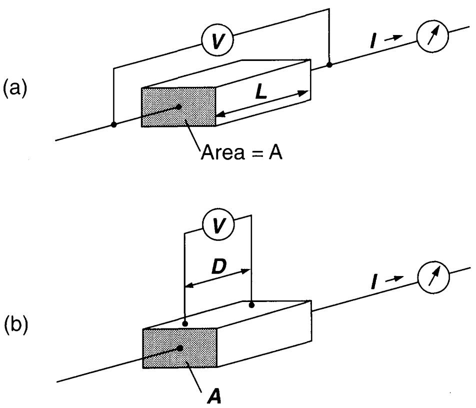

FIG. 1. Arrangements for measuring resistance or conductance. (a) Two-terminal method, (b) four-terminal method.

1.2 Phenomenological Classification of Contact Behavior

Contacts on an insulator or semiconductor may be operationally classified as Ohmic, finite injecting, or blocking. To understand these classifications it is necessary to review the elements of injection theory (see, for example, Lampert and Mark, 1970). We simplify the discussion by assuming that only one type of carrier is present. Consider the fate of a single excess carrier injected by a contact into a solid under the condition that the contact can act as an infinite reservoir of charge. The bulk dielectric relaxation time $\tau_r=\rho\epsilon$, where ϵ is the permittivity, may be defined as the time it takes for charges in the solid to rearrange themselves so as to neutralize any excess injected carrier. In a metal the relaxation is effectively instantaneous, while in a nearly perfect insulator τ_r is essentially infinite. Two regimes need to be considered, depending on the relative values of the injected carrier transit time (time to traverse the region between the contacts under the action of a field) and τ_r:

1. When the transit time is greater than the dielectric relaxation time, the carrier is neutralized before completing a transit, and the current at a given field is controlled in the usual way by the product of the resident thermal-equilibrium carrier population n and the mobility μ. In other words, Ohm's law is valid.
2. When the transit time is less than the dielectric relaxation time, the magnitude of the injected charge is limited only by the repulsion of the space charge already in the sample, including carriers that have been immobilized in traps. Such traps are quite common in high-resistivity materials.

In the simplest case of a trap-free specimen film configured as a plane parallel capacitor with capacitance C, under bias V the amount of charge injected per transit time to sustain this space-charge–limited current is about *CV* (Lampert and Mark, 1970). This injection rate can far exceed the rate required merely to sustain the equilibrium current. Thus, with increasing field, the onset of space-charge–limited injection occurs at the threshold field that just makes the transit time less than the dielectric relaxation time. The onset is marked by *I* increasing more rapidly than linearly with *V*, thus by Ohm's law no longer being valid. It is clear that the onset initiates a process that significantly increases the demand of the bulk on the interfacial source of injected charge. An Ohmic contact is generally defined as one fully capable of sustaining the demands of the bulk up to and including space-charge–limited conditions. A contact that is finite injecting imposes a supply limitation. The contact interface supply limitation can itself depend on field, temperature, and even the mobility of the solid. Thus there are circumstances in which it can be difficult experimentally to distinguish finite injecting from Ohmic contacts. A blocking contact is one that completely impedes injection. Usually a contact is blocking for only one sign of a carrier. Finally it is not uncommon for a given contact to evolve from Ohmic to finite injecting and then blocking with increasing field and for this entire process to be temperature dependent. For further discussion of the behavior of insulators see DIELECTRIC PROPERTIES OF INSULATORS.

1.2.1 Preparation of Contacts. Connection of specimens to measuring circuitry is made by contacts that are most commonly of the following types:

1. diffused;
2. painted (typically with metallic emulsions);
3. soldered, brazed, or spot welded;
4. alloyed;
5. evaporated or sputtered (commonly used on amorphous semiconductors, molecular crystals, and polymer films);
6. plated; or
7. pressure probe.

Diffused contacts are commonly used for semiconductors. A large dopant concentration is introduced by diffusion to bring their surfaces to a nearly metallic state. Metallization of the surface then produces a perfectly injecting electrical interface. It should be noted that contacts that work well on metals are relatively unpredictable on semiconductor surfaces because the interface typically undergoes uncontrolled compositional and thermal modification during the forming process. It is desirable to have current paths parallel to the surface of the specimen, which requires interelectrode spacing large compared to the specimen thickness. For further details on contacts and resistivity measurements, see Dunlap (1959).

1.3 Two- and Four-Probe Conductivity Measurements

The simplest arrangement for the measurement of dc conductivity is the terminal mode shown in Fig. 1(a). Here the voltage drop across the specimen and the current in series with the specimen are simultaneously recorded. It is necessary that the potential drops at the contacts to the specimen, i.e., the current contacts, be small compared to the drop across the specimen. In a typical configuration, the voltage source is an electronically regulated supply, sometimes buffered by a large storage capacitor. Voltage can be measured with an electrometer or electrostatic voltmeter, and current with an electrometer or picoammeter. When isolation or noise considerations are paramount, a shielded battery box still makes the best dc supply.

For high-resistivity materials, or cases where the contact potential drops are relatively large, measurements should be carried out in a four-terminal configuration, illustrated in Fig. 1(b). In this configuration the voltage drops across the contacts are unimportant because they are in series with much higher resistances in the voltage-measuring circuit. One such mode of measurement using a linear array of pin probes (commercially available) is commonly deployed for rapid routine evaluation of Si and Ge semiconductor specimens, or other materials with volume resistivities in the range 10^{-5} to about 10^{2} Ω m. Voltage measurements are taken across the innermost probes with both polarities of a constant-current source and averaged to eliminate extraneous thermal emf's or rectifying contact effects. If the probe spacing *D* is small compared to the smallest sample dimension and the contact area is negligible, the conductivity is given by $I/2\pi VD$. For high-resistivity materials, up to about 10^{9} Ω m, a particular four-probe configuration due to van der Pauw, which is commercially available, may be used (Dunlap, 1959). For $\rho > 10^9$ Ω m the two conditions specified in Sec. 1.1 are not likely to be satisfied. Values of $\rho > 10^9$ Ω m are probably qualitative at best.

1.4 Mobility Measurements

In addition to measuring conductivity or resistivity, it is possible in many materials to measure directly the mobility of the current carriers. The mobility may be obtained by measuring the transit time t_t over a known distance d of injected carriers in a known electric field. The drift velocity is $v_d = d/t_t$. Once v_d is measured, the mobility may be obtained from Eq. (2). There are basically two methods for measuring the mobility, one applicable to semiconductors, the other to insulators.

In the case of semiconductors the technique is applicable to a specimen in which one sign of carrier, either electrons or holes, is dominant under thermal-equilibrium conditions. This carrier is called the majority carrier. The technique relies on the fact that a suitable point contact applied to a semiconductor sample can inject or emit minority carriers into the sample for one sign of voltage relative to the sample, while it can collect, and thus detect, them for the reverse sign of voltage. The sample is fabricated as a uniform cylindrical rod and fitted with blocking contacts at each end. A dc voltage is applied between these contacts. Emitter and collector point contacts are located along the rod spaced a distance d apart. A pulse of minority carriers, typically of microsecond duration, is emitted into the sample at some time t_1 and drifts along the rod under the applied field, reaching the collector point contact at time t_2. The concentration of injected carriers is kept much less than the thermal-equilibrium carrier concentration to ensure that the transit occurs in a uniform field. The carrier mobility is then given by $\mu = d/E(t_2 - t_1)$, where t_1 and t_2 are determined by monitoring the voltage pulses induced across a sensing resistor in series with the specimen.

In the case of insulators, carriers are injected by means of light (see Sec. 9). The sample is prepared as a film of thickness d with semitransparent blocking contacts at the front and back through which the field $E = V/d$ is applied. Exposing the samples, through a contact, to a pulse of strongly absorbed light creates holes and electrons just below the contact. A sheet of either electrons or holes will be swept into the bulk, depending on the direction of the electric field, and through the sample to the other contact. To ensure that the transit occurs in a uniform field the amount of photoinjected charge must be kept small, below $0.1CV$ where C is the sample capacitance. The transiting carrier sheet induces a voltage across a series resistor that drops when the sheet exits through the other contact. The time between the creation of the sheet and its exit is the transit time t_t provided it is long compared to the duration of the light pulse, a condition that can usually be satisfied. Again, the mobility is given by $\mu = d/Et_t$.

If there are traps in the sample, μ measured as described above, called the drift mobility, will not agree with the conductivity mobility defined in Eq. (2). The conductivity mobility is a microscopic mobility, the mobility of an untrapped particle. For the case of shallow traps, where a carrier may be trapped and released from a trap many times during a transit, the drift mobility is the microscopic mobility times the fraction of time that the carrier is free. When the traps are not shallow, and there is a range of trap depths and thus a range of trapping times, the carriers straggle to the contact and it becomes impossible to define a transit time. Such dispersive transport is frequently seen for amorphous semiconductors and disordered materials.

1.5 Measurement of Carrier Concentration

Another important measurement for semiconductors is the Hall effect, from which the carrier concentration of samples with one type of carrier predominant may be determined. For good accuracy the sample should be long compared to the transverse dimensions. An electric field E_x applied along the long dimension, to be taken as x, sets up a current j_x. When a magnetic field is applied in a transverse direction, to be taken as z, it deflects the carriers in the y direction, whether toward $+y$ or $-y$ depending on their sign. During the initial transient phase a current flows in the y direction, causing charge to accumulate on the two faces perpendicular to y. This process continues until the field E_y due to this charge just balances the deflecting effect of the magnetic field. In the steady state the current again flows in the x direction. It is found that E_y is proportional to j_x and H_z, with the constant of proportionality being R_{H}, the Hall coefficient. The importance of the Hall effect lies in the fact that

$$R_{\mathrm{H}}=r/ne \quad \text{or} \quad R_{\mathrm{H}}=r/pe\,, \tag{5}$$

the proportionality constant r being of the order of unity, as will be shown in Sec. 5. Note that the sign of R_{H} is given by the sign of e. It is seen from Eqs. (3) and (5) that the product $R_{\mathrm{H}}\kappa$ equals $r\mu$. It is usual to call the product $R_{\mathrm{H}}\kappa$ the Hall mobility, μ_{H}.

2. BAND STRUCTURE

2.1 What Determines Whether a Material Is an Insulator, Conductor, or Semiconductor?

It is well known that the electrons in an atom or molecule occupy a set of discrete, well-separated energy levels (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES). When atoms or molecules are brought close together to form a solid, electrons on different atoms or molecules interact and the energy levels spread into bands (see ELECTRONIC STRUCTURE OF SOLIDS). The deeper-level electrons, most tightly bound to the nuclei, interact least, forming low-lying narrow bands, well separated from each other. The electrons in the highest level (or levels) go into wide bands. These bands of allowed levels may be separated from each other, may overlap each other, or may overlap bands coming from levels ordinarily not filled in the atom.

It might be thought that, with the outermost electrons close to each other, they could move freely from one atom to another. All solids should then be conductors. The band picture given above can explain why this is not so. An electric field exerts a force on an electron, tending to increase its energy. This can only occur if there are unfilled levels nearby for the electron to move into. Thus if the uppermost band occupied by electrons were incompletely filled, or if it overlapped unfilled bands, the material would be a good conductor. This situation describes metals. It follows from these arguments that if the uppermost occupied band were completely filled, and did not overlap any unfilled bands, the material would not conduct. How then does one explain semiconductors? The band picture offers two possibilities. If the energy gap between the uppermost filled band, called the valence band, and the next higher unfilled band, called the conduction band, is small enough, electrons may be thermally excited into the unfilled band. This process will be discussed further in Sec. 4. This type of semiconductor is called an intrinsic semiconductor. The second possibility is that impurities or defects in the material give rise to energy levels in the energy gap between valence and conduction bands. Ordinarily electrons in these levels are bound or localized and cannot give rise to current. However, they can, at finite temperatures, produce unfilled bands in either of two ways. In one way an electron in a level close to the conduction band is excited into the conduction band by thermal energy. In the other way an electron from the valence band is thermally excited into an empty level close to the valence band. Both of these situations will be discussed further in Sec. 4. As a by-product of this discussion it is clear why some materials are insulators. An insulator is a material with a large gap between valence band and conduction band, typically greater than several electron volts. In materials with such large gaps it is not usual to find impurity levels close to the bands.

2.2 Hole Conduction

It has been found, e.g., by measurements of the Hall effect, that some metals and semiconductors act as though positive charges, rather than electrons, were the current carriers. Explanation of this apparent anomaly was another success of the band model. From the discussion in the last section it follows that semiconductors are characterized by a small fraction of filled states in the conduction band and/or a small fraction of unfilled states in the valence band. It is the latter states, called holes, that act like positive charges. This can be understood as follows. A filled band carries no current because every electron motion in a particular direction is canceled by an exactly opposite motion. When one electron is removed from the band the cancellation is no longer exact. In the presence of a field the net motion of all the remaining electrons is opposite to the field direction because of their negative charge. This results in the hole having a net motion in the field direction, like a positive charge. In fact, it can be shown that the behavior of all the remaining electrons in the band is equivalent to the behavior of a singly positively charged particle. The properties of this particle, the hole, can be deduced from the properties of the missing electron to which it corresponds. It is clear from its definition that the minimum energy for a hole occurs when it is at the top of the valence band.

2.3 Energy, Momentum, and the Brillouin Zone

The energy E of a free electron is given by $p^2/2m_0$, where p is its momentum and m_0 its mass. The electron may also be characterized by a wave vector k, which equals $p/\hbar$, $\hbar$ being Planck's constant, 6.63×10^{-34} J s, divided by 2π. An electron inside a crystal, which has a periodic arrangement of atoms, may still be characterized by a p value, or a k value. (Note, however, that it is no longer true that momentum is a constant as it is for a free electron.) However, unlike the free-electron case, for the electron in the crystal there is only a finite, although very closely spaced, set of allowed values of these quantities. That set is equal in number to the number of atoms in the crystal and is confined to a unit cell in k space. This unit cell is called the Brillouin zone (see ELECTRON STRUCTURE OF SOLIDS). The detailed boundaries, and thus the shape, of the Brillouin zone depend on the detailed geometry of the crystal lattice. For the diamond structure, possessed by Si and Ge, and the zinc-blende structure, which is the structure of GaAs, InSb, most of the other III-V compounds, and some of the II-VI compounds, the Brillouin zone is a truncated octahedron, shown in Fig. 2.

2.4 Band Structure of Column-IV and III-V Semiconductors

Although many features of the band structure may be obtained from experiments, complete determination of the band structure for any particular material requires solution of the wave equation for that material (see ELECTRON STRUCTURE OF SOLIDS). The result of the band-structure calculation is a detailed relation between electron energy E and k. Because we have confined the possible **k** values to the Brillouin zone, there is for each **k** a set of E values, each corresponding to a different band. The significant energy bands for conduction are the valence and conduction bands, and in fact only the upper and lower edges of these bands, respectively, for low electric fields.

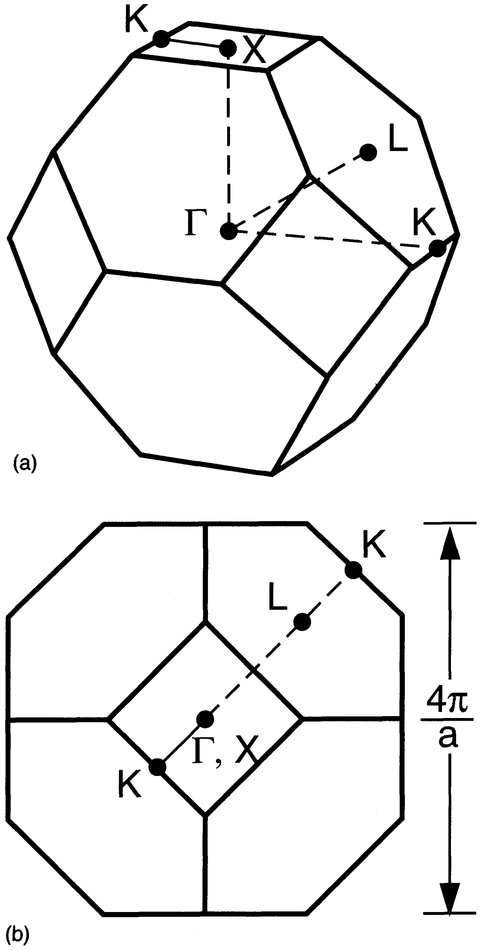

FIG. 2. The Brillouin zone and several symmetry points for the diamond and zinc-blende lattices. The view at the bottom is along a [110] (face diagonal) axis; that at the top has been tilted. The locations of the points shown are $\Gamma = (0,0,0)$; $X = (2\pi/a)(1,0,0)$; $L = (2\pi/a)(\frac{1}{2}, \frac{1}{2}, \frac{1}{2})$; $K = (2\pi/a)(\frac{3}{4}, \frac{3}{4}, 0)$, where a is the side of a cubic unit cell and the numbers in parentheses are the components of **k** along the cubic x, y, and z axes. (After Harrison, 1980).

It is instructive to consider what some possible results of band-structure calculations could be for the column-IV and III-V zinc-blende semiconductors before going on to the actual results for these materials. In Fig. 3 we show some possible results for the band edges.

FIG. 3. *E* vs **k** and constant-energy surfaces for some possible semiconductor band structures. (Adapted from Conwell, 1958).

In the first column is the so-called simple model, where the energy measured from the edge of the band is a constant times k^2. *E* vs *k* for electrons is then a parabola as in the free-electron case and an inverted parabola for holes. To maintain the analogy between this model and the free-electron case, the proportionality constant between *E* and k^2 is taken as $\hbar^2/2m^*$, the m^* thus defined being called the effective mass of the carrier in the crystal. In the simple model the same parabola for *E* vs *k*, thus the same m^*, is obtained for all directions of **k**. This type of band structure could occur if the band edge were at the center of the Brillouin zone, the Γ point. Another way of representing this result is shown at the bottom of the first column. If all **k**'s belonging to the same *E* are connected, a single sphere is obtained, just like that for a free electron. As a result of this simple relation between *E* and **k**, for this model of the band structure it is possible for most purposes to treat the electron inside the crystal as a free electron, using, however, a different number for the mass.

When the minimum energy is not at the center of the zone there is a further complication. Symmetry requires that all equivalent **k**'s i.e., all **k**'s reachable from each other by crystal symmetry operations (rotations, reflections, or inversions that transform the crystal into itself), have the same energy. Thus the band edge or position of minimum energy must be multiple, and the electron (or hole) population must be divided among the various minima, or valleys. This band structure is therefore called the many-valley model. Within each valley, not far from the minimum energy, *E* can be represented as a quadratic function of the components of **k** measured from the minimum energy point. Thus the points in **k** space belonging to a particular energy are on a set of ellipsoids, one for each minimum. Actually, these are ellipsoids of revolution here, and so the energy can be written as a constant times k_l^2 plus another constant times k_t^2, where k_l and k_t are longitudinal and transverse components. In Fig. 3 the lower half of the second column illustrates the case for the minimum energy located at a point on a cube axis, in which case there are six equivalent valleys. This is the case for the conduction band of silicon. Because $m_l \neq m_t$, we must deal with two effective masses in this case. In later sections we will discuss how this type of band structure complicates transport.

A third possible type of band structure for the semiconductors we consider is the degenerate band structure shown in the third column of Fig. 3 for the case of the valence band. This is a set of three bands, one split off by an energy ΔE from the other two. This is the structure for the top of the valence band in Si, Ge, and the III-V compounds with zinc-blende structure. It is the result of the wave function at the top of the valence band having within each cell the character of an atomic p state, which is triply degenerate. The interaction of spin and orbital motion of the electron partially breaks up the degeneracy of the p states, leaving two states stuck together at $k=0$ and the third split off by a small amount ΔE (see ELECTRON STRUCTURE OF SOLIDS).

As is the case for the many-valley model, E vs $\mathbf{k}$ for the degenerate model is different in different directions. This results in the constant-energy surfaces being warped rather than spherical. The surfaces from the two upper bands belonging to a given energy are shown, again rather schematically, in the lower part of the third column of Fig. 3; their equation is given also. The values of A, B, and C are different for different materials. Because of the warping of the surfaces, the effective masses are functions of direction. The anisotropy is not very great, however, and for most purposes the holes in bands 1 and 2 may be described by constant masses. The band with the smaller curvature has the larger mass. Holes in this band are called heavy holes, while those in the other band are called light holes. At temperatures low enough that the thermal energy $kT \ll \Delta E$, only these two bands will be populated.

The calculated energy-band structure for GaAs is shown in Fig. 4. Note that many features of the band structure have been verified by other calculations and by experiments. The band structures of the other column-IV and the other III-V zinc-blende semiconductors are quite similar to that in Fig. 4. (For a tabulation of band structures and other data for all the column-IV and III-V compounds see Madelung, 1991). Plotted in this figure is E vs $\mathbf{k}$ of a number of bands for some high-symmetry directions in the Brillouin zone. Thus, referring to Fig. 2, we see that the curves from Γ to X represent the cube axis direction and those from Γ to L the cube diagonal direction, etc. Looking at the borders of the crosshatched region, which represent the lowest conduction band and the highest valence band, we see that the only case where the simple model comes close to being realized is the conduction band of GaAs, centered at Γ_6. The mass for that band is quite small, $\cong 0.06m_0$, where m_0 is the free-electron mass.

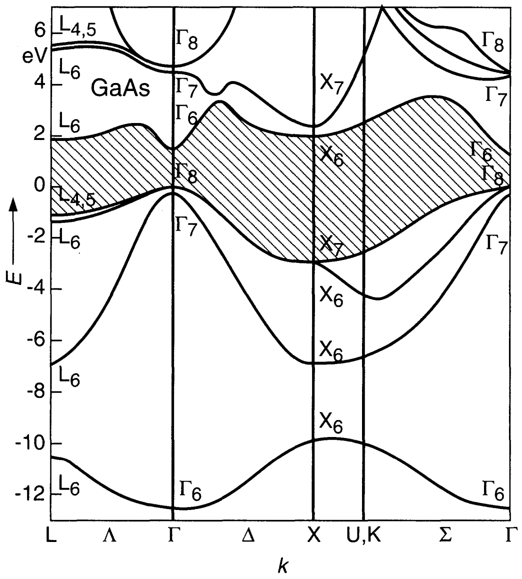

FIG. 4. Calculated band structure of GaAs. The crosshatched region represents the gap between the highest valence band and the lowest conduction band. (Adapted from Madelung, 1991.)

In the case of Si the conduction-band minimum is along the cube axis direction, actually close to the X point. Thus, as noted earlier, the conduction band of Si has six equivalent valleys, the situation depicted in Fig. 3. The ellipsoids are quite anisotropic, with $m_l = 0.92m_0$, $m_t = 0.19m_0$. The valence band of GaAs clearly fits the degenerate model of Fig. 3 with a spin-orbit splitting $\Delta E = 0.34$ eV. Light- and heavy-hole masses are well approximated by $0.08m_0$ and $0.05m_0$ (Madelung, 1991). The valence band of silicon also has the degenerate band structure, but the spin-orbit splitting is only 0.04 eV, so small that all three bands are populated at room temperature. Light- and heavy-hole masses are $0.15m_0$ and $0.54m_0$.

The band structures of semiconductors other than those in group IV and III-V compounds have not been studied as extensively. Regardless of the detailed lattice structure, band edges should still be described by the simple, many-valley, and degenerate models. Of course differences must be expected due to different symmetry when the lattice structure is not cubic.

3. STATES DUE TO DEFECTS IN CRYSTALLINE SEMICONDUCTORS

As indicated in the last section, impurities or defects give rise to energy levels in the forbidden gap that localize electrons. There is a great deal of information about such levels in silicon (see SEMICONDUCTORS, ELEMENTAL—ELECTRONIC PROPERTIES) and GaAs, for example (see SEMICONDUCTORS, COMPOUND—ELECTRONIC PROPERTIES). In this article we limit discussion to those impurities that are important for conduction. Specifically, we will discuss those that

1. provide energy levels close to the conduction- or valence-band edges, and
2. can be introduced into the semiconductor in relatively large concentrations.

The impurities that best satisfy these conditions are those that substitute for host atoms in the lattice and differ from the host in having one more or less valence electron. For Ge and Si these are the atoms of columns III and V of the periodic chart. For the III-V compounds such impurities include atoms from columns II, IV, and VI. As will be seen, the last electron in an impurity with one more electron than the atom it substitutes for is weakly bound to the impurity, i.e., occupies a level only a little below the conduction band. This last electron can easily be detached by thermal energy, going into the conduction band. Such an impurity is called a donor. By similar reasoning, an impurity with one less electron than the atom it substitutes for provides a level just above the valence band into which a valence electron can be excited by means of thermal energy, leaving a hole in the valence band. Such an impurity is called an acceptor. We show now that both donors and acceptors can be described by a simple intuitive picture that predicts reasonably well the energy levels they provide.

3.1 The Hydrogen Model

Consider as an example the case of a column-V donor atom, say P, substituting for a Si atom. P has five valence electrons. Four of these go into covalent bonds with the four nearest neighbors just as the electrons on a Si atom would. This results in a P^+ ion that attracts the fifth electron. This fifth electron uses wave functions from the conduction band. If the conduction-band structure were that of the simple model, the electron would move around the P^+ ion essentially as an electron in free space moves around the proton in a hydrogen atom, or more generally around a nucleus of charge Ze. The theory of such motion is well understood (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES) It is found that the most probable distance a_H of the electron from the nucleus is given by $a_H = \hbar^2/Zm_0e^2$. The binding energy E_b of the electron to such a nucleus is $E_b = m_0e^4Z^2/2\hbar^2$. To utilize these results for the electron bound to a substitutional P^+ ion in Si it is necessary to take into account two important differences between the situations. Because the P^+ ion is embedded in a medium of permittivity ϵ, the attractive potential of the ion for the electron when they are separated by a distance r is reduced from e^2/r to $e^2/\epsilon r$. as though the nuclear charge $Z = 1/\epsilon$. The other difference arises from the band structure. In the case of the simple model (see Fig. 3) the free-electron mass m_0 may be replaced by m^*. For the simple model of the band structure, a_H then becomes

$$a_H^* = \varepsilon\hbar^2/m^*e^2, \tag{6}$$

and the binding energy becomes

$$E_b^* = m^*e^4/2\varepsilon^2\hbar^2. \tag{7}$$

E_b^* in this case represents the distance of the energy level below the conduction-band edge.

For typical semiconductors ε is large, ~12 to 16. This results in a_H^* being large and E_b^* quite small. For Si, for example, with $\varepsilon = 12$, by Eq. (6) the binding energy of the fifth electron to a P^+ ion would be $0.1m^*/m_0$ eV if the conduction-band structure were the simple model of Fig. 3. The measured value of this binding energy is 0.045 eV (Madelung, 1991), close to the value that would be obtained from Eq. (6) by inserting for m^* the geometric mean mass $(m_t^2 m_l)^{1/3}$ for a conduction electron in Si. Thus the simple H model we have used gives a reasonably good value for the binding energy. A detailed calculation for the many-valley model is a great deal more complicated [see Altarelli and Bassani (1982)]. Equations (6) and (7) should be valid for the appropriate impurities in GaAs, where the simple model of the band structure does apply reasonably well for the conduction band. Some impurities for which the theory should be valid are column-IV impurities—C, Si, and Ge—substituting for a Ga atom, and column-VI impurities—S and Se—substituting for an As atom. With $\varepsilon=12.4$ for GaAs, and $m^*=0.06m_0$, Eq. (7) leads to $E_b^*=5.3$ meV. This is in good agreement with the observed value of 6 meV for all the impurities listed but S, for which the observed E_b^* is closer to 7 meV. Refinements in the theory bring the theoretical values close to the experimental values (see Altarelli and Bassani, 1982).

In the case of a substitutional impurity with one less electron than the atom it replaces, when the four covalent bonds with nearest neighbors are filled, it results in a net charge of $-e$ in the region. This negative charge attracts a hole, which can be treated just as the bound electron was in the previous case. The most probable distance of the hole from the impurity is given by Eq. (6), and the binding energy of the hole by Eq. (7), with m^* the hole effective mass. Note that in this case E_b^* equals the distance above the valence band of the electronic energy level provided by the acceptor. Again the actual calculation is more complicated because of the complications of the band structure, in this case the degenerate model for the semiconductors of most interest. The measured binding energies for holes arising from the substitution for Si atoms of column-III acceptors—B, Al, Ga, and In—range from 40 to 150 meV. For holes arising from column-II elements—Be, Mg, Zn, and Cd—substituting for Ga in GaAs, the measured binding energies range from 28 to 35 meV. The tendency of the binding energies to increase with increasing atomic number is due to the fact, not acknowledged in the hydrogen model, that the bound electron or hole does actually spend some time close to the impurity, where ε has less than its full value.

The energy required to release a bound electron or hole from a donor or acceptor, respectively, is also called the activation energy because it is the energy required to give rise to conductivity. The activation energies cited for hydrogen-model donors and acceptors are typical for such donors and acceptors in the other column-IV and III-V semiconductors (see Madelung, 1991). They are also the smallest activation energies; other impurities may also supply conduction-band electrons or valence-band holes, but greater energy is required to achieve this. The activation energies for the hydrogen-model impurities cited above are generally <25 meV, the thermal energy at room temperature, with the consequence that the bound electrons and holes will be mostly or entirely free at room temperature and even below. The detailed variation of carrier concentration with temperature to which they give rise will be taken up in the next section.

3.2 Effects at High Impurity Concentration

In this section so far we have considered the activation for a single isolated impurity. When there is a high concentration of impurities, so that the wave functions of bound electrons or holes begin to overlap, the activation energy decreases. In a process similar to that described earlier for band formation, as the impurities come closer the energy levels spread into bands. Band formation occurs first for excited electronic levels, which we have not considered so far in this section, because their wave functions extend further. When the hydrogen model is strictly applicable the excited levels are analogous to those of the H atom (see ELECTRONIC STRUCTURE OF ATOMS AND MOLECULES). Otherwise they are different in detail. Overlap of the higher excited levels to form bands, which then overlap (and mix with) the conduction band, clearly decreases the activation energy, one of a number of effects that do so. For impurity concentration large enough that the ground states of adjacent impurities overlap, an impurity band is formed. We can estimate the impurity concentration N_I at which this occurs by equating a_{H}^* of Eq. (6) to $N_I^{-1/3}$, a rough measure of the average distance between impurities. For the conduction band of GaAs this yields $N_I \simeq 10^{21}\ \mathrm{m}^{-3}$ for formation of an impurity band. By this criterion a concentration several times as large would be required for impurity-band formation in Si or Ge. Such concentrations are not far below the maximum that can be incorporated into these semiconductor lattices for any impurity. The impurity band that results would be expected to have somewhat different properties from the bands we have been discussing because, apart from its being quite narrow at concentrations of 10^{21} or $10^{22}\ \mathrm{m}^{-3}$, the impurities are distributed randomly rather than on a regular lattice. Impurity-band conduction will be taken up in Sec. 8.

4. DENSITY OF CURRENT CARRIERS

A pure, perfect semiconductor crystal at the absolute zero of temperature would have no electrons in the conduction band and no holes in the valence band. The current carriers present at higher temperatures are excited both from the valence band and from donor and acceptor impurities by thermal energy. In what follows we will consider first the thermal-equilibrium carrier concentration in pure specimens, the so-called intrinsic carrier concentration, and then in doped or extrinsic specimens. The section will end with an introduction to nonequilibrium carrier concentrations. These lead to enhanced conductivity and other phenomena of great technological importance in semiconductors and insulators. The nonequilibrium carriers may be excited by light, in which case the enhanced conductivity is called photoconductivity. They may also be created by injection at contacts, as discussed in Sec. 1, and by ionizing radiation.

4.1 Intrinsic Carrier Concentration

The probability $f(E)$ of an electron occupying a state of energy E is given by the Fermi–Dirac distribution function (see STATISTICAL MECHANICS, QUANTUM)

$$f(E)=\{1+\exp[(E-E_F)/kT]\}^{-1}, \tag{8}$$

where E_F is the electrochemical potential, called the Fermi level in discussions of solids. The number of electrons per unit volume in the conduction band of a semiconductor is given by

$$n=\int f(E)N(E)dE, \tag{9}$$

where $N(E)dE$ is the number of available states per unit volume of the sample in the energy range dE at E, measured from the band edge, and the integration is taken over the conduction band. For the simple model of the band structure the states in the conduction band up to energy E occupy a sphere in k space of radius $k=[2m^*(E-E_c)/\hbar^2]^{1/2}$, where E_c is the energy of the conduction-band edge. From this, plus the fact (due to the uncertainty principle) that each state must occupy a volume of k space equal to $(2\pi)^3$/(volume of the sample), we deduce that

$$N(E)dE=(1/2\pi^2)(2m^*/\hbar^2)^{3/2} \times(E-E_c)^{1/2}dE. \tag{10}$$

This result may be formally generalized to other models by replacing m^* by $m^{(N)}$, called the density-of-states effective mass. For the many-valley model

$$m^{(N)}=g^{2/3}(m_t^2m_l)^{1/3}, \tag{11}$$

where g is the number of equivalent valleys.

We may now obtain n as a function of temperature by inserting Eqs. (8) and (10) in Eq. (9). Except for very heavily doped semiconductors, $E-E_F \gg kT$, and Eq. (9) may be approximated by the Maxwell–Boltzmann distribution

$$f(E)=\exp[(E_F-E)/kT]. \tag{12}$$

This allows the integration to be simplified by taking the limits from 0 to ∞. The result is

$$n=N_c\exp[-(E_c-E_F)/kT] \equiv 2(2\pi m_n^{(N)}kT/h^2)^{3/2}\exp[-(E_c-E_F)/kT], \tag{13}$$

which serves to define N_c, the effective density of states in the conduction band. Similar calculations may be made for holes in the valence band, starting from the probability $1-f(E)$ of finding a hole in the level at energy E. The result is that the hole concentration p varies with temperature according to

$$p=N_v\exp[-(E_F-E_v)/kT] \equiv 2(2\pi m_p^{(N)}kT/h^2)^{3/2}\exp[-(E_F-E_v)/kT], \tag{14}$$

which defines N_v, the effective density of states in the valence band. Because of the approximations made in the derivation, the expressions for n and p are accurate only when E_F is at least several kT from the respective band edge. As will be seen, this condition is always met for intrinsic samples. Multiplying together the expressions (13) and (14) we obtain the equilibrium value for the product np. For an intrinsic sample, in which the number of carriers is denoted n_i, $np=n_i^2$. We can use Eqs. (13) and (14) to obtain

$$n_i=p_i=(N_cN_v)^{1/2}e^{-E_g/2kT}. \tag{15}$$

Thus the intrinsic carrier concentration depends exponentially on the energy gap $E_g/$

$2kT$. Note that E_g is also somewhat temperature dependent, decreasing ~5% from 0 to 300 K for Si, for example. Using the fact that E_g for Si is 1.12 eV at 300 K (Madelung, 1991) and the effective masses given previously, we find that $n_i = 1\times10^{16}\ \mathrm{m}^{-3}$ ($1\times10^{10}\ \mathrm{cm}^{-3}$) at 300 K for Si. For GaAs, with a gap of 1.4 eV at 300 K, n_i is only $2\times10^{12}\ \mathrm{m}^{-3}$ at that temperature. Particularly in the case of GaAs the intrinsic number of carriers is so small that carriers coming from impurities, which cannot be reduced to such a low level, must always be dominant.

We can use the equations derived in this section to determine the location of E_F in intrinsic material, E_F^i. To do this it is convenient to use as our reference point, i.e., the zero of energy, the top of the valence band. Equating n_i obtained from Eq. (13) to p_i obtained from Eq. (14) we find

$$E_\mathrm{F}^i = (E_g/2) + \tfrac{3}{4}kT\ln(m_p^{(N)}/m_n^{(N)}). \qquad (16)$$

If $m_p^{(N)} = m_n^{(N)}$ the Fermi level for intrinsic material is at midgap, independent of temperature. Although this is generally not the case, E_F^i is usually not far from midgap because $m_p^{(N)}$ is usually relatively close in value to $m_n^{(N)}$.

4.2 Carrier Concentration in Doped Samples

4.2.1 Moderately Doped Samples. To illustrate the way in which carrier concentration varies with temperature in a doped sample, we will discuss the case of a donor-doped, or n-type, sample for specificity. The results apply to acceptor-doped samples with the obvious modifications. In the present section we discuss samples for which Maxwell–Boltzmann statistics, Eq. (12), are valid, typically samples with $N_d < 10^{22}\ \mathrm{m}^{-3}$. Actually, because it is not possible to control impurity content totally, the typical n-type sample with N_d donors/m^3 will also have some acceptors, present in concentration N_a/m^3. We will assume, as shown in Fig. 5, that the N_d donors all provide the same energy level E_d, while the N_a acceptors all provide the energy level E_a. In crystalline semiconductors that are not as well under control as column-IV and III-V semiconductors there may be different sets of donor and acceptor levels, or even a continuous range of levels across parts of the energy gap; the results we derive in this section will not apply in detail to such materials. As seen in Fig. 5, the energy required to raise an electron from a donor level to the conduction band, i.e., the electron binding energy, is $E_c - E_d$, while that required to raise it from the valence-band edge to the acceptor level, the hole binding energy, is $E_a - E_v$. Given N_d, N_a, N_c, N_v, and the various energy levels, it is in principle possible to determine the variation of n with T from Eq. (13), provided E_F is known as a function of T. A procedure for determining $E_\mathrm{F}(T)$ will be given later. It is useful to precede this with a qualitative view of the situation.

Let n_d represent the number of electrons in donor levels. In the limit of low temperatures ($kT \ll E_c - E_d$), n is negligible and $n_d = N_d - N_a$, i.e., there are N_a empty donors because electrons on the donors can lower their energy by going into the empty acceptor levels. For a moderately doped sample with $N_a < N_d/2$, a typical situation, the majority of the donor levels are filled. Consequently the probability of an electron having energy E_d, $f(E_d)$, must be not much less than unity and, by Eq. (8), E_F must be within a few kT of E_d. With E_F close to E_d, the number of electrons in the conduction band, according to Eq. (13), is given by

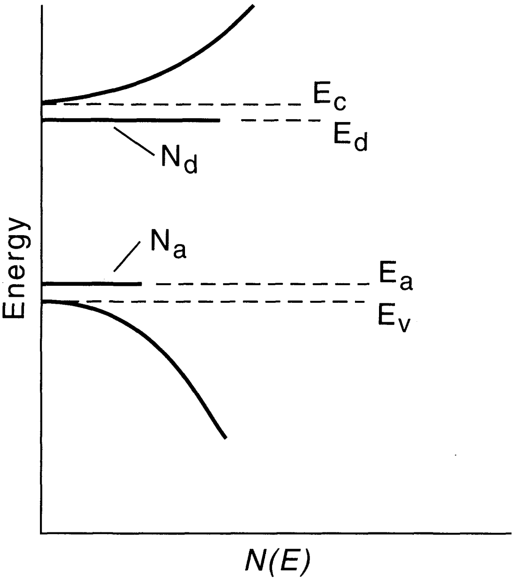

FIG. 5. Distribution of states in a lightly doped n-type crystalline semiconductor. The variation of $N(E)$ with E is given by Eq. (10).

$$n \simeq N_c \exp[-(E_c - E_d)/kT] \quad \text{for } kT \ll E_c - E_d. \qquad (17)$$

Note that relation (17) is frequently used for the experimental determination of $E_c - E_d$, or the activation energy. It is valid more generally than for the model of Fig. 5, requiring only that other donor and acceptor levels be more than several kT below E_d. What is required for its use is the observation of a range of temperatures in which ln n increases linearly with $1/T$.

When $E_c - E_d$ is small, as is true for many of the semiconductors of interest, the exponential increase in n with T predicted by Eq. (17) occurs over only a small temperature range. As the temperature is increased further, more electrons are excited to the conduction band. The conduction band is preferred over the donor levels in the competition for electrons because of its greater density of states. With more electrons in the conduction band E_F must move down; the total number of disposable electrons, $N_d - N_a$, is kept constant by reducing the number in the donor levels. There follows a temperature range in which, as E_F is moving down, there is substantially complete ionization of the donor levels, and $n \simeq N_d - N_a$. This temperature range starts as soon as E_F has fallen several kT below E_d, and is called the saturation range. With further increase in temperature E_F continues to drop until it reaches a position a few kT above midgap. When this occurs, holes begin to be produced, indicating the approach of intrinsic conductivity. Further increase in temperature brings E_F close to E_F of Eq. (16), thus essentially to the intrinsic condition.

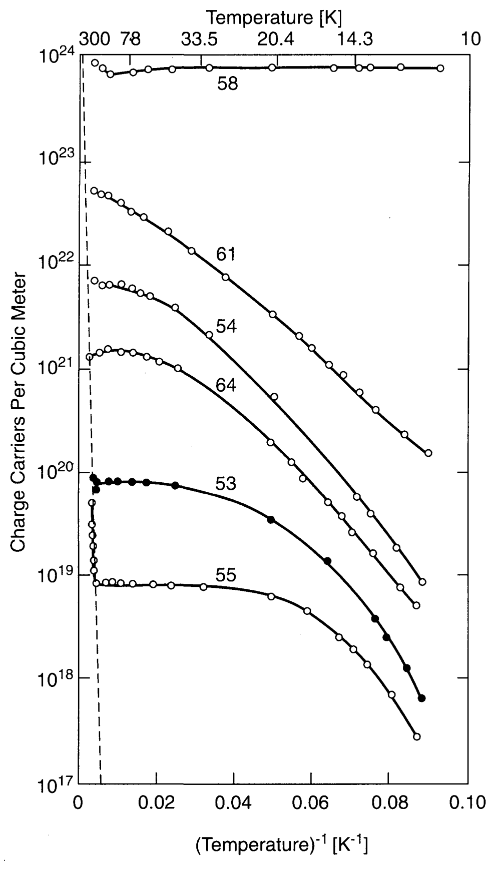

FIG. 6. Density of charge carriers vs the reciprocal of temperature for a set of As-doped Ge samples identified by numbers 55,53,.... The dashed line represents the density of intrinsic carriers. (Adapted from Debye and Conwell, 1954.)

Experimental data (obtained from Hall measurements) for n vs $1/T$ of a set of Ge samples doped with different amounts of As are shown in Fig. 6. In accordance with the above results it is seen that for all but the most heavily doped sample n is small and increases exponentially with $1/T$ at low temperatures. The increase becomes less rapid as T grows, and finally n reaches a saturation value, $N_d - N_a$, when essentially all the donors are ionized. With further increase in T the sample goes into the intrinsic range, n and p both increasing rapidly. For more heavily doped (or small-gap semiconductor) samples the intrinsic range may set in before saturation is achieved. The case of the most heavily doped sample, number 58, will be taken up in the next section.

A systematic procedure for finding E_F as a function of T is based on the requirement for electrical neutrality: the sum of the positive charges in the sample must equal the sum of the negative charges. The statement of this requirement for the situation of Fig. 5 is

$$p + p_a + N_d = n + n_d + N_a, \qquad (18)$$

where p_a is the number of holes in acceptor levels. From the definition of $f(E)$, $p_a = N_a[1 - f(E_a)]$ and $n_d = N_d f(E_d)$. With these expressions for p_a and N_a, and Eqs. (13) and (14), all quantities in Eq. (18) that depend on E_F are expressed in terms of E_F. Equation (18) may then be solved graphically for E_F for any set of N_d and N_a at any desired temperature (Shockley, 1950).

4.2.2 Heavily Doped Samples. For $N_d > 10^{24}$ m^{-3} it is found, as seen in the most heavily doped sample of Fig. 6, that $n \simeq N_d$ and essentially constant up to room temperature. (N_a should be negligible for such high doping.) This is the behavior of a metal. Material with such high doping is called degenerate because the carriers obey degenerate or Fermi–Dirac statistics, Eq. (8) rather than Eq. (12). The constancy of n with T means E_F must be constant with T in this case. This requires that E_F be at least several kT above the conduction-band edge. An exact description of the situation is not easily made because at such high concentration impurity levels overlap and mix with the conduction band. For further discussion see Sec. 8.

4.3 Nonequilibrium Carrier Concentration: Photoconductivity

4.3.1 Intrinsic Photoconductivity. In a semiconductor a photon of energy greater than the energy gap may raise an electron from the valence band to the conduction band, creating an electron and a hole (see Ryvkin, 1964). In some materials, particularly at low temperatures, the attraction of the electron and hole causes them to be bound to each other, the bound entity being called an exciton (see EXCITONS). In many materials, however, the electron and hole are free and may add to the conductivity. The number of electrons or holes generated per unit time per unit volume is given by the product of the number of photons (of energy greater than E_g) absorbed per unit time per unit volume and the probability β that an absorbed photon will create an electron–hole pair. β is called the quantum yield and in many cases has the value unity. For a thin sample and a wavelength of light not strongly absorbed, the number of photons absorbed per unit time per unit volume is the product of the number I incident on unit area of the surface per unit time and α, the fraction absorbed per unit distance the light travels in the sample. When the fraction of photons absorbed is not small it is necessary to allow for the decrease in the number as the light travels.

When a sample is illuminated with a light source of constant I it is found that the number of electrons and holes grows with time, at first rapidly and then more slowly, reaching a steady value or saturation. The rate of growth decreases because excess carriers tend to recombine. Saturation occurs when the recombination rate equals the generation rate. We can characterize the recombination rate by introducing average lifetimes τ_n and τ_p for electrons and holes, respectively. Using the generation rate $\beta\alpha I$ obtained above, we may write for the steady-state densities of electrons and holes $\beta\alpha I\tau_n$ and $\beta\alpha I\tau_p$, respectively. The lifetimes vary widely, typically ranging from 10^{-2} s to fractions of a microsecond.

Electrons and holes may recombine directly, i.e., an electron falls into a hole in the valence band, in which case $\tau_n = \tau_p$. The energy given up in this process, essentially E_g, may be in the form of heat (specifically phonons; see Sec. 6.1) or radiation. Radiative recombination is the process that results in light-emitting diodes (*q.v.*) or semiconductor lasers (see LASERS, SEMICONDUCTOR). The alternative to direct recombination is sequential capture of an electron and a hole, or vice versa, by a defect. Such defects are called recombination centers. When these centers mediate the recombination process, τ_n may be quite different from τ_p.

4.3.2 Extrinsic Photoconductivity. In a semiconductor with electrons in a donor level $E_c - E_d$ below the conduction band, a photon of energy $E_c - E_d$ or greater can raise electrons to the conduction band, resulting in a conductivity increase. Similarly, photons could excite electrons from the valence band into empty acceptor levels in the gap, resulting in an increase in hole concentration. The resulting increase in κ can be used for photodetection. (see PHOTODETECTOR DEVICES). The small amount of energy required to free an electron or a hole from a hydrogenic center in Ge or Si, for example, makes these and other semiconductors useful for infrared detectors.

5. FORMAL THEORY OF CONDUCTIVITY AND THE HALL EFFECT

5.1 Effects of Electric and Magnetic Fields on the Carriers

The force on an electron or hole due to an electric field **E** and a magnetic field **H** is given by

$$\mathbf{F}=e\mathbf{E}+e\mathbf{v}\times\mathbf{H}\,, \tag{19}$$

where e is negative for electrons, positive for holes, and **v** is the velocity of the electron or hole. The velocity of an electron or hole in a lattice is shown by band theory (see ELECTRONIC TRANSPORT IN SOLIDS) to be

$$\mathbf{v}=\nabla_p E=(1/\hbar)\nabla_k E\,. \tag{20}$$

For the simple model of band structure, with E given in Fig. 3, Eq. (20) leads to $\mathbf{v}=\mathbf{P}/m^*=\hbar\mathbf{k}/m^*$, the free-electron result with m_0 replaced by m^*. Thus **v** is parallel to **k**. For the many-valley model that need not be the case. By definition of the ∇ operator, **v** must be perpendicular to the constant-energy surfaces. Only for **k** along one of the ellipsoid axes will **v** be parallel to **k**.

As is expected by analogy with Newton's second law, the effect of a force on an electron or hole in a lattice is to change its momentum, i.e.,

$$\mathbf{F}=\frac{d\mathbf{P}}{dt}=\hbar\frac{d\mathbf{k}}{dt}\,. \tag{21}$$

5.2 The Relaxation Time

In the absence of an electric field the carriers are moving with random thermal velocities, but of course the net velocity vanishes when the velocities of all the carriers are summed up. In the presence of the field each carrier experiences the force $\mathbf{E}e$, which accelerates it and increases its velocity in the direction of the force. If the lattice were perfect the increase would continue indefinitely and the conductivity would be infinite. Of course the lattice is not perfect and the acceleration is interrupted on the average after a time τ when the carrier is scattered by, or collides with, a defect. We will assume, as turns out to be the case for most types of defect, that after each collision, i.e., after the time τ, the carrier has forgotten the acceleration it gained from the field and the acceleration process starts anew. We may therefore take the rate of loss of momentum due to collisions to be

$$\frac{d\mathbf{P}}{dt}=-\frac{\mathbf{P}}{\tau}\,. \tag{22}$$

Integration of this equation shows that excess momentum decays exponentially as $\exp(-t/\tau)$. τ is therefore called the momentum relaxation time. In the remainder of this section we will derive expressions for the conductivity, Hall effect, and magnetoresistance in terms of τ. Section 6 will be devoted to calculating τ for the most important scatterers: lattice atoms out of place as a result of their thermal vibrations, and foreign ions or atoms.

5.3 Calculation of dc Conductivity

Combining Eqs. (19) and (22) we obtain for the rate of momentum change of a single carrier

$$\frac{d\mathbf{P}}{dt}=e\mathbf{E}+e\mathbf{v}\times\mathbf{H}-\frac{\mathbf{P}}{\tau}\,. \tag{23}$$

Let us assume for the moment that all carriers have the same τ, i.e., that τ is not a function of the energy of the carrier. We may then sum Eq. (23) over all the carriers and obtain, for the simple model of the band structure,

$$\frac{d(m^*\mathbf{v}_d)}{dt}=e\mathbf{E}+e\mathbf{v}_d\times\mathbf{H}-\frac{m^*\mathbf{v}_d}{\tau}\,, \tag{24}$$

$\mathbf{v}_d$ being the drift velocity. For the steady state in a constant dc field $d(m^*\mathbf{v}_d)/dt=\mathbf{0}$. In the absence of a magnetic field Eq. (24) then gives

$$\mathbf{v}_d=(e/m^*)\tau\mathbf{E}\,. \tag{25}$$

With this equation and the definition, Eq. (2), of the mobility μ, we find for the simple model

$$\mu=(e/m^*)\tau\,, \tag{26}$$

and the dc conductivity is given by

$$\kappa_0=(ne^2/m^*)\tau\,. \tag{27}$$

Allowing for the variation of τ with energy E, we find with a more accurate theory (see, for example, Herring, 1955, or Conwell, 1982) that τ in Eqs. (25)–(27) is replaced by the weighted average $\langle E\tau\rangle/\langle E\rangle$.

For the many-valley model μ is a tensor. But the semiconductor crystals of greatest interest are cubic, and for low electric fields the mobility must be the same in all directions. To obtain the correct μ we must therefore average over the different valleys. The result is to replace $1/m^*$ in Eqs. (25)–(27) by an average inertial mass

$$1/m^{(I)}=\tfrac{1}{3}\,(2/m_t+1/m_l) \tag{28}$$

when the constant-energy surfaces are ellipsoids of revolution.

5.4 ac Conductivity

Consider now the case where the electric field applied to the sample is oscillatory, i.e., $\mathbf{E}=\mathbf{E}_0\, e^{i\omega t}$, where ω is the angular frequency. Such a field sets up an oscillatory current with the same frequency and thus a drift velocity $\mathbf{v}_d=\mathbf{v}_d^0\, e^{i\omega t}$. When these expressions for $\mathbf{E}$ and $\mathbf{v}_d$ are inserted into Eq. (24) with $\mathbf{H}=\mathbf{0}$, and the solution rationalized, we find the ac conductivity

$$\kappa(\omega)=\frac{ne^2\tau/m^*}{1+\omega^2\tau^2}-i\omega\,\frac{ne^2\tau^2/m^*}{1+\omega^2\tau^2}\ . \tag{29}$$

The conductivity being complex reflects the fact that, at all frequencies for which $\omega\tau$ is not negligible compared to unity, the carriers can no longer follow the field. The current then consists of a part in phase with the applied field, the first term, and a part 90° out of phase, the second term. Comparing with Eq. (27) we see that the in-phase conductivity is κ_0 reduced by the factor $(1+\omega^2\tau^2)^{-1}$. By inserting the current $\kappa(\omega)\mathbf{E}_0e^{i\omega t}$ into Maxwell's equations it is found that $1/\omega$ times the imaginary part of $\kappa(\omega)$ represents a contribution to the permittivity ε. This free-carrier contribution to ε is negative because it is 180° out of phase with the displacement current. For n and τ large and $\omega\tau$ not too large, this contribution may be large enough to make ε negative. Again, when τ is allowed to be a function of E the quantities involving τ must be replaced by averages. For the many-valley model $1/m^*$ is replaced by $1/m^{(I)}$ defined in Eq. (28).

5.5 The Hall Effect

5.5.1 Low Magnetic Fields. From Eq. (24), using Eqs. (1) and (27), we find for the steady state of electrons with the simple model of the band structure in a magnetic field

$$\mathbf{E}=(\mathbf{j}/\kappa_0)-(1/ne)\mathbf{j}\times\mathbf{H}\ . \tag{30}$$

If we assume the conditions of a Hall-effect experiment—$\mathbf{H}=H_z$, applied field $\mathbf{E}_x$, and current flowing only in the x direction—we find from Eq. (30) to terms linear in H that $E_x=j_x/\kappa_0$ and

$$E_y=(1/ne)j_xH_z,\quad \tau\neq\tau(E)\ . \tag{31}$$

According to Eq. (31) the Hall constant R_H, defined in Sec. 1.5 as E_y/j_xH_z, is

$$R_\mathrm{H}=-1/n|e|\ \text{for electrons,}\quad \tau\neq\tau(E)\ ; \tag{32}$$

$$R_\mathrm{H}=1/p|e|\ \text{for holes,}\quad \tau\neq\tau(E)\ . \tag{33}$$

If we allow τ to be a function of energy, the quantity $R_\mathrm{H}ne$ or $R_\mathrm{H}pe$ is no longer unity but is given by μ_H/μ, according to Sec. 1.5. Calculations (for example, Herring, 1955, or Conwell, 1982) lead to

$$\frac{\mu_\mathrm{H}}{\mu}=\frac{\langle E\tau^2\rangle\langle E\rangle}{\langle E\tau\rangle^2}\,B\,, \tag{34}$$

where B depends on the shape of the constant-energy surfaces. Such a dependence is to be expected because a magnetic field, which cannot change the energy of a carrier, causes the carriers to rotate around the constant-energy surfaces. $B=1$ for spherical constant-energy surfaces and is generally of the order of unity. The other factor in μ_H/μ will be seen to lie between 1 and 2 for the important scattering mechanisms.

5.5.2 The Hall Effect for Two Types of Carriers. There are two situations in which we must deal with more than one type of carrier. In intrinsic or nearly intrinsic samples both electrons and holes are present. In a semiconductor with degenerate bands we must deal with sets of electrons or holes with different effective masses or, more generally, different effective-mass tensors. It is usually a good approximation to treat the different types as independent. When an electric field is applied without a magnetic field, j and κ are given by the sum of the contributions of each kind of carrier regardless of sign. When a magnetic field is applied in addition to the electric field, this is no longer the case. Holes drifting in an electric field are pushed by a magnetic field in the same direction as electrons because both v_d and e are opposite in sign to those of electrons. The resulting Hall field is then the difference of the two fields.

Quite generally, for two types of carriers, denoted by subscripts 1 and 2, it is found that

$$R_\mathrm{H}=\frac{n_1e_1\mu_1\mu_{\mathrm{H}1}+n_2e_2\mu_2\mu_{\mathrm{H}2}}{(n_1|e_1|\mu_1+n_2|e_2|\mu_2)^2}\ . \tag{35}$$

If the two carriers are opposite in sign, the Hall voltage will go through zero when

$$n_1\mu_1\mu_{H1}=n_2\mu_2\mu_{H2}\ . \tag{36}$$

For the semiconductors we are discussing this will happen when p is somewhat greater than n because μ_n is generally larger than μ_p. If there are two carriers present with the same sign, as is generally the case for p-type column IV and III-V semiconductors, the ratio of R_H to the total carrier concentration may be increased by as much as a factor of 2 because μ of the light holes is much greater than μ of the heavy holes.

5.5.3 High Magnetic Fields. In the limit of high magnetic fields, although not so large that quantum effects occur, it is found theoretically that R_H goes to the value $1/ne$ or $1/pe$. Thus μ_H/μ is unity at high fields independent of the details of band structure and energy dependence of τ. For a sample with both electrons and holes, R_H in the high-field limit goes to $1/(n-p)e$.

As will be seen in Sec. 5.6, a high magnetic field is specified by the condition $\mu H\gg 1$. Thus, for example, the high-field condition is satisfied at lower values of **H** for light holes than for heavy holes. This can explain the fact that R_H for p-Ge, measured at a typical field (3000 Oe), was observed to decrease by a factor of 1.6 as T was decreased from 300 to 78 K. Clearly this decrease could not represent an increase in p with decreasing T. Nor, as will be seen, could it be accounted for by a change in $\tau(E)$. The explanation is that, with decreasing T, μ increases for both light and heavy holes. The light holes, with their higher μ, go into the high-**H** regime at a higher temperature than the heavy holes, decreasing their value of μ_H. As can be seen from Eq. (35) this decreases R_H considerably.

It can be concluded from this section that the carrier concentration deduced from measurements of the Hall effect is uncertain within about a factor of 2 unless one knows a great deal about the carrier mobilities and the detailed scattering mechanisms.

5.6 Magnetoresistance

It is readily seen from Eq. (30) that for the simple model with $\tau\neq\tau(E)$ there is no change in resistance in a magnetic field, i.e., no magnetoresistance. The resistivity may be calculated from the component of **E** along **j** divided by **j**, i.e., $\rho=\mathbf{j}\cdot\mathbf{E}/|j|^2$. According to Eq. (30) $\rho=1/\kappa_0$, independent of **H**. Magnetoresistance is a result of $\tau=\tau(E)$ or of nonspherical constant-energy surfaces.

To understand the situation for $\tau=\tau(E)$ we solve Eq. (30) for **j**, with the result

$$\mathbf{j}=\frac{\kappa_0\mathbf{E}}{1+\mu^2H^2}+\frac{\kappa_0\mu(\mathbf{E}\times\mathbf{H})}{1+\mu^2H^2}\ . \tag{37}$$

We have simplified the situation by assuming that $\mathbf{E}\perp\mathbf{H}$. For $\mathbf{E}=E_x$, $\mathbf{H}=H_z$, the first term on the right-hand side of Eq. (37) represents j_x, the second j_y. It is seen that

$$j_y=\mu Hj_x=(He/m^*)\tau j_x. \tag{38}$$

This equation expresses the fact that j_y is produced by rotation of j_x in the magnetic field. The quantity He/m^*, called the cyclotron frequency, is the rate at which carriers rotate around the constant-energy surfaces in a magnetic field, while τ is the mean time to undergo a collision, which redirects the carrier and effectively interrupts the rotation. Because carriers with different τ have different j_y, it is not possible to find an electric field that will keep currents due to carriers with different τ's in the same direction. The net current is therefore reduced, making the apparent resistance of the medium larger.

Because the magnetic field dependence of **j** occurs in the form μH, a small magnetic field is defined by $\mu H\ll 1$. From Eq. (37) it is seen that for small μH, where $(1+\mu^2H^2)^{-1}$ may be expanded as a power series in μ^2H^2, $\Delta\rho$ increases as H^2. It is also seen that, in the limit $\mu H\gg 1$, ρ does not keep on increasing, but saturates.

For ellipsoidal constant-energy surfaces the magnetoresistance is a function of the orientation and shape of the constant-energy ellipsoids. As a result, measurements of magnetoresistance may make it possible to determine the location and parameters of the ellipsoids in a many-valley structure. For detailed calculations of magnetoresistance for the many-valley model see Herring (1955).

5.7 Thermoelectric Effect

A temperature gradient across a sample causes the Fermi energy to vary with position. This can give rise to a current even in the absence of an applied field. In an isolated sample the flow of charge results in an electric field that prevents further charge from flowing. Thermoelectric power, or thermopower for short, is defined as the ratio of the field developed to the temperature gradient. The thermopower Q is related to the Peltier coefficient Π, defined as the energy flux, measured relative to E_F, per unit current. The relation is $Q = \Pi / T$. It follows from this relation that, when one type of carrier is present,

$$Q = \mp \frac{k}{|e|} \left(\frac{|E_F - E_b|}{kT} + \frac{|\Delta E_T|}{kT} \right), \tag{39}$$

where the upper sign is for electrons, the lower for holes, $|E_F - E_b|$ is the distance of E_F from the conduction- or valence-band edge, and $|\Delta E_T|$ is a weighted average of the energy transported per carrier (across unit area in unit time) relative to the band edge. Specifically $\Delta E_T = \langle v^2 (E - E_b) \tau \rangle / \langle v^2 \tau \rangle$. The dependence of Q on the sign of the carriers means that, like the Hall effect, it can be used to determine whether the dominant carriers are electrons or holes. For a moderately doped semiconductor sample, Q varies a great deal with T because, as we have seen, E_F does. Q can be expressed in terms of the carrier concentration by using relation (13) or (14) to express E_F in terms of n or p, respectively. Other things being equal, Q is smaller for more heavily doped samples. In samples where electrons and holes are present in comparable numbers we have

$$Q = (Q_n \kappa_n + Q_p \kappa_p) / (\kappa_n + \kappa_p) . \tag{40}$$

5.8 Galvanomagnetic and Thermomagnetic Effects

These effects occur when a conductor carrying an electric current or thermal current, which may arise as a result of a thermal gradient, is placed in a magnetic field. In the isothermal situation discussed earlier in this section, introduction of a transverse magnetic field was found to give rise to the Hall effect and magnetoresistance. When thermal gradients are permitted, many additional galvanomagnetic effects occur. One of these is the Ettingshausen effect, the appearance in a transverse magnetic field of a temperature gradient perpendicular to both **H** and the current direction. Another is the Nernst effect in which, due to the transverse magnetic field, a temperature gradient appears parallel to the current direction. This by no means exhausts the possible galvanomagnetic effects. Among the thermomagnetic effects are magnetic field effects on thermal conductivity (analogous to magnetoresistance) and thermopower. The Righi–Leduc effect, a thermal analog of the Hall effect, is the appearance in a transverse magnetic field of a thermal gradient perpendicular to both **H** and the thermal current direction. In the Ettingshausen–Nernst effect the combination of thermal current and transverse magnetic field produces an electric field perpendicular to both. Many additional thermomagnetic effects could be specified. For a systematic listing of these effects see, for example, Conwell (1982).

6. RELAXATION TIMES AND MOBILITIES

Mobility in semiconductors is found to vary greatly with temperature and doping. In Fig. 7 are shown Hall mobility data versus temperature for the set of Ge samples whose carrier concentration variation with T was shown in Fig. 6. The least doped, thus purest, sample has the highest μ_H. Comparing it with the dashed line indicating a $T^{-3/2}$ dependence, we see that above ~100 K, μ_H for this

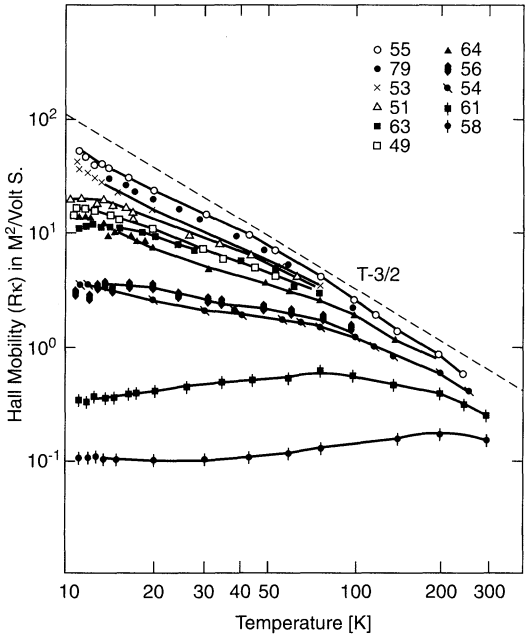

FIG. 7. Hall mobility vs temperature for the set of As-doped Ge samples for which n vs T is shown in Fig. 6. (After Debye and Conwell, 1954.)

sample decreases more rapidly with increasing T, while below ~100 K, the decrease is less rapid than $T^{-3/2}$. It will be shown shortly that the $T^{-3/2}$ dependence arises from scattering due to one kind of thermal vibration, the so-called acoustic modes. The steeper slope above 100 K indicates that another type of scattering, which can be attributed to another type of thermal vibration, is also operative. The progressively smaller mobility, and the less steep decrease with increasing temperature, seen with increasing doping will be shown to result from scattering by the doping ions.

In this section we discuss the momentum relaxation time τ defined in Eq. (22) for the most important scattering mechanisms. Also mobilities are given for these scattering mechanisms. At the end of the section we will present a more detailed comparison with experimental data.

6.1 Scattering Due to Lattice Vibrations

6.1.1 Acoustic and Optical Modes. The random thermal motion of the lattice atoms can be described as the superposition of a set of normal modes, each mode describing the displacement of every atom in the sample in terms of a propagating wave of a single frequency (see PHONONS IN CRYSTAL LATTICES). Because of the periodicity of the lattice, there is associated with each wave, as with each electron wave function, a wave vector in the direction of propagation. This wave vector will be denoted by **q** to distinguish it from the electron wave vector **k**. By the same reasoning as employed earlier for the **k**'s, the **q**'s have a closely spaced set of discrete values and occupy the first Brillouin zone. Frequency ν of the normal modes in Si versus wave vector is shown in Fig. 8. It is seen that in most directions there are four branches. These are labeled L for longitudinal and T for transverse, indicating that the vibrations are parallel to **q** and perpendicular to **q**, respectively. Actually the vibrations are not purely longitudinal or transverse in an actual crystal, but the difference is usually neglected. It is also usual, at least in conductivity theory, to neglect the differences between ν vs q for a given branch in different directions.

The branches that start at $q=0$ (the Γ point) are called acoustic branches. The low-frequency modes of the LA branch are familiar as sound waves. The other branch is called transverse acoustic (TA). In the low-frequency acoustic vibrations the two atoms in the unit cell move almost together, i.e., with only a small phase difference between them. Another type of long-wavelength vibration is possible: the two atoms in the unit cell move opposite to each other, with the same motion repeated in the next cell slightly earlier or later depending on the propagation direction of the wave, i.e., in a slightly different phase. These vibrations can also be both longitudinal and transverse. They are called optical modes (TO or LO) because, in a lattice with ions of opposite sign, they produce a polarization that can interact with light waves.

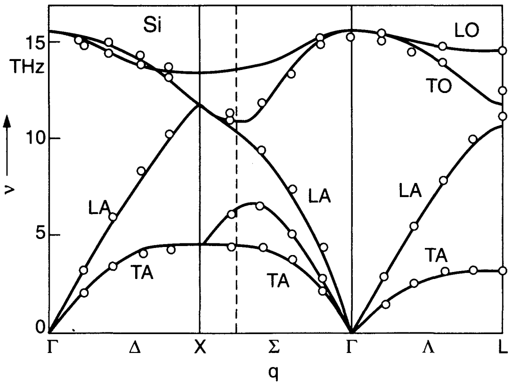

FIG. 8. Frequency ν vs wave vector **q** of normal modes of lattice vibration in Si for various directions in the Brillouin zone. (Adapted from Madelung, 1991.) See Fig. 2 for identification of the directions.

For the long-wavelength acoustic waves ν and the wavelength λ are related according to $\nu\lambda=\text{const}$. This constant is identified as the phase velocity, which for the LA branch is the sound velocity. In contrast to the acoustic branches, for the two optical branches ν is quite large for long wavelengths, i.e., close to $q=0$. The reason is that the opposing motion of the two atoms in the unit cell gives rise to a large restoring force and therefore a high frequency of vibration even for very large wavelengths. This has the further consequence that ν is not strongly dependent on λ, i.e., the optical branches are relatively flat, because λ only determines the relative phase of adjacent unit cells.

The vibrational energies of each normal mode can only have certain discrete values differing by amounts $h\nu$. The energy steps or quanta are called phonons, as suggested by the analogy with light quanta or photons. For a crystal in thermal equilibrium the average number of phonons n_q in a normal mode having frequency ν_q is given by Planck's law:

$$n_q = 1/(e^{h\nu_q/kT} - 1) \ . \qquad (40)$$

Thus around room temperature and below, the average number of optical phonons will be small because $h\nu$ for these phonons is larger than kT at room temperature.

6.1.2 Mobility Due to Acoustic-Mode Scattering. In the process of being scattered by the thermal vibrations, a carrier must emit or absorb a phonon. If the carrier wave vector changes from **k** to **k**′ in the process, while the phonon wave vector is **q**, conservation of momentum requires $\mathbf{k}' = \mathbf{k} \pm \mathbf{q}$. Energy must also be conserved, requiring $E_{\mathbf{k}'} = E_{\mathbf{k}} \pm h\nu_{\mathbf{q}}$, $h\nu_{\mathbf{q}}$ being the energy of the phonon with wave vector **q**. The upper sign is required for absorption and the lower for emission. The probability of absorption or emission of a phonon, thus of scattering, is proportional to the number of phonons, given by Eq. (40). Let us consider first the case of long-λ, or low-q, acoustic phonons. For these phonons, at all but extremely low temperatures, $h\nu_q$ is small compared to kT; Eq. (40) then gives $n_q \propto kT/h\nu_{\mathbf{q}}$. The small energy of the phonons, coupled with the conservation of momentum and energy conditions, results in these acoustic phonons causing scattering only within a valley.

The probability of scattering by any given vibrational mode also depends on how strongly the carrier is coupled to that mode, which in turn depends on the strain caused by that mode. For acoustic waves the coupling is described by a deformation potential E_1, which is the shift in the band-edge energy per unit strain (for a cubic crystal the strain is the fractional change in volume of a small region of the crystal) due to the wave. Combining the various factors described above, we find for the relaxation time τ_{ac} due to long-λ acoustic-mode scattering of a carrier with the simple model of band structure

$$\tau_{\text{ac}} = \frac{\pi\hbar^4 \rho u_l^2}{2^{1/2} E_1^2 (m^*)^{3/2} kT} E^{-1/2} \ , \qquad (41)$$

where ρ is the density of the material and u_l the sound velocity. (Note that TA waves do not scatter in this case.) It is seen that τ_{ac} depends inversely on $E^{1/2}$, or the velocity of the carrier, resulting in slow carriers having longer relaxation times or being scattered less.

Inserting Eq. (41) in Eq. (26), allowing for the averaging over carrier energy, thus over the Maxwell–Boltzmann distribution in this case, we obtain the mobility for long-λ acoustic-mode scattering:

$$\mu_{\text{ac}} = \frac{2(2\pi)^{1/2} e\hbar^4 \rho u_l^2}{3E_1^2 (m^*)^{5/2} (kT)^{3/2}} \ . \qquad (42)$$

Thus μ_{ac} decreases with increasing T as $T^{-3/2}$, $T^{-1/2}$ coming from the fact that $\langle E^{-1/2} \rangle \propto (kT)^{-1/2}$ for the Maxwell–Boltzmann distribution. The calculation of τ_{ac} and μ_{ac} for the many-valley model is more complicated because τ may not be constant over a constant-energy surface, and shear strains may also be important (see Herring and Vogt, 1956). However, the dependence on carrier energy and T remain the same.

In III-V and II-VI semiconductors, because they are somewhat polar and lack inversion symmetry, the strain of an acoustic wave produces also an electric polarization (see DIELECTRIC PROPERTIES OF INSULATORS). This causes scattering in addition to the scattering studied above, which may be called deformation-potential scattering. The additional scattering is called piezoelectric or piezoacoustic scattering. In contrast to τ_{ac} of Eq. (41), the relaxation time τ_{pe} for piezoelectric scattering is directly proportional to $E^{1/2}$. As a result, except for strongly piezoelectric material such as CdS or ZnO, it is expected to be important only for low-energy carriers, and thus for low temperatures only. It will be seen that, except for very pure samples, impurity scattering is the dominant scattering mechanism at low temperatures. Thus, in materials that are not strongly piezoelectric, piezoelectric scattering need only be considered at low temperatures in pure samples. For further discussion of piezoelectric scattering see Zawadzki (1982) and references therein.

6.1.3 Mobility Due to Nonpolar Optical-Mode Scattering. Optical-mode scattering in nonpolar crystals may be treated quite similarly to acoustic-mode scattering. For the coupling to the optical modes it is necessary to introduce a different deformation potential because the strain, in contrast to that due to an acoustic phonon, is not simply a change in linear dimensions or volume. In the case of a zinc-blende or diamond structure the strain is a displacement of the two sublattices, based on the two atoms in a unit cell, with respect to each other. The appropriate deformation potential is D, the shift of the band edge per unit relative displacement of the two sublattices. Another difference between optical- and acoustic-mode scattering is that, because of the larger size of the optical phonons, the exponential in Eq. (40) may not be expanded; n_q must be taken from Eq. (40). The relaxation time for optical-phonon scattering (all phonons assumed to have the same frequency ν_0) is given by

$$\tau_{\mathrm{op}}=\frac{2^{3/2}\pi^2\hbar^3\rho\nu_0}{D^2(m^*)^{3/2}}\,[n_q(E+h\nu_0)^{1/2} + (n_q+1)(E-h\nu_0)^{1/2}]^{-1}\,. \tag{43}$$

The first term in the square brackets represents relaxation due to phonon absorption and the second relaxation due to phonon emission. The emission probability is proportional to n_q+1, n_q representing stimulated emission and 1 spontaneous emission. Emission is only possible, however, if $E>h\nu_0$. If $h\nu_0$ were negligible compared to E, as is the case for long-λ acoustic phonons, n_q and n_q+1 could be replaced by $kT/h\nu_q$ and τ_{op} would have the same dependence on E and T as τ_{ac}. Generalizing τ_{op} to the many-valley model is simple; it requires only replacing m^* by the geometric mean mass $(m_l m_t^2)^{1/3}$.

The mobility μ_{op} obtained after averaging τ_{op} over energy is usually larger than μ_{ac} because of the relatively small number of optical phonons. This same feature, however, results in μ_{op} decreasing more rapidly with increasing T as n_q increases, according to Eq. (40).

6.1.4 Mobility Due to Intervalley Scattering. Because of conservation of momentum, the **q** of a phonon that causes an intervalley transition will be approximately equal to the difference between the **k** vectors of the valley minima. This difference is usually of the order of the radius of the Brillouin zone, which means that the energy of the phonon required is comparable to the optical-phonon energy. The intervalley scattering may then be treated much like the optical-phonon scattering, leading to an expression for the intervalley scattering relaxation time τ_{iv} of the same form as τ_{op}. Of course, the deformation potential is different for this case, and high-energy acoustic phonons as well as optical phonons may be involved in the transition. Note that the energy in Eq. (41) or (43) must be measured from the bottom of the valley into which the carrier is scattered, which need not be the same energy as the bottom of the valley in which it originates. Also m^* of Eq. (42) must be replaced by the geometric mean mass.

6.1.5 Mobility Due to Polar Optical-Mode Scattering. Nonpolar optical scattering, discussed in Sec. 6.1.3, may exist in polar as well as nonpolar crystals. In polar crystals, however, the polarization of the crystal arising from the vibrations of the LO branch results in an additional interaction with the carriers, or scattering, the polar optical scattering. In the III-V semiconductors of most interest, GaAs and InSb, the polar optical scattering dominates over nonpolar scattering for electrons in the conduction band because the latter vanishes for spherically symmetric wave functions, which is more or less the situation for the conduction-band minimum at the Γ point. Polar optical-mode scattering is much more difficult to treat theoretically than nonpolar. A relaxation time does not exist unless $E\gg h\nu_0$, which requires temperatures well above room temperature. It is possible to get a qualitative idea of what is important by considering the mean free time between collisions, τ_{po}. For the simple model

$$\tau_{po}=(2m^*E)^{1/2}/2eE_0\{n_q\sinh^{-1}(E/h\nu_0)^{1/2} + (n_q+1)\sinh^{-1}[(E-h\nu_0)/h\nu_0]^{1/2}\}, \tag{44}$$

where $E_0=m^*e^2h\nu_0(1/\epsilon_\infty-1/\epsilon_0)/\hbar^2$, ϵ_∞ and ϵ_0 being the high-frequency and static permittivities, respectively. Note that Eq. (44) applies only for low carrier concentration because it neglects the screening of the electric fields due to the free carriers, which decreases the scattering effect.

Equation (44) may be used to predict the temperature dependence for polar optical scattering. For $\langle E\rangle\ll h\nu_0$ the energy dependence cancels out and the temperature dependence of μ_{po} is that due to $1/n_q$. In the other limit, $\langle E\rangle\gg h\nu_0$, the E dependence arising from the

$\sinh^{-1}$ terms becomes logarithmic and may be neglected. The combination of $E^{1/2}$ and n_q^{-1} dependence in this limit yields $\mu_{\mathrm{po}} \propto T^{-1/2}$. For a detailed treatment of polar optical scattering see Zawadzki (1982) and references therein.

6.2 Impurity Scattering

The donors and acceptors that have given up an electron to the conduction band, or a hole to the valence band, are left charged. The charge results in an attraction or repulsion of the carriers, depending on the sign of the charge. In either case the carriers are deflected, thus scattered. There have been many calculations of the relaxation time for scattering by impurity ions, τ_I, varying in degree of sophistication and in which refinement of the process they concentrated on. A treatment that gives reasonably good agreement with experiment for not too heavily doped (nondegenerate) samples leads to

$$\tau_I = \frac{2^{1/2}}{\pi} \frac{(m^*)^{1/2}\epsilon^2}{e^4 N_I} \frac{E^{3/2}}{\ln(1+\xi) - \xi/(1+\xi)}, \tag{45}$$

where, for a sample with carrier concentration n, $\xi = (8\pi\epsilon m^* kT/ne^2h^2)E$, N_I being the number of ionized impurities per unit volume. The quantity ξ arises from the screening of the ions by the free carriers. For degenerate samples ξ is independent of T, although it still depends on E. Unless the sample has almost as many acceptors as donors (the reverse for a p-type sample), n may be taken equal to N_I. For moderately doped samples around room temperature $\xi \gg 1$, and Eq. (45) predicts that τ_I decreases as N_I increases, and that slow carriers are deflected or scattered more than fast carriers, both of these effects being expected. As the temperature decreases the terms involving ξ have more effect and τ_I increases less rapidly with E. The expression given above for ξ no longer represents the screening properly when many of the carriers have dropped out of the conduction band (or valence band), and n must be replaced by a quantity involving both the donor and acceptor concentrations. See, for example, Chattopadhyay and Queisser (1981), where also many of the improvements on the theory presented above are discussed.

Carrying out the averaging over carrier energy, we obtain from Eq. (45) the impurity mobility

$$\mu_I = \frac{2^{7/2}}{\pi^{3/2}} \frac{\epsilon^2 (kT)^{3/2}}{(m^*)^{1/2} e^3 N_I} \frac{1}{\ln(1+\bar{\xi}) - \bar{\xi}/(1+\bar{\xi})}, \tag{46}$$

where $\bar{\xi} = 24\pi\epsilon m^* (kT)^2/ne^2h^2$. In this form μ_I is valid for nondegenerate samples at temperatures where most of the carriers are still free. It increases with T less rapidly than $T^{3/2}$ because of the terms in $\bar{\xi}$. For degenerate samples $E \simeq E_{\mathrm{F}}$, independent of temperature, and with ξ independent of T, as pointed out earlier, μ_I is independent of T. This explains the fact that the Hall mobility of sample 58 in Fig. 8, which is both degenerate and so heavily doped that impurity scattering dominates, is essentially independent of T.

6.3 Neutral-Impurity Scattering

As the temperature falls carriers return to the donors or acceptors and the number of neutral impurities increases. When neutral the impurities still scatter carriers. Because of the analogy, discussed in Sec. 3, between a neutral impurity and a hydrogen atom, the scattering has been treated similarly to scattering of a free electron by hydrogen (see ELECTRON SCATTERING BY ATOMS AND MOLECULES). The result is that at low temperatures ($T < 20$ K for Si and < 4 K for Ge) the relaxation time τ_N for scattering by a concentration N_N of neutral impurities is given by

$$\tau_N = (m^*/2)^{1/2} \pi (a_{\mathrm{H}}^*)^2 N_N \times [(E/E_b^* + 0.0275)^{-1} + 10]^{-1} E^{-1/2}, \tag{47}$$

where a_{H}^* and E_b^* are defined in Eqs. (6) and (7), respectively (Zawadzki, 1982). Modifications for the many-valley model do not change τ_N greatly. Experimental verification of Eq. (47) is difficult because there are few free electrons at such low temperatures, and the effects of other scattering mechanisms must be subtracted. Nevertheless there are low-temperature data for Ge that indicate that μ_N

varies as $T^{-1/2}$, as predicted by Eq. (47). At higher temperatures μ_N is predicted to go to a constant value (Zawadzki, 1982).

6.4 Combination of Mobilities

In general, at any given temperature, more than one scattering mechanism is operative. To find the mobility one must first calculate an overall relaxation time τ by combining the τ's for the individual scattering mechanisms (which are essentially probabilities of scattering per unit time) according to $1/\tau = \Sigma_i(1/\tau_i)$. The resulting τ must then be averaged over energy to obtain μ. It is not unusual for this procedure to be simplified by calculating μ's for each scattering process and combining the reciprocals of these μ's to obtain the reciprocal of the overall μ. For the combination of acoustic-mode and ionized-impurity scattering the error due to this simplified procedure may be as much as 30%.

6.5 Comparison with Experimental Data

For well-characterized semiconductors, such as Si, Ge, and GaAs, the foregoing theory, with some refinements, agrees well with experiment for moderately doped and intrinsic samples. For *n*-Si around room temperature in very pure samples $\mu \propto T^{-2.42}$, resulting from an admixture of μ_{ac} ($\propto T^{-1.5}$) and μ_{iv} due to scattering between the [100] valleys. The latter has a much steeper T dependence arising from the large energy of the phonons required. Below 50 K the energy required for the intervalley process is too high to allow this process to occur, and in pure samples $\mu = \mu_{\text{ac}}$. For pure samples of *p*-Si and *p*-Ge around room temperature $\mu \propto T^{-2.33}$ from a mixture of μ_{ac} and nonpolar optical scattering. Plots of experimental and theoretical μ vs T for the cases just cited and for other intrinsic semiconductors may be found in Madelung (1991). Comparison of theory with experiment for a moderately doped *n*-type GaAs sample is shown in Fig. 9. It is seen that polar optical scattering dominates at high temperatures while impurity scattering dominates at low temperatures. In purer samples piezoelectric scattering may dominate at low temperatures.

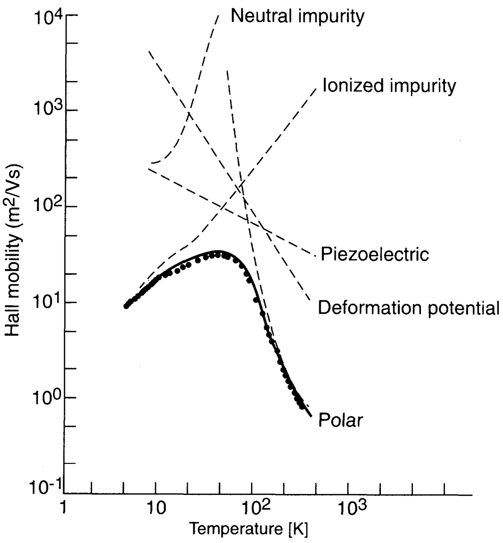

FIG. 9. Dots: The measured mobility of electrons in a sample of *n*-GaAs vs temperature. Dashed lines: Theoretical mobilities calculated for the various scattering process indicated. Solid line: The combined mobility calculated from all the scattering processes. (After Fletcher and Butcher, 1972.)

7. HIGH-FIELD TRANSPORT

7.1 Hot Carriers

In this section we consider only nondegenerate samples, i.e., samples in which the carrier energies in the absence of an electric field are given by the Maxwell–Boltzmann distribution, Eq. (12). The effects to be described cannot be achieved with heavily doped samples. In the absence of an electric field the carriers interact with phonons, emitting and absorbing them, while the Maxwell–Boltzmann distribution of carrier energies and the Planck distribution of phonon numbers, Eq. (40), are maintained. Application of an electric field, which accelerates the carriers, increases their energy. This results in an increase in their rate of phonon emission, giving rise to the well-known Joule heating that accompanies a current. Achievement of a steady state, the situation for dc current, requires that the rate at which the electric field puts energy into the carriers equals the rate at which they lose energy through phonon emission. The rate of energy gain is $\mathbf{F}\cdot\mathbf{v}_d$, which, given Eqs. (19) and (2), equals $e\mu|\mathbf{E}|^2$. With $\langle dE/dt\rangle$ representing the average rate of energy loss, the steady-state condition may be written

$$e\mu|\mathbf{E}|^2=\left\langle\frac{dE}{dt}\right\rangle . \qquad (48)$$

In small electric fields, satisfying the condition (48) requires little change in the distribution, the essential change being the addition of a small drift term to the Maxwell–Boltzmann distribution. A high electric field may be defined as one for which this is no longer true. In semiconductors a steady state is always possible, but in high fields the drift term may not be small and the part of the distribution that is independent of the field direction no longer corresponds to an average energy of $\frac{3}{2}kT$, where T is the lattice temperature. It may still be the case that the latter part of the high-field distribution is reasonably described by a Maxwell–Boltzmann distribution, but the carrier temperature involved, denoted by T_e, is greater than the lattice temperature. For this reason the carriers are called "hot." Even when the high-field distribution is not Maxwellian it is usual to speak of a carrier temperature, which may be defined by equating the average carrier energy to $\frac{3}{2}kT_e$. It should be noted that to perform clear-cut experiments to measure hot-carrier effects it is necessary to apply the high electric field in pulses of low repetition rate to avoid raising the lattice temperature. When that is not possible it is necessary to consider the effects of a nonequilibrium phonon distribution along with the hot-electron effects.

From the preceding discussion it is clear that the higher the mobility of a material, the lower will be the magnitude of the electric field required to create hot carriers. High mobility means that the field can give the carriers energy at a high rate. It also suggests that the coupling to phonons is not strong, with the consequence that the rate of energy loss to phonons is not large.

Hot electrons may also be created by light. When a photon is absorbed by an electron, the electron energy is increased by the amount of the photon energy. Another method of creating hot electrons is through a potential step. A junction of two semiconductors with different band gaps (heterojunction) constitutes such a step. When an electric field is applied in the appropriate direction, electrons moving with thermal energy in the wide-band-gap region cross into the narrow-band-gap region. There they find themselves well above the conduction-band edge. In other words, the energy difference between the conduction-band edges in the two regions is converted into kinetic energy. In such a situation, before the carriers have undergone the collisions that set up a steady state their velocities exceed the steady-state drift velocity. This phenomenon is called velocity overshoot. It occurs also when, because of a sudden change in electric field intensity, the distribution of carriers has not yet reached its steady state. Velocity overshoot has been detected by electrical methods (Hess, 1990) and optical methods (Auston, 1990). It is of practical interest because it could be used to make faster devices. A potential step such as the heterojunction described above can also be used as a barrier, making possible the measurement of electron energies. This procedure could be called hot-electron spectroscopy (Hess, 1990).

In the remainder of this section we discuss some of the more striking hot-electron effects. Computer simulations of some of these effects are displayed in Hess (1990).

7.2 Mobility Changes in High Fields

Because the relaxation times for most scattering processes depend on carrier energy, as shown in Sec. 6, it is expected that the mobility will change in high electric fields. At fields where the carrier "temperature" is not much increased over the lattice temperature, called the warm-electron range, it is expected that μ in a field $\mathbf{E}$ depends on μ_0, the low-field (Ohmic) mobility, according to

$$\mu=\mu_0(1+\beta|\mathbf{E}|^2) , \qquad (49)$$

where β is independent of field. The lowest-order deviation of μ from μ_0 must be quadratic in field because μ should not change on reversal of the field duration. The behavior of μ predicted by relation (49) has been verified by many experiments, in which lattice temperature, impurity content, and crystal orientation have been varied (for data and references for the material in this section see Conwell, 1967).

We can predict how μ changes from the energy dependence of τ for the scattering mechanisms that operate. Thus, if acoustic or nonpolar optical or intervalley scattering is dominant, according to Eqs. (41) or (43) μ must decrease on electron heating. This has been verified for Ge and Si, with reasonably good agreement with theory. For *n*-Ge at 300 K the decrease in μ starts at $\sim 10^5$ V/m, while at 77 K, where the low-field mobility in highly purified samples is higher by an order of magnitude, it starts at $\sim 10^4$ V/m. For *n*-Si, with lower mobility, higher fields are required to reach the non-Ohmic region.

A by-product of the mobility changes in the many-valley model is that current is no longer parallel to **E**, as it must be at low fields because we are dealing with cubic crystals. The nonparallelism occurs for **E** in directions that are not axes of rotational symmetry. Although the current direction for a given valley is at an angle to the valley axes because of the mass variation in the valley, in low fields the components perpendicular to **E** cancel out. In high fields, valleys with **k** vectors of small-mass (m_t) electrons more closely aligned with **E** get hotter, and their contribution decreases relative to the other valleys. This has the result that the perpendicular contributions to **j** no longer cancel out. The effect is magnified by the fact that the hotter valleys lose carriers by intervalley scattering to the cooler valleys.

As the field increases in the non-Ohmic region, v_d continues to increase, but more and more gradually. For Ge, Si, and many other semiconductors at 300 K, v_d tends to saturate at high fields at a value of $\sim 10^5$ m/s. This value is important for devices, which are frequently operated at high fields, because it determines the transit time through the device. Interestingly, this drift velocity is high enough so that, in the very small devices that are now being investigated, a sizable fraction of the carriers can make the transit through the device without a collision. Such collisionless transport is called ballistic transport. It is of particular interest because it provides a way of making faster devices.

In many of the group-IV and III-V semiconductors, when the field is raised beyond the range where v_d tends to saturate, to close to 10^7 V/m for *n*-Ge or 1.2×10^4 V/m for InSb to cite two examples, the current begins to rise very steeply. It has been shown that this rise represents an increase in carrier concentration due to impact ionization of the lattice atoms by the hot carriers. This process will be discussed in Sec. 7.3. A different phenomenon, called the Gunn effect, occurs at high fields in GaAs, GaP, InAs, and some other materials. This will be taken up in Sec. 7.4.

The discussion so far in this section has focused on phenomena from room temperature down to ~78 K in relatively pure samples. We consider now the situation at low temperatures, typically 20 K and below, where impurity scattering is important and a sizable fraction of the carriers have been frozen out of the conduction and valence bands. According to Eq. (45) τ_I and therefore μ_I should increase when the carriers are heated. Thus in this range β of Eq. (49) should be positive. This was in fact found for Ge samples at 20 K. However, there is another reason for conductivity to increase with field in this temperature range: hot carriers can cause impact ionization of neutral donors or acceptors. Hall measurements made as a function of field were able to show that both effects occur at this temperature. The initial non-Ohmic behavior is due to increase in mobility, but once the carriers are hot, impact ionization dominates, with the rise in current with field becoming so steep at temperatures where most of the carriers are frozen out as to be called a breakdown. The field required for this type of breakdown is less than 10^3 V/m for *n*-Ge.

7.3 Impact Ionization

In the temperature range where the donors or acceptors are fully ionized or almost so, an electron or hole that has gained sufficient energy from the field may give up its energy to a valence electron, raising the latter into the conduction band and leaving a hole in the valence band. The threshold energy required for an electron to create a hole–electron pair in this way is readily found for a semiconductor with the simple model of the band structure by applying the conditions of conservation of energy and momentum. For electron and hole masses m_n^* and $m_p^*=\gamma m_n^*$, respectively, the threshold energy for pair creation by an electron is $E_g(2+\gamma)/(1+\gamma)$. Thus for equal electron and hole masses an electron must have a minimum energy $3E_g/2$ to create an electron–hole pair. An initiating hole would also require only $3E_g/2$ for pair creation if $m_p^*=m_n^*$. With the gap in silicon, for example, 1.1 eV, at 300 K the field must raise the energy of an average electron, 0.025 eV, by a factor close to 60 to achieve pair creation. The field required is over 10^7 V/m. For InSb, with a much smaller gap and higher mobility carriers, only 1.2×10^4 V/m is required.

At fields just above threshold, ionization is due to a relatively few "lucky" carriers that have, fortuitously, been scattered less than others. This leads to an ionization rate changing roughly with field as $\exp(-A/|\mathbf{E}|)$, where A is a constant. At still higher fields, where most of the carriers are raised to a higher temperature T_e, the ionization rate is expected to depend on field as $\exp(-B|\mathbf{E}|^2)$.

7.4 The Gunn Effect

In n-type GaAs and a number of other materials, instead of the near saturation at high fields with subsequent impact ionization of the lattice found in Si, for example, a different and unique phenomenon called the Gunn effect is observed. Application of a field results in little departure from Ohm's law until after attainment of a threshold field in the range $(2\text{–}4)\times10^5$ V/m at 300 K in GaAs. Beyond this field the current is found to vary strongly with time, its average value dropping below the threshold value. Many different types of time variation have been seen in different samples, the simplest being an oscillation between the value at threshold and a value as low as half the threshold. The period of the oscillations was found to be about equal to the transit time of an electron between the electrodes as calculated from the threshold current, the number of electrons, and the length of the sample. The oscillations are typically of microwave frequency and the Gunn effect is used for microwave generation.

The current oscillations arise from the mobility change that occurs on heating of the carriers. As seen in Fig. 9, polar optical scattering is dominant in GaAs at high temperatures. According to Sec. 5, this means that electrons that acquire $E>h\nu_0$, ~400 K in GaAs, are scattered progressively less as their energy increases. In a strongly polar insulator with no other important scattering mechanisms, this would lead to the electron energy growing without limit as the field increases, causing impact ionization, severe lattice heating, changes in chemical and mechanical properties, and, most important, breakdown of the insulating properties. In fact, this mechanism has been suggested as the reason for breakdown of polar insulators. In GaAs, however, when an electron reaches 0.3 eV it can be scattered, by a phonon, from the Γ minimum to one of the L valleys in the conduction band (see Fig. 4). At 0.46 eV it can also be scattered into one of the X valleys in the conduction band. The probability of these processes is quite high because the densities of states in the X and L valleys are much higher than that in the Γ valley. This intervalley scattering has been detected by picosecond optical measurements (Auston, 1990). The mobility of electrons in the L and X valleys is also considerably smaller than that of electrons in Γ. Similar mobility changes due to intervalley electron transfers of hot electrons occur in GaAs-GaP alloys, InP, CdTe, ZnSe, InSb, and GaSb-InSb alloys, which also show the Gunn effect. In InSb the effect can be observed only for a nanosecond after the beginning of current flow because, the energy gap being smaller than the energy separation between valleys, impact ionization dominates after a short time. Interestingly, the Gunn effect is found under uniaxial stress in p-Ge. Although p-Ge has the degenerate band structure, under appropriate stress it goes over into one with two sets of valleys appropriately separated.

The result of the intervalley transfers is that beyond the threshold field further increase in $\mathbf{E}$ causes a decrease in current. This is an example of negative differential conductivity. How this phenomenon leads to a current that oscillates in time is discussed in the next section.

7.5 Negative Differential Conductivity

Negative differential conductivity (NDC) is characterized by regions of negative slope in plots of current density versus field. There are two types of NDC, shown schematically in Fig. 10, distinguished by their behavior in circuits.

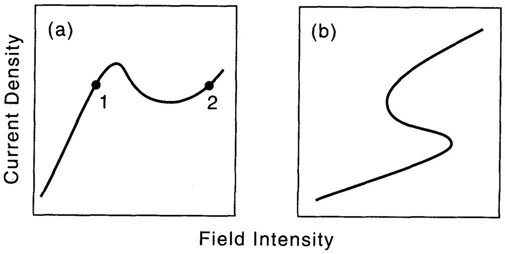

FIG. 10. The two types of negative differential conductivity. (a) The N-shaped curve representing voltage-controlled NDC, and (b) the S-shaped curve representing current-controlled NDC. (After Conwell, 1970.)

Unique electrical behavior results when a system operates in a region of NDC. In particular, a departure from equilibrium such as a fluctuation of field or of current will tend to grow rather than dissipate. In a sample with the voltage-controlled type of NDC, consider a small nonuniformity of the field at some point such that the field upstream (as regards current flow) is higher than the field downstream. This nonuniformity may be caused by a momentary deficiency of positive charge or accumulation of electrons, or by a permanent nonuniformity in impurity concentration or conductivity. If the differential conductivity of the sample is positive, a higher current will flow into the region than flows out, and any accumulated negative charge will be dissipated. If the differential conductivity is negative, however, a smaller current will flow into the region than out; more negative charge will accumulate and the original field discontinuity will be enhanced.

In a rectangular sample, as is ordinarily used, the equipotentials must be planes perpendicular to the sides of the sample, and the tendency will be to build up a plane of negative charge, an electron accumulation layer, at the discontinuity. If the initial nonuniformity or fluctuation had been of the opposite sign, there would be a tendency for a layer of positive charge, that is, an electron depletion layer, to grow. This is the type of instability that leads to the Gunn effect.

Imagine now a fluctuation in a sample with current-controlled NDC such that at some instant two adjacent lateral regions of filaments are carrying different currents. If the differential conductivity were positive, the filament with the higher current would have the higher field. A transverse current would then flow in such a direction as to equalize the currents. In a sample with NDC, however, the filament with the higher current would have the lower field, and transverse current would flow in the direction that increases the difference between the currents. Stability will be reached when the currents in the different filaments all correspond to the same value of electric-field intensity. Current-controlled NDC has been observed in Ge at low temperatures in situations where the carriers are hot enough to cause impact ionization of impurities, and in Ge and InSb at room temperature where the carriers are hot enough to ionize the lattice. In both these situations, once breakdown is achieved, the current can be carried at a lower voltage than was required for breakdown.

As has been seen, in the context of the Gunn effect, voltage-controlled NDC occurs in many materials because of mobility changes caused by the electric field. It also occurs in some semiconductors, notably CdS and high-resistivity GaAs, because the number of conduction electrons n decreases with increasing field. In CdS it is found that, beyond a threshold field $\sim 2 \times 10^4$ V/m, $n \propto E^{-m}$, where $m > 1$. This behavior has been attributed to "field quenching," in which the field serves to free holes from hole traps so that conduction electrons can combine with them. NDC in CdS is convenient for study because in the high-field regions E_g is decreased, making these regions opaque to light for which the low-field regions are transparent. It is found that with a blocking contact, which makes n at the cathode smaller than the value in the bulk, a high-voltage domain originates at the cathode at ~ 500 V and becomes larger with increasing voltage.

In GaAs exhibiting the Gunn effect a high-voltage region is also likely to form in the neighborhood of the cathode because of a small high-resistivity region there. The high-voltage region results from a dipole, with an accumulation of electrons in one region, a depletion in another. If the product of n and the sample length is large enough, the dipole will detach itself from the cathode and continue to grow until the upstream and downstream fields have a set of values such as 1 and 2 in Fig 10(a). The domain moves down the sample with the drift velocity because it is made of moving electrons. When it reaches the anode it exits from the sample, the current rises, and the process of building up another domain at the cathode begins. For further discussion and references see Conwell (1967, 1970).

7.6 Acoustoelectric Effect

In CdS, ZnO, and a number of other II-VI and III-V compounds for certain crystallographic directions, Ohm's law is obeyed only up to the field for which the drift velocity $v_d \simeq v_s$, the sound velocity. Note that this is not a high enough field for carrier heating. Further increase in **E** results either in saturation, i.e., a time-independent current that increases little with further increase in field, or in time-dependent behavior in which the current oscillates between the Ohmic value appropriate to the particular field and the lower, saturation value (Einspruch, 1965). In the latter case, probing the sample electrically led to the discovery that, similar to the Gunn effect, a high-resistance domain is generated at the cathode and moves down the sample. In this case, it moves with v_s. After it leaves at the anode a new domain is generated, etc. In the time-independent case, as in the Gunn effect, a high-resistance region is generated but the conditions for it to move are not satisfied.

A clue to the origin of these effects is that the directions for which they are observed are those for which there is piezoelectric coupling between an acoustic wave traveling in that direction and an electric field along the direction. An acoustic wave introduced from outside, through a transducer, for example, in such a direction produces an alternating electric field that bunches the conduction electrons or holes in its potential-energy minima. In the absence of an applied dc field the acoustic wave must drag the electron bunches along with it and experiences attenuation. If, however, a dc field is applied in this direction of sufficient magnitude to make the electrons drift with $v_d > v_s$, the electrons drag the wave, i.e., the wave experiences gain. Of course, there are acoustic waves, the phonons, present in these materials even when acoustic energy is not put in from the outside. Application of a dc field high enough to make $v_d > v_s$ in one of the piezoelectrically active directions results in amplifying acoustic waves that happen to be traveling in the field direction. The traveling domains have been found to be regions of high acoustic flux. The high resistance associated with these domains, or with stationary domains, is due to the large rate of momentum loss of the electrons in acoustic-wave generation. The acoustic-wave amplification we have been discussing may be usefully thought of as stimulated emission of phonons.

8. IMPURITY-BAND CONDUCTION

8.1 Semiconductor Conductivity at Low Temperatures

As discussed in Sec. 4, with decreasing temperature conductivity decreases rapidly in all but the most heavily doped (degenerate) semiconductor samples because electrons and holes fall back into the impurity levels. The decrease in n with T was shown in Fig. 6 for a set of n-Ge samples down to ~10 K. According to Eq. (17), the slope represents the activation energy, 0.01 eV for this case. A plot of $\ln\kappa$ vs $1/T$ for these samples would show the same decrease, with essentially the same activation energy, because the mobility has much weaker T dependence than n in this range. A set of p-Ge samples would give very similar data, with the same activation energy. As T is lowered further, carriers must continue to drop out of the conduction or valence band at the same rate, but the conductivity does not continue the rapid rate of decrease. This is shown in Fig. 11 where the logarithm of resistivity ρ is plotted versus $1/T$ for a set of p-Ge samples with acceptor concentrations ranging from 2×10^{22} to 7.3×10^{22} m^{-3}. From the minimum in ρ around 78 K, corresponding to all holes being in the valence band, ρ

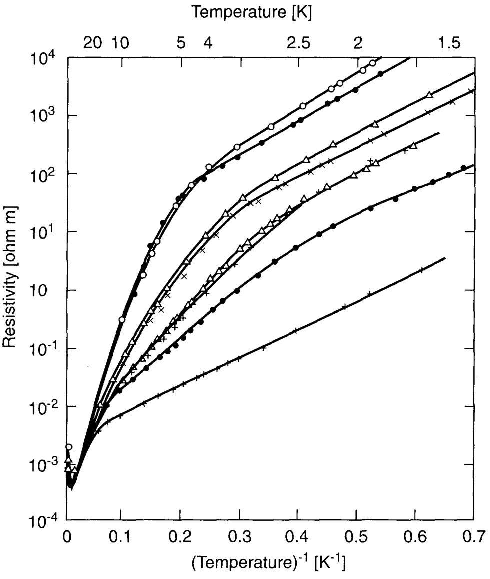

FIG. 11. Resistivity vs temperature for a set of p-Ge samples with acceptor concentrations ranging from 7.3×10^{22} m^{-3} for the lowest curve to 2×10^{22} m^{-3} for the uppermost curve. (After Fritzsche, 1955.)

rises exponentially for all samples, with a slope corresponding to the activation energy, 0.01 eV; this is a repetition of the data in Fig. 6 with a more compressed scale. However, beyond some temperature, ranging from 20 K for the lowest ρ (most doped) to 5 K for the highest ρ (least doped) sample, the rate of increase of resistivity with decreasing T is markedly smaller. Processes with lower activation energy are now dominating the conductivity.

The experimental curves of Fig. 11, from ~78 K on down, can be fitted by a sum of terms of the form

$$\rho=\rho_1 e^{\mathscr{E}_1/kT}+\rho_2 e^{\mathscr{E}_2/kT}+\rho_3 e^{\mathscr{E}_3/kT}, \tag{50}$$

where $\rho_1 \gg \rho_2 \gg \rho_3$ and $\mathscr{E}_1 > \mathscr{E}_2 > \mathscr{E}_3$. From the discussion above $\mathscr{E}_1=0.01$ eV. The second term is not seen for the lowest- and highest-resistivity samples but is seen in between. The third contribution, $\rho_3 \exp(\mathscr{E}_3/kT)$, is seen over the lowest temperature range for all samples.

8.2 Conduction Mechanisms at Very Low Temperatures

The $\mathscr{E}_2$ and $\mathscr{E}_3$ contributions can be understood in terms of the expected density of states. We will describe the situation in terms of electrons, but the description applies to holes with the obvious modifications. Figure 5 gives the density of states for a lightly doped semiconductor, Ge with $\sim 10^{20}$ donors/m^3, for example. At $\sim 10^{22}$ m^{-3}, as discussed in Sec. 3, the hydrogenic orbits of electrons bound on adjacent donors begin to overlap and the discrete level at E_d begins to spread into a band. The random arrangement of the impurities results in the overlap, and therefore the bandwidth, being somewhat greater than it would be for a regular arrangement. Nevertheless, the band is quite narrow at this concentration and the repulsion U_r for a second electron on a donor site is larger than the bandwidth B. In that situation the impurity band splits into two subbands, the upper band separated from the lower by an energy $\sim U_r - B$. In Fig. 12 the lower band is identified as the (a) band, the upper the (b) band. To explain the exponential temperature dependence of ρ in the (a) band, and other measured properties, it is necessary to assume that the electrons in this band are localized, one to a donor, for $N_d < 7\times10^{22}$ m^{-3}, the highest concentration in Fig. 11.

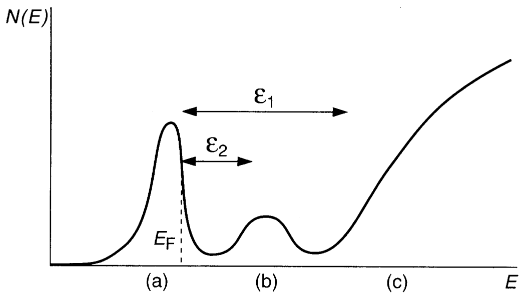

FIG. 12. Distribution in energy of the states in an *n*-type semiconductor showing the splitting of the impurity band into two bands (a) and (b). (c) is the conduction band. The position of the Fermi level is shown for the case $N_a < N_d/2$. (After Mott and Davis, 1971.)

In the limit of very low temperatures the (a) band would be completely filled with one electron per site if there were no acceptors, while the higher bands would be empty. Actually there are always some acceptors present in an *n*-type sample, with the result that in the low-T limit $E_{\rm F}$ lies in the (a) band as shown in Fig. 12, and the band has a number of vacancies equal to N_a. It is this fact that makes conduction possible within the (a) band. Conduction takes place by an electron hopping from a neutral donor, i.e., a filled donor site, to a positively charged donor, or empty donor site. It is clear that the amount of conductivity due to this mechanism depends on N_a/N_d. For $N_a \ll N_d$, κ will increase as N_a increases. However, if N_a is close to N_d, κ would decrease with further increase in N_a because there would be fewer electrons to hop.

The randomness of donor and acceptor distributions results in electrons on different donors having somewhat different energies. To enable an electron on site i to hop to a donor on site j, where the energy level is higher by W_{ij}, the energy W_{ij} must be provided by a phonon. The hopping probability therefore depends on the abundance of phonons of energy W_{ij}, which at low temperatures ($kT \ll W_{ij}$) is given by $\exp(-W_{ij}/kT)$. It also depends strongly on the overlap of the electron wave functions in the initial and final states. This dependence, for two donors separated by a distance R_{ij}, is given by $\exp(-2R_{ij}/a_{\rm H})$, where $a_{\rm H}$ is the radius of the ground-state (hydrogenic) orbit. Thus the probability ν_{ij} of a transition per unit time between sites i and j may be written

$$\nu_{ij}=\nu_0 \exp(-2R_{ij}/a_{\mathrm{H}}-W_{ij}/kT), \qquad (51)$$

where ν_0 depends on the coupling to the phonons, given by the deformation potential (see Sec. 6.1) in this case, R_{ij}, and other factors. In calculating κ or ρ from Eq. (51) it is useful to distinguish between two ranges:

1. the "high-temperature" range where kT is large enough so that an electron can usually find a phonon of sufficient energy to jump to a nearest neighbor;
2. the "low-temperature" range where kT is small enough so that the electron will preferentially jump to a further site for which W_{ij} is smaller despite the decrease in $\exp(-2R_{ij}/a_{\mathrm{H}})$.

The latter hopping process is called variable-range hopping (VRH) because the average hopping distance increases with decreasing T.

8.2.1 Variable-Range Hopping. It is readily shown that the optimum range $(R_{ij})_m$ is $[9a_{\mathrm{H}}/8\pi N(E_{\mathrm{F}})kT]^{1/4}$, where $N(E_{\mathrm{F}})$ is the density of states at $E=E_{\mathrm{F}}$. When $(R_{ij})_m$ and the W_{ij} that corresponds are inserted in Eq. (51) we find the hopping rate

$$\nu_{ij}=\nu_0 \exp[(-T_0/T)^{1/4}], \qquad (52)$$

where $T_0=16/kN(E_{\mathrm{F}})a_{\mathrm{H}}^3$. The diffusion coefficient D that results from the hopping is given by $\langle \nu_{ij} R_{ij}^2 \rangle$. From this the mobility may be obtained with the use of the Einstein relation $\mu=De/kT$. To calculate κ or ρ, n is taken as the number of electrons per unit volume within kT of E_{F} because essentially only those will be able to hop to an empty site by finding a phonon to assist them, or by emitting a phonon. This number is $2N(E_{\mathrm{F}})kT$, the factor 2 resulting from the fact that electrons of both spins may occupy each state.

In carrying out the averaging over R_{ij} and W_{ij} required to obtain D it is necessary to take into account not only the variations of these quantities but the fact that carriers may take different paths through the sample, avoiding those with particularly unfavorable R_{ij} or W_{ij}. For the high-temperature case, or nearest-neighbor hopping, the T dependence of κ will be dominated by the exponential in Eq. (51) with $\mathscr{E}_3$ representing a suitably averaged W_{ij}. For the "low-temperature" or VRH case the T dependence of κ will be essentially that shown in Eq. (52). The experimental T dependence seen in Fig. 11 in the lowest temperature range can clearly be well fitted by $\exp(\mathscr{E}_3/kT)$, consistent with nearest-neighbor hopping. Perhaps VRH can be seen at lower T's. Variable-range hopping will be found to fit the observations for amorphous semiconductors quite well.

8.3 Criterion for Localization

Conduction in the (b) band requires that an electron in (a) absorb a phonon of sufficient energy to make the transition to (b). Once the electron is in the (b) band, the conduction mechanism depends on whether the states are localized or extended. A criterion for determining this has been set up by Anderson (1958). He finds that if the actual energy spread ΔE of the states in a band is greater than ~5 times the bandwidth B that there would be due to overlap if the (isolated) states all had the same energy, all the states in the band are localized. If $\Delta E/B<5$ the states in the outer edges of the band may still be localized. The condition $\Delta E>5B$ apparently applies to the (a) band. It need not apply to the (b) band. It is not unlikely that the extent of the higher-energy state is larger, which would make B larger and the ratio $\Delta E/B$ smaller. The available data suggest that the (b) states are extended in the doping range of Fig. 11. In that case (see Fig. 11) $\mathscr{E}_2=E_i-E_{\mathrm{F}}$, the energy required to get the electron into the level E_i in the (b) band.

At concentrations higher than those of the Fig. 11 samples, probably $>10^{24}\ \mathrm{m}^{-3}$, the (a) and (b) bands have spread out and strongly overlap each other and the conduction band. The states at E_{F} are now extended, and the sample is degenerate, as can be seen from the experimental data for sample 58 in Figs. 6 and 9. The states in the low-energy tail of the impurity band are still expected to be localized, however; these correspond to electrons that, because of the randomness of the impurity distribution, are in particularly deep potential wells.

9. AMORPHOUS SEMICONDUCTORS

9.1 Atomic Structure

Amorphous materials lack the lattice periodicity that characterizes the crystalline solid state. The departure of the atomic positions in an amorphous solid from a periodic array is often represented by a radial distribution function (RDF). The RDF displays a number of peaks at r values giving the average distance between nearest neighbors, next-nearest neighbors, and so on. The radial fluctuation in these interatomic distances is manifested in the peak width. The lower part of Fig. 13 compares the RDFs for an assembly of identical atoms arranged in (a) crystalline form, (b) a glass, and (c) the gas phase (instantaneous picture). The RDF for the first few atomic positions in the amorphous solid is similar to that of the crystal because short-range order in the solid state is controlled by the dictates of chemical bonding. Beyond the first few neighbor distances in the amorphous solid, however, the RDF becomes progressively featureless, thus more gaslike than crystallike. Experimentally the RDF is determined by a complex procedure (Zallen, 1983) from the real-space Fourier transform of the x-ray scattering interference function.

One important result of the application of RDFs to the analysis of covalent amorphous semiconductors is the demonstration of the general applicability of the continuous random network (CRN) model first introduced by Zachariasen (1932) as an idealized description of covalent glasses such as silica. In the CRN model it is assumed that each constituent atom (including any impurity atom) is able to optimize its own bonding coordination needs. The optimum coordination number Z of any atom in a CRN is given by the Mott $8-N$ rule, where N is the number of valence electrons. According to the $8-N$ rule, which is based on elementary chemical reasoning, when $N \geqslant 4$ the coordination is $Z=8-N$, while for $N<4$ the optimum coordination is N. Figure 13 (upper part) illustrates the two-dimensional CRN of a three-coordinated (i.e., each atom has three bonds) glass. For a given composition all configurations of the glass that allow the constituent atoms to satisfy their local bonding requirements are equally probable. The effect of the long-range disorder on the electronic structure is expressed in terms of a randomly varying disorder potential (Mott and Davis, 1979).

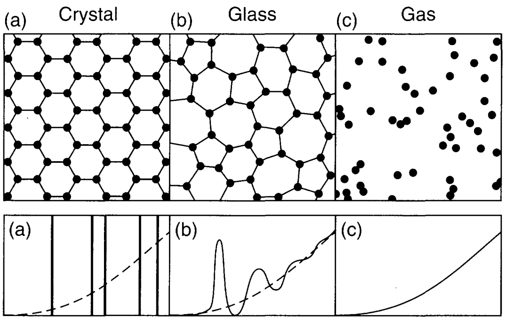

FIG. 13. Upper: Schematic representation of the atoms in (a) a covalent crystal, (b) a covalent glass network, and (c) a gas. Lower: Schematic represention of the corresponding RDFs (see text). (After Zallen, 1983.)

What, then, is the meaning of a structural defect in the CRN framework? In a crystal any atom not in a proper position in the lattice is a defect. In amorphous semiconductors, where CRN represents the ideal, the elementary defect is a miscoordinated atom, that is to say an atom with too few or too many bonds. Bonding miscoordination defects typically give rise to electronic states deep in the gap. These defects are now understood to play a major role in many of the key photoelectronic properties exploited in device applications (Street, 1991).

9.2 Electronic States

In the absence of lattice periodicity the vector **k** defined in Sec. 2.3 no longer has a meaning. For covalent-network amorphous solids whose crystalline counterparts have wide bands of order 5 eV or more, energy bands are still retained in the presence of disorder, but these must now contain localized as well as delocalized electronic states. Such disorder-modified bands can no longer be characterized by E-**k** dispersion relations such as that in Fig. 4, but must instead be described in terms of a density of states function $N(E)$. Important physical parameters like the carrier effective masses, defined in terms of the dispersion relations in the crystalline solid state, must be reformulated for amorphous semiconductors. The general problem of disorder-induced localization and its influence on the electronic band structure of amorphous covalent networks is very complex. It was elucidated by Anderson (1958), as discussed in Sec. 8. In hydrogenated amorphous silicon, *a*-Si:H, and in chalcogenide glasses, bandwidths are of order 5–10 eV, and the disorder estimated to be present, about 100–500 meV, is clearly too small to satisfy the Anderson criterion for complete localization. When the disorder potential is insufficient to induce complete localization of all states in the band, it can still act, as discussed earlier, to broaden the band edges into tails of localized states that extend into the gap. There is a significant difference in the mobility of carriers depending on whether they occupy extended or band-tail states. As a result, a demarcation energy separating extended states in the band from localized band-tail states was proposed (Mott, 1967). Because it was originally thought that the mobility should undergo a discontinuous change associated with the transition from band to hopping transport, this demarcation energy was said to define a mobility edge. It was suggested that for an amorphous semiconductor the appropriate analogy to the band gap of an intrinsic semiconductor crystal is the pseudogap bounded by the conduction- and valence-band mobility edges, denoted by E_C and E_V, respectively. The gap in an amorphous semiconductor is referred to as a pseudogap because it can be populated by a more or less continuous distribution of disorder-induced localized states (see Fig. 14). In addition to the band tails there are electronic states typically located deep in the gap, which arise from characteristic native defects associated with short-range disorder. Deep defects that can act as traps and recombination centers significantly influence the transport and photoelectronic properties of amorphous semiconductors and are believed to be involved in the mechanism of doping.

9.3 Native Defects

Every energy level of a defect can contain up to two electrons. For simplicity consider a defect that introduces a single level into the gap. That defect can exist in any of three charge states, corresponding to empty, singly, or doubly occupied, and its occupancy determines the position of the level it contributes to the gap relative to a mobility edge. The energies of the doubly occupied states differ from those of the singly occupied states because

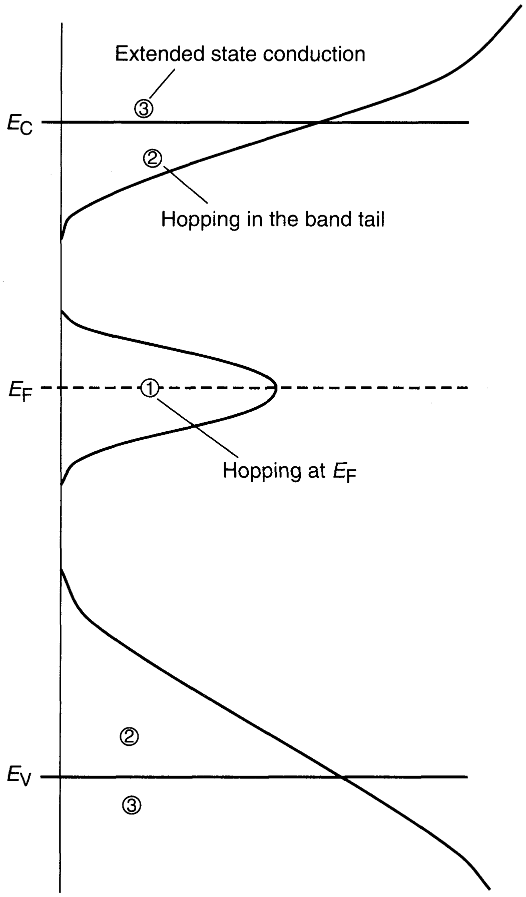

FIG. 14. Distribution in energy of the states, i.e., $N(E)$ vs E, in a prototypical undoped amorphous semiconductor.

1. the two electrons repel each other (Coulomb energy) and
2. addition of an electron can induce a bonding change or relaxation, which may either raise or lower the energy.

The algebraic sum of the two energies is called the correlation energy U. Both negative and positive correlation-energy defects exist and they have significantly different electronic properties. It can, for instance, be shown (Street, 1991) that for positive-U defects

1. the singly occupied, paramagnetic state has the minimum energy;
2. the Fermi level position is sensitive to dopants and there is minimal lattice relaxation.

On the other hand, for a negative-U defect

1. a large lattice relaxation is required for its formation;
2. the lowest energy state is diamagnetic; and
3. the Fermi level is constrained to lie between the defect energy levels.

The canonical example of a negative-U defect system is the valence alternation pair (VAP) that exists in chalcogenide glasses (Kastner *et al.*, 1976). *a*-Se, an elemental chalcogenide glass, provides the simplest example. According to the $8-N$ rule every Se atom should be bonded to two others, forming a one-dimensional network glass. A chain-terminating Se atom might be expected to have one unpaired or unbonded electron, called a dangling bond. Estimates based on viscosity data indicate that the number of such dangling bonds should exceed 10 ppm, which would be easily detectable by electron spin resonance (ESR). ESR is, however, not observed (Abkowitz, 1967), in *a*-Se or in any of the more complicated chalcogenide glasses. The neutral dangling-bond defect must be unstable against conversion to a diamagnetic species during glassy solidification. It has been proposed that this conversion process occurs by valence alternation and involves bond switching and electron transfer between chains (see AMORPHOUS MATERIALS, STRUCTURE OF).

9.4 Conductivity Mechanisms

It is clear from the preceding discussion that the analysis of conductivity in amorphous solids is greatly complicated by the broad energetic distribution and varied character of the states that can contribute channels for carrier motion. Instead of defining a single mobility for all states in the conduction band, or valence band, as done in Eqs. (2) and (26), it is useful to introduce a mobility $\mu(E)$ characteristic of the group of states in the range dE at E. The appropriate generalization of Eqs. (4) and (9) is then

$$\kappa=\int N(E)e\mu(E)f(E)dE\,. \tag{53}$$

Figure 14 is a schematic illustration of $N(E)$ vs E.

In Fig. 14 the Fermi level is shown contained in a submanifold of localized states near midgap. If the density of such states near the Fermi level is sufficiently high then, because their occupancy is heavily favored, these states will completely dominate the transport at low temperatures. For evaporated unhydrogenated amorphous Si, where the density of paramagnetic dangling-bond levels at the Fermi level is very large, it is found experimentally that $\ln\kappa\propto T^{-1/4}$ over a wide range of temperatures starting from the lowest (Street, 1991). As discussed in Sec. 8, this is the T dependence expected for VRH. In hydrogenated amorphous Si the dangling-bond defects from which the near-midgap states arise are in large measure eliminated by hydrogen complexation (i.e, passivation) and VRH is not observed.

At higher temperatures, nearest-neighbor hopping of carriers through band-tail states, regions 2 in Fig. 14, will contribute to the conductivity. When carriers of a single sign dominate, $1/\kappa$ vs T is activated, like the terms of Eq. (50). At still higher temperatures carrier transport is dominated by carriers that have been excited to states above the mobility edge E_C. κ may then be written

$$\kappa=\kappa_{E_C}\exp[-(E_C-E_F)/kT]\,, \tag{54}$$

where κ_{E_C} is the conductivity at the mobility edge and presumably also just above it. κ_{E_C} is called the minimum metallic conductivity. Mott and Davis (1979) have argued that for a three-dimensional case $\kappa_{E_C}=2.2e^2/Z^2\hbar a_E$, where Z is the coordination number and a_E the distance between localized states. It is difficult to verify this experimentally.

A reliable way of inferring the existence of localized states near band edges is via their influence on time-of-flight (TOF) drift mobility of injected carriers (Marshall, 1989). As discussed in Sec. 1.4, when the effective or drift mobility μ_d is limited by trapping it is reduced from the conductivity (free carrier) mobility μ_0 by the fraction of time that a carrier on average spends in traps, in this case the localized states adjacent to the mobility edge. When the injected carriers establish quasiequilibrium with trap and extended states in a small fraction of a transit time, the time of flight and the drift mobility are experimentally well defined. This condition is not satisfied, however, when there are deep traps with a range of depths, resulting in the carriers straggling to the contact. This behavior, called dispersive transport, is clearly exhibited by photoinjected holes in *a*-As_2Se_3. A successful statistical treatment of this type of transport has been carried out by Scher and Montroll (1975). On the basis of the Scher–Montroll treatment applied to time-of-flight and transient (bulk) photoconductivity data, *a*-As_2Se_3 is now generally believed to be characterized by a nearly exponential band tail, as suggested in Fig. 14.

9.5 Doping

It was thought earlier that the $8-N$ rule and the CRN model discussed in Sec. 9.1 would rule out the possibility of modifying the dc conductivity of an amorphous semiconductor by substitutional doping. In fact, *a*-Si:H exhibits doping phenomena (Spear and LeComber, 1975) with elements in groups V and III of the periodic table that are comparable to those in crystalline Si, though the underlying mechanism is believed to be quite different. Less widely appreciated and more subtle in its manifestations is a systematic doping effect in certain Se-rich chalcogenide glasses that is induced by both strong electropositive elements like the alkalis and electronegative substituents like the halogens. In both *a*-Si and *a*-Se (and related glasses) the underlying mechanism of doping is surprisingly similar and involves the interaction of dopant atoms with native defects.

The modification of conductivity by the doping of *a*-Si:H with P and B is dramatically illustrated in the data of Spear and LeComber (1975) shown in Fig. 15. Consider the case of P in *a*-Si:H. According to the $8-N$ rule P should be threefold coordinated (i.e., make three bonds) in its lowest-energy configuration. In fact the P doping efficiency in *a*-Si:H is very low, and it is generally believed that this is so because most of the substitutionally incorporated P is in threefold coordination, precisely as suggested by bonding and topology arguments. The smaller proportion of electronically active P dopant atoms that act as donors must be incorporated in fourfold coordination. The excess charge must somehow be compensated, and a large body of experimental evidence points to the dangling-bond defect D^- as the compensation center, with the Fermi level situated at an energy between P^+ and D^- levels. A complementary argument applies to the formation of ionized acceptors by B doping.

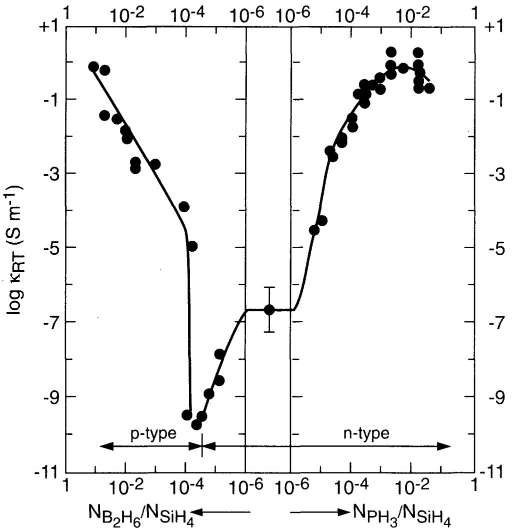

FIG. 15. Conductivity of *a*-Si:H at room temperature as a function of the dopant gases phosphine (PH_3) and borane (B_2H_6) introduced into silane (SiH_4), the deposition gas. (After Spear and LeComber, 1975.)

It should be noted that Mott (1976) suggested an analogous mechanism for the doping of *a*-Se by alkalis and halogens involving the native, negative-*U*, VAPs discussed earlier. In this case the VAPs, which normally exist in undoped material only as autocompensated defect pairs, would associate with some fraction of electropositive (e.g., Na) or electronegative (e.g., Cl) dopant atoms, thereby altering their relative populations while satisfying the requirement of overall charge neutrality. These predictions have been experimentally verified (Abkowitz, 1987). The doping effect of halogens on Se-rich chalcogenide alloys (e.g., Se:Te:As ternaries) is in fact systematically utilized in the design of the large-area photoconductors used in xerographic copiers and printers.

10. TWO-DIMENSIONAL AND ONE-DIMENSIONAL BEHAVIOR

The materials we have been discussing are all three dimensional (3D), in fact isotropic in most of their low-field properties. They can be made highly anisotropic, essentially 2D, by three different methods:

1. application of a high magnetic field;

2. confining the carriers in a thin layer at the surface; or
3. confining them in a thin layer of semiconductor between layers of different semiconductors, which may also be thin.

In the latter two cases further structuring the material to confine the carriers in one of the two dimensions can lead to quasi-one-dimensional behavior. This section is devoted to discussing the first two methods listed above; the third is the subject of HETEROSTRUCTURES, SEMICONDUCTOR.

10.1 Quantizing Magnetic Fields

10.1.1 Landau Levels. Solution of the wave equation has been carried out for a free electron in magnetic field. The same solution may be used for a carrier in the simple model of the band structure, with the replacement of m_0 by m^*. It is found that for a field **H** in the z direction the possible energy levels of the carrier are

$$E=(\hbar^2/2m^*)k_z^2+(\nu+\tfrac{1}{2})\hbar\omega_c, \tag{55}$$

where ν takes on integer values 0, 1, 2, ..., and ω_c is the cyclotron frequency He/m^*, the rate at which carriers rotate around the constant-energy surfaces in a magnetic field (see Sec. 5.6). It is seen that the energy of motion in the z direction is unaffected by the field, as expected because, as is seen in Eq. (19), there is no component of force parallel to **H**. The energy of motion perpendicular to the field, however, is quantized in steps of $\hbar\omega_c$. The set of all levels with a given ν and arbitrary k_z is referred to as the νth Landau level. The effect of the field has been to cause all the states with different k_x and k_y to "condense" on the nearest Landau level.

If an electromagnetic field of frequency ω_c is applied together with the magnetic field, a carrier can absorb a photon $\hbar\omega_c$, making a transition to the next Landau level. The transition corresponds to the carrier going from the orbit in **k** space characterized by ν to the $\nu+1$ orbit. This phenomenon is called cyclotron resonance. Its realization requires well-defined Landau levels ($kT\ll\hbar\omega_c$) and well-defined orbits (scattering time $\tau>2\pi/\omega$, the time of one rotation). Cyclotron resonance experiments, with **H** applied in different directions, have been very important for determining the band structure of semiconductors. In the electromagnetic field with frequency ω_c transitions are also possible from the level ν to $\nu-1$. The interlevel transitions are seen as magnetic-field–produced structure in optical transitions between bands, called magneto-optical absorption.

Quantization of the energy levels, Eq. (55), is accompanied by quantization of the areas of the orbits in **k** space corresponding to the allowed levels (Ziman, 1972). The quantization conditions result in a sharp oscillatory structure in the electronic density of states $N(E)$. $N(E)$ will have a sharp peak whenever E is equal to the energy corresponding to an orbit with maximum or minimum area, called an extremal orbit. This is an important effect for metals and for degenerate semiconductors, where many properties depend on $N(E_F)$, the density of states at the Fermi energy. At a value of **H** for which E of an extremal orbit coincides with E_F, $N(E_F)$ will be large. Thus it is expected that the values of many properties of metals and semiconductors, among them magnetoresistance, will have an oscillatory behavior as **H** varies. Specifically, the properties depending on $N(E_F)$ are periodic in $1/H$ (Ziman, 1972). The resulting oscillations in magnetoresistance, called the Shubnikov–de Haas effect, have been seen at low temperatures in HgSe and a number of other degenerate semiconductors. Oscillations with a period of $1/H$ have also been seen in interband optical absorption and magnetic susceptibility (de Haas–van Alphen effect).

10.1.2 The Quantum Hall Effect. At low temperatures and high magnetic fields, in a situation where a high density of electrons is confined in two dimensions (see Sec. 10.2), unusual behavior of the Hall effect has been found. The ratio of j_x to E_y, which by Eq. (31) should be ne/H_z, is found to change discontinuously with H_z, showing plateaus. It has been found that the plateaus correspond to the filling of successive Landau levels as the field changes. This effect, with accompanying phenomena, is known as the quantum Hall effect (*q.v.*).

10.2 Transport in Inversion Layers

10.2.1 Effect of Electric Field on Semiconductor Surface. Early in the modern history of semiconductors (1948) it was discovered that application of an electric field perpendicular to the surface of a semiconductor could increase or decrease carrier concentration at the surface, depending on the polarity of the field. Because it is required that, in thermal equilibrium, the Fermi level must be the same throughout a sample, the effect of the field is to bend the bands at the surface. In Fig. 16 we show some of the possible situations that can occur for a *p*-type semiconductor. The same situations occur, of course, for an *n*-type semiconductor. As can be seen from Eq. (14), when E_F is closer to the valence-band edge at the surface than in the interior, the hole density is greater at the surface, making it an accumulation layer. Where E_F is further from E_V in the surface than in the bulk, the surface is depleted. When the bands are bent further still, so that at the surface E_F is closer to E_C than E_V, the surface becomes *n* type, constituting an inversion layer. We should note, however, that the band bending may not be entirely due to the field; the bands are usually bent at the surface in the absence of the field because the surface has different defects and different defect levels from the bulk, and in fact may have a much larger number of defect levels.

10.2.2 Quantization in the Inversion Layer.

The case of the inversion layer is of particular interest. If the direction perpendicular to the surface is taken as *z*, electrons whose kinetic energy in the *z* direction lies below the bulk E_c are confined in a potential well. As is well known, if the well is deep enough, such electrons have quantized energy levels, the lowest level corresponding to a wave function with no nodes within the well, the next to a wave function with one node within the well, etc. (see QUANTUM MECHANICS). Some of these energy levels are indicated schematically in Fig. 16(c). The existence of these quantized levels was demonstrated by magnetoconductance measurements in which the Fermi level was swept through the Landau levels by varying the carrier concentration in the inversion layer as discussed in the last section. The characteristics of the Landau levels were those predicted for carriers confined to distances from the interface as small as 1–10 nm (Fowler, 1982). For such narrow wells the separation between levels is much larger than kT at 4 K and even somewhat higher temperatures, and the carriers occupy only the lowest quantum level at these temperatures. Of course, for each level there is a band of energies in the *x* and *y* directions, corresponding to all allowed wave vectors k_x and k_y, because motion parallel to the surface is unconfined. Thus 2D subbands are formed with electron energies, for the simple model of the band structure, given by the sum of E_n^0, the *n*th quantized energy level, and the kinetic energy $\hbar^2(k_x^2+k_y^2)/2m^*$.

10.2.3 Transport in the Inversion Layer.

Transport in inversion layers can be conveniently studied in a MOSFET, a metal-oxide-semiconductor field-effect transistor (see TRANSISTORS, FIELD EFFECT). The MOSFET structure is shown in Fig. 17. The silicon dioxide (SiO_2) thickness at the gate varies from ~10 nm to 1 μm. When $V_g=0$, electrons in the source cannot get to the drain, even though there is an attractive field due to the gate voltage V_D, because the *p*-Si region separating source and drain is a barrier. Application of a positive gate voltage creates an *n*-type channel, i.e., an inversion layer, at the *p*-Si surface with the SiO_2, permitting the electrons to go through. The voltage V_{sub} also affects the field at the SiO_2 interface and thus the number of carriers in the inversion layer. Thus varying V_{sub} and V_g appropriately allows a variation of electron concentration in the inversion layer at constant surface field or alternatively a variation of surface field at constant electron concentration.

Most of the transport measurements made on bulk samples may be made on the surface. Mobility may be determined from the measured conductivity of the surface layer in the usual way, using Eq. (3), but it is difficult to determine accurately the carrier concentration in the inversion layer. Hall measurements may be made and Hall mobility obtained from them, but, as discussed in Sec. 5.5, the ratio μ_H/μ is uncertain within about a factor of 2.

Conductivity and Hall-mobility measurements have been made for different orientations of the surface. Among the simplest to interpret is the [100] orientation. For that orientation in Si four of the valleys have the light mass in the *z* direction, while the other two have the heavy mass in that direction. The field in the potential well results in the latter two valleys having lower energies than the other four.

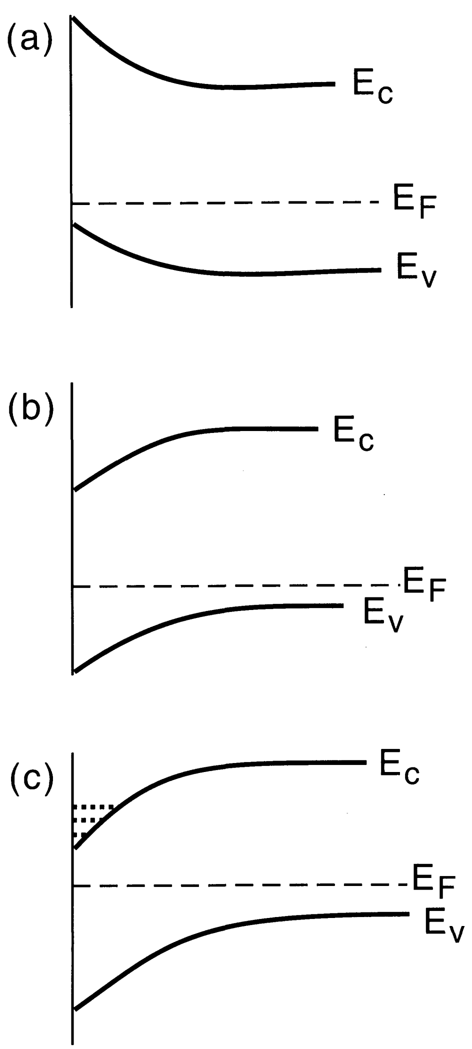

FIG. 16. Possible surface conditions for a *p*-type semiconductor: (a) accumulation layer; (b) depletion layer; (c) inversion layer. The dotted lines in (c) indicate, schematically, quantized energy levels.

The processes that scatter the carriers in the inversion layer are those discussed in Sec. 6, plus surface scattering. At low temperature, e.g., 4 K, the problem is relatively simple in that only the lowest quantized states are occupied and only impurity and surface scattering are significant. Impurity scattering can be due to either ions in the bulk or charges in the insulating SiO_2 layer. In practice, except for very heavy doping ($>10^{22}$ m^{-3}) in the bulk and for very clean oxides, the oxide ions are dominant. The samples in which impurity scattering is dominant at 4 K are likely to be degenerate, i.e., obey Fermi–Dirac statistics. For impurity scattering in a three-dimensional degenerate case we may use Eq. (45) for τ_I, replacing E by E_F. As the density of electrons in the inversion layer increases, E_F increases. Thus this equation predicts that at low temperatures impurity scattering gets less effective as the density of carriers in the inversion layer increases, which is in agreement with experiment. For detailed comparison with experiment, however, the Sec. 6 calculation of μ_I must be modified in a number of ways to describe better the inversion-layer situation (see Ando *et al.*, 1982).

As the carrier density increases and impurity scattering becomes less effective, surface roughness scattering comes to dominate. The surface roughness scattering is assumed to be due to random deviations from planarity of the Si–SiO_2 interface. It is characterized by two parameters, the rms deviation from surface planarity and the correlation length of the deviations. Information on these parameters may be obtained by transmission electron microscopy. The theory for this scattering process appears to be in reasonable agreement with experiment (Fowler, 1982).

At temperatures higher than 4 K phonon scattering is also important, specifically acoustic-phonon, nonpolar optical-phonon, and intervalley scattering. Extensive calculations are needed to take into account all the different phonons, and scattering within and between the different quantized bands and within and

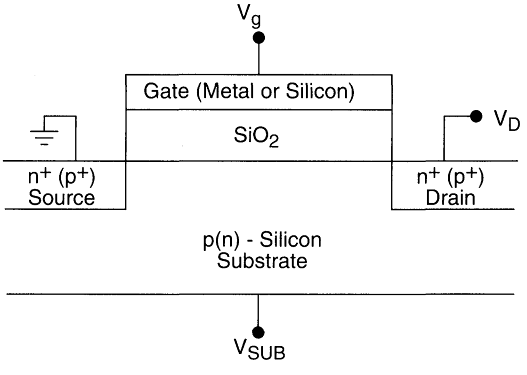

FIG. 17. Schematic MOSFET structure in cross section. The device may have a highly doped *n*-type (n^+) source and drain and a *p*-type substrate or a p^+ source and drain and an *n*-type substrate. (After Fowler, 1982.)

between valleys. For a review of the measurements and theoretical work see Ando *et al.* (1982).

10.2.4 Hot Electrons. Particularly at low temperatures, where the electron mobilities are high, the conductance is found to depend on the source–drain electric field. At 4 K mobility changes are observed at fields as low as a fraction of a V/cm. The mobility is found to rise initially when the electrons are heated by the field, as expected when the dominant scattering mechanism is ionized impurity scattering (see Sec. 7). The energy-loss mechanism that allows achievement of a steady state is acoustic-phonon scattering. For higher fields at 4 K impurity scattering becomes ineffective and optical-phonon scattering comes to dominate the scattering. In this field range mobility decreases with increasing field, as was described in Sec. 7 for hot carriers in the bulk. In the high-field limit drift velocity tends to saturate, as was also found for bulk *n*-Si. At 300 K, where impurity scattering is negligible, v_d vs $\mathbf{E}$ for the inversion layer is quite similar to that obtained for bulk *n*-Si, with no change up to $\sim 10^6$ V/m, beyond which v_d decreases with further increase in $\mathbf{E}$ and tends to saturate.

10.2.5 Localization. It is observed from ~2 to 50 K for samples with electron concentration in the inversion layer, n_{inv}, less than $10^{16}\ \mathrm{m}^{-2}$ that the conductivity is activated, i.e., proportional to $\exp(-W/kT)$ with W a constant. W decreases monotonically with increasing n_{inv} until it vanishes (Fowler, 1982). It was early suggested that these phenomena indicate localization, attributed to potential fluctuations due to charges known to be in the oxide layer. When the fluctuations are of short range they produce a band tail similar to the impurity band (see Sec. 8), as is found also in amorphous semiconductors. Indeed, the data for samples showing this type of behavior agree well with the prediction [Eq. (54)] for transport in a band with a localized tail. k_{E_C} is found to be approximately equal to the value $0.1e^2/\hbar$ predicted for electrons propagating above the mobility edge in a two-dimensional case. The activation energy decreases as n_{inv} increases, raising E_{F}, and vanishes when E_{F} goes through the mobility edge. Further evidence that this model is correct is provided by the fact that as the temperature is lowered κ is no longer activated, but rather $\ln\kappa \propto T^{-1/3}$. This is the temperature dependence predicted for variable-range hopping (see Sec. 8) in two dimensions.

10.2.6 Conductance Fluctuations. More recently work in this area has focused on transport properties of localized electrons at temperatures below 4 K in very small Si metal-oxide field-effect transistors, patterned to have widths as small as 50 nm. Conduction processes expected to be important for strongly localized electrons when $T < 1$ K are VRH and tunneling. Devices appropriate for studies of hopping conductivity are long ones (because tunneling decreases exponentially with distance), with narrow Si accumulation layers. In a system with dimensionality d when VRH dominates $\ln\kappa \propto -(T/T_{0d})^{1/d+1}$, where T_{0d} is a characteristic temperature that depends on the density of states $N(E_{\mathrm{F}})$ and d. It is found experimentally for these devices that, at temperatures $0.2\ \mathrm{K} < T < 3\ \mathrm{K}$, VRH may be either 1D or 2D depending on the value of V_g, which affects $N(E_{\mathrm{F}})$. (See ELECTRON STATES IN ZERO-, ONE-, AND TWO-DIMENSIONAL STRUCTURES for further discussion.)

A more striking effect in these samples is that at millikelvin temperatures conductance versus V_g has, superimposed on a general upward trend, a spiky behavior. The spikiness increases as T is lowered, the peaks being orders of magnitude above the background with widths at the top that are fractions of a millivolt. The spiky behavior results from the small size of the samples. As discussed in Sec. 8, an electron can hop only to states within a few kT of E_{F}. At 50 mK, for example, $2kT \simeq 10^{-5}$ eV. In a small device the number of states lying within this range is very small. Changing the gate voltage alters the energy of the electronic states in the channel relative to E_{F}. A small change in V_g may result in a large change in conductance G, for example, if it results in a particularly long hop being replaced by a short one. Further, each sample will have its own characteristic dependence of G on V_g because the locations of the levels, being determined by fluctuations in the oxide charge, are different in every sample.

Similar considerations apply to devices in which tunneling is dominant. In a short enough device an electron could tunnel directly from source to drain. Such short devices are difficult to make. In devices where the distance between source and drain is $\geqslant 500$ nm, resonant tunneling has been found of importance. In this process the electron tunnels from the source contact to a localized state in the channel and subsequently tunnels out of that state to the drain contact. For this process to occur the energy of the resonant localized state must equal, or be very close to, E_F in the source and drain contacts. Thus the situation is quite similar to that for VRH, and a similar spiky behavior is found in plots of G vs V_g (Fowler *et al.*, 1988).

GLOSSARY

Acceptor: Impurity that can accept an electron.

Accumulation Layer: Surface region in which the carrier density is greater than that in the bulk of the sample.

Activation Energy: When conductivity varies with temperature T as $\exp(-C/kT)$, C is called the activation energy.

Band Structure: The set of allowed energy E values of an electron in a crystal as a function of wave vector $\mathbf{k}$. The kinds of band structure referred to are (1) simple model—E vs $\mathbf{k}$, a parabola; (2) many valley—E vs $\mathbf{k}$ has a set of minima; (3) degenerate—E vs $\mathbf{k}$ consists of two bands, approximately parabolic, stuck together at $k=0$, and a third separated by a small energy interval.

Blocking Contact: A contact that completely cuts off the supply of charge to a sample.

Brillouin Zone: Unit cell in wave-vector or momentum space containing all the possible (discrete) wave-vector or momentum values.

Conduction Band: The lowest unfilled, or mostly unfilled, band of allowed energies.

Constant-Energy Surface: The surface or surfaces connecting points having the same energy in the Brillouin zone.

Dangling Bond: An unbonded electron. In amorphous silicon, for example, the paramagnetic defect state associated with a threefold-coordinated silicon atom.

Density of States: Number of states available for an electron per unit volume of a sample per unit energy range.

Density-of-States Effective Mass: The geometric mean effective mass for a given valley multiplied by the number of equivalent valleys to the 2/3 power.

Depletion Layer: Surface region in which the carrier density is smaller than that in the bulk of the sample.

Donor: Impurity that can give up an electron.

Doping: Addition of impurities that can increase conductivity of a semiconductor sample by adding electrons to the conduction band or holes to the valence band.

Effective Mass: A mass, which may be anisotropic, assigned to an electron or hole in a solid according to the energy–wave-vector relationship of the state it occupies.

Energy Gap E_g: The gap in energy between valence and conduction bands, empty of states in a sample without defects.

Fermi Energy E_F: The energy at which the probability of a state being occupied by an electron, under thermal equilibrium, is $\frac{1}{2}$.

Hall Effect: Application of a magnetic field perpendicular to the direction of current flow is found to give rise to an electric field perpendicular to both the magnetic field and the current. The Hall coefficient R_H, defined as the electric field developed per unit magnetic field per unit current density, is approximately equal to the reciprocal of the electron (hole) concentration times the charge on the electron.

Hall Mobility μ_H: The product of R_H (see **Hall Effect**) and conductivity, thus approximately equal to the mobility.

Hole: An unfilled state in a band more than half filled with electrons. The unfilled state acts as though it were filled with a charge equal in magnitude but opposite in sign to that of the electron.

Impurity Band: The group of states pulled out of the conduction (valence) band by the addition of donor (acceptor) impurities.

Inertial Mass: The reciprocal of the sum of reciprocals of the effective masses in the three principal-axis directions of the constant-energy surfaces for a given valley.

Injecting Contact: A contact able to supply charge to a semiconductor under the action of an electric field. An injecting contact that can be regarded as an infinite (i.e., nondepletable) charge reservoir, one able to fully satisfy the demands of the semiconductor even under space-charge–limited conditions, is called Ohmic.

Intrinsic Semiconductor: One in which carriers arise primarily from electrons that have crossed the gap into the conduction band, leaving behind holes in the valence band.

Inversion Layer: Surface region in which the current carriers have opposite sign to that of the carriers in the bulk.

Magnetoresistance: The change in resistance of a sample on application of a magnetic field.

Mobility μ: The net velocity in the electric field direction developed by an electron or hole due to acceleration by unit electric field.

Mobility Edge: The energy that separates localized from extended states near the band edge of an amorphous semiconductor.

Momentum Relaxation Time τ: The time for excess momentum, such as that created by an electric field, to decay to $1/e$ of its original value when the source of the excess is removed. τ is approximately equal to the mean free time of an electron or hole between scattering processes.

Ohm's Law: The statement that current increases linearly with applied voltage or electric field. This ceases to be true at high enough fields.

Phonon: A quantum of vibrational energy of one of the normal modes into which the random thermal motion of the lattice atoms may be decomposed.

Photoconductivity: An increase of electrical conductivity induced by the absorption of light.

Space-Charge–Limited Current (SCLC): The current demanded by a solid at fields that make the transit time of an excess injected carrier passing through the bulk to a collecting contact less than the time required to induce its local neutralization. Under these conditions the current is limited by the mutual repulsion of the transiting carriers.

Valence Band: The uppermost filled or nearly filled band of allowed energies.

Variable-Range Hopping: The transfer of an electron between localized sites at temperatures for which the thermal energy (required to make up the energy difference between sites) is so small that progressively larger hops are required with decreasing temperature for sites close enough in energy to the original to be found.

INTRODUCTION

Most of the substances around us, whether natural or synthetic, are electrical insulators. The distinction between insulators and metals has been recognized for centuries, and even children can tell the difference: metals are typically soft and malleable and can be polished to a high luster, while common insulators are hard, brittle, and often rather dull. Most electrical insulators are also thermal insulators. Hot beverages are served in electrical insulators, not metals, to retain the heat better and to prevent injury to the hand while drinking. These are among the more common properties, but insulators exhibit a broad range of characteristics that are perhaps less obvious, but just as important.

Insulators are needed whenever electrical current flow must be controlled, whether as a nerve impulse in a living organism, a bit of information in a digital computer, or the industrial transmission of electrical power. Certain insulators greatly enhance the performance of capacitors by increasing the amount of charge that can be maintained using a particular applied voltage. Other insulators respond to mechanical, thermal, magnetic, electrical, or optical stress in ways that make possible a wide variety of applications such as transducers, filters, motors, detectors, resonators, oscillators, imagers, memory devices, video displays, and many more. The tremendous variation of the properties of insulators plays a major role in the modern technological world, and it is important, therefore, to have some understanding of the relationship between their structure and their properties.

An insulator may be defined as any material that does not allow net movement of electric charge from one region of the material to any other region. The distinction between insulator and conductor, however, is relative and concerns both the conductivity of

the surrounding medium and the duration of the observation. Every material conducts electricity to some extent, so that given enough time even the best electrical insulators will allow some charge motion. Among the best electrical insulators are diamonds, with electrical conductivities of 10^{-13} S m^{-1} or less. But the best metals, like silver, have conductivities of around 10^{8} S m^{-1}, more than 20 orders of magnitude larger. As a rough guideline, anything with a conductivity less than 10^{-3} S m^{-1} may be considered an insulator.

All materials are composed of atomic nuclei and enough electrons to maintain charge neutrality. An electron in such a material may be tightly bound, always remaining near a particular atomic nucleus (or group of nuclei), or it may be free to migrate from one region in the material to another. A material with a large number of free electrons is either a semiconductor or a metal. In an insulator, there is a negligible number of free carriers and a substantial activation energy for the creation of free carriers from the bound electrons.

Electrical insulation can result from a number of distinct mechanisms. In gases, the thermal activation energy is a result of the high ionization energy of isolated atoms. In liquids, glasses, and amorphous solids the thermal activation energy is a result of the atomic disorder that makes migration of carriers a relatively tortuous process. Crystalline solids sometimes have exactly enough electrons to fill entire bands of electronic states completely, leaving the next state available for free electrons at a significantly higher energy, called the band-gap energy. In plastic, polymeric, and liquid-crystal materials various combinations of ionization energies, disorder, and band filling may contribute to a substantial activation energy.

This binding of electrons in an insulator implies that the electrical conductivity, which is proportional to the number of free carriers, will be thermally activated:

$$\sigma=\sigma_o e^{-E_g/2kT}, \tag{1}$$

where E_g is the band-gap energy (or possibly some other, related activation energy). The division is somewhat arbitrary, but typically the term "electrical insulator" is reserved for a material with a band gap of at least 3 eV. The following sections are most appropriate for the properties and structure of homogeneous, crystalline insulators, but some other insulators will be briefly mentioned, and the concepts involved are of general utility. For more detailed information on amorphous materials, electronic structure of solids, polymers, liquid crystals, ceramics, and composite materials see the related articles in this encyclopedia. An overview of the important properties of insulators follows, including a brief discussion of the "soft mode" concept. The section on materials discusses the occurrence of insulating solids among the elements, binary compounds, and certain classes of more complex materials.

1. PROPERTIES OF INSULATORS

1.1 Dielectric Properties

The term "dielectric" emphasizes the response of an insulator to an applied field. The principal properties of interest in this regard are the permittivity (ϵ) and the loss tangent ($\tan\delta$), which characterize both the degree of polarization in an applied field and the losses that result from application of an alternating frequency field. A brief outline of dielectric properties is provided below, but for a more complete discussion see DIELECTRIC PROPERTIES OF INSULATORS.

1.1.1 The Complex Permittivity. When an electric field E is applied to a dielectric material, the charges within the material experience forces that tend to redistribute the charges. This redistribution is characterized by the polarization P, which represents the electric dipole moment induced in the material by the applied electric field. It is also convenient to define a third quantity, called the displacement field D, which represents the effects of the actual charges in the material and is given by

$$D=\epsilon_{\mathrm{v}}E+P, \tag{2}$$

where ϵ_{v} is the permittivity of the vacuum.

In an ordinary dielectric, the polarization, the electric field, and the displacement field will all be proportional to each other. We define

$$D=\epsilon E=\epsilon_{\mathrm{v}}\epsilon_r E, \tag{3}$$

where ϵ_r is the relative permittivity, a unitless quantity sometimes called the dielectric constant, although this term is more properly reserved for situations in which ϵ_r is actually independent of frequency. The polarization is now given by

$$P=\epsilon_{\text{v}}(\epsilon_r-1)E. \tag{4}$$

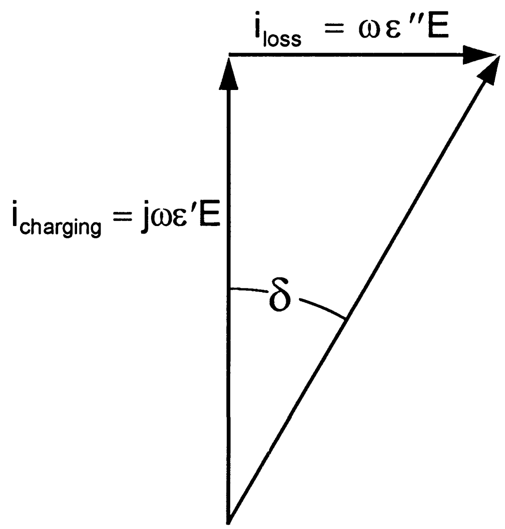
The vacuum clearly has no polarization and $\epsilon_r^{\text{vacuum}}=1$.

As an example, consider a capacitor in a simple charging circuit. The effect of inserting a dielectric material between the plates of the capacitor is to increase the capacitance (the charge the capacitor can hold) by the factor ϵ_r. If the applied voltage is held constant, eventually only a small leakage current will flow because of parasitic conduction through the dielectric material. If the applied voltage is sinusoidal in time, there will be a leakage current in phase with the applied voltage as well as a charging current that precedes the applied voltage by a 90° phase angle.

Thus, the total current through the capacitor (Fig. 1) is given by

$$i=j\omega\epsilon' E+\omega\epsilon'' E=\epsilon\frac{dE}{dt}, \tag{5}$$

where the first term represents the charging current and the second term represents the loss current. The permittivity is now considered to be a complex quantity with both a real and an imaginary component:



$i_{\text{loss}} = \omega\varepsilon'' E$
$i_{\text{charging}} = j\omega\varepsilon' E$
δ

FIG. 1. Charging and loss currents, where tanδ is the loss tangent.

$$\epsilon=\epsilon'-j\epsilon'', \tag{6}$$

where the imaginary component is connected to the frequency-dependent electrical conductivity as

$$\sigma=\omega\epsilon''. \tag{7}$$

A useful quantity for characterizing an insulator is the so-called loss tangent (also called the dissipation factor), defined as the ratio of the loss current to the charging current:

$$\tan\delta=\frac{i_{\text{loss}}}{i_{\text{charging}}}=\frac{\epsilon''}{\epsilon'}. \tag{8}$$

The loss tangent is a material property related to the complex permittivity, which characterizes the electrical losses in an insulator.

1.1.2 Polarization Mechanisms. To understand the origin of polarization effects in materials it is best to begin with the smallest structural units involved, either the individual atoms or small groups of atoms. The electric dipole moment of a single atom (or small group) is taken to be proportional to the local electric field as

$$p_i=\alpha_i E_{\text{local}}, \tag{9}$$

where α_i is the polarization factor. The polarization factor is a microscopic quantity and is convenient because it can be calculated from theory. However, the α_i's are connected to the local electric field, not to macroscopic quantities that may be measured in the laboratory: E, P, and D. In the simplest approximation, the local field is given by

$$E_{\text{local}}=E+P/3\epsilon_{\text{v}}. \tag{10}$$

Combining Eqs. (4), (9), and (10) leads to the Clausius-Mossotti equation, completing the required relationship between the microscopic polarization factors and the macroscopic relative permittivity:

$$\frac{\epsilon_r-1}{\epsilon_r+2}=\frac{1}{3\epsilon_{\text{v}}}\sum_i N_i\alpha_i, \tag{11}$$

where N_i is the number density of dipoles with polarization factor α_i.

The polarization has its origins in the structure of the insulator and may have a number of contributing factors. Figure 2 summarizes the most important mechanisms for polarization in a solid. All materials are subject to *electronic polarization* (also called *atomic* or *optical polarization*) because in an applied electric field the atomic nucleus is displaced with respect to the surrounding electrons, inducing a dipole moment. In the absence of an applied field, the charges within an atom will tend to restore the symmetry of the atom and remove the dipole moment. An atom, therefore, may be thought of as a simple harmonic oscillator with a rather high natural frequency, typically in the ultraviolet range due to the small mass of the electrons. Using this description, and including a damping term to represent losses in the oscillator, the electronic polarization can be shown to have the form given in Fig. 3.

Ionic polarization results from the displacement of cations (positive ions) in the direction of the applied field and anions (negative ions) in the opposite direction, as indicated schematically in Fig. 2. These processes also may be thought of as resulting from simple harmonic oscillators, in this case involving the relative motion of cations and anions in the crystal. Ionic polarization, then, has the same functional form as electronic polarization, but since the motion here involves entire atoms, the natural frequencies of the oscillators are much lower and correspond to lattice vibration frequencies, typically in the infrared or visible region.

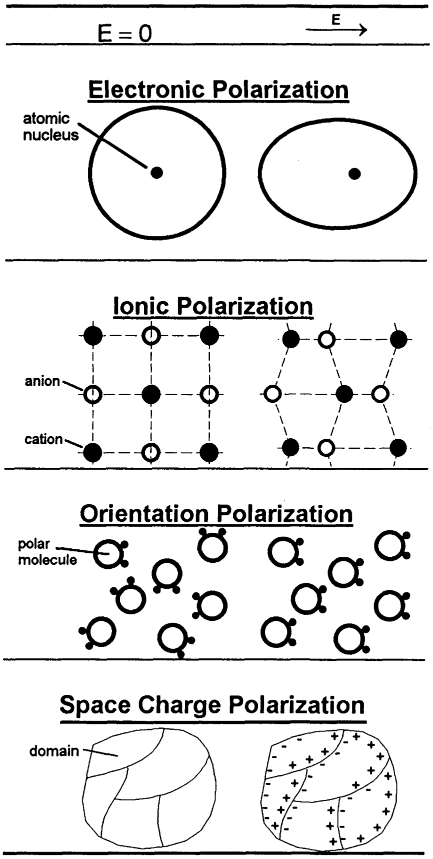


FIG. 2. Major polarization mechanisms. The displacement of the charges has been strongly exaggerated.

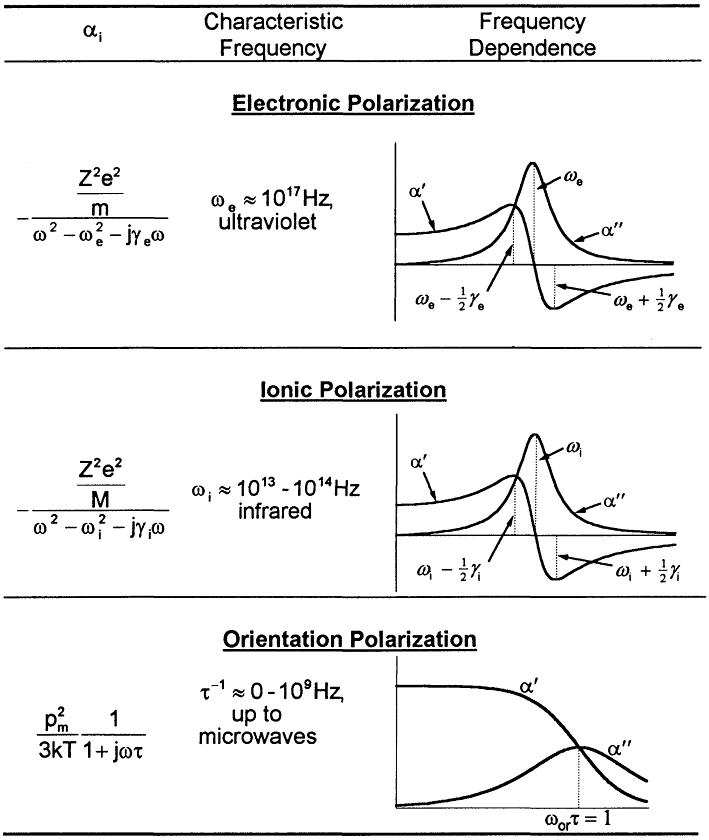
Orientation (or *dipole*) *polarization* occurs when a structural repeat unit or a polar domain with a permanent dipole moment (p_m) experiences a torque, tending to orient the dipole in the direction of the applied field. Thermal motion tends to randomize the orientation of dipoles. In the absence of an applied field a system of oriented dipoles will "relax" toward a random distribution of orientations with a characteristic time τ, called the relaxation time. Using this relaxation model, the orientation polarization can be shown to have the form shown in Fig. 3, with characteristic frequencies (τ^{-1}) ranging into the microwave region.

Space charge (or interfacial) polarization represents the contribution from charge carriers that normally are free to move through the solid, but become impeded by grain boundaries, electrodes, and the like as suggested in Fig. 2. In this case, a space charge eventually builds up, generating a field to counter the applied field until current ceases to flow.

1.1.3 Typical Permittivity Behavior. For the electronic, ionic, and orientational mechanisms three distinct frequency regimes may be identified: first, a low-frequency regime, where the applied field varies slowly enough for the polarization to track the applied field closely and the polarization factor is essentially a real constant; second, a high-frequency regime where the applied fields vary so rapidly that the polarization can not track the applied field at all and the polarization factor tends to zero; and finally, an intermediate regime near the characteristic frequency of the oscillators or relaxation mechanism, where both the real and imaginary components of the polarization factor vary relatively rapidly with frequency. It is only in this intermediate-frequency regime that α'' becomes of significant magnitude.



α_i
Characteristic Frequency
Frequency Dependence
Electronic Polarization

α''
$\omega_i-\frac{1}{2}\gamma_i$
$\omega_i+\frac{1}{2}\gamma_i$
Orientation Polarization
$\frac{p_m^2}{3kT}\frac{1}{1+j\omega\tau}$
$\tau^{-1} \approx 0-10^9$Hz, up to microwaves
α'
α''
$\omega_{or}\tau = 1$

FIG. 3. Frequency dependence of the major polarization mechanisms.

Ordinarily the four polarization mechanisms may be considered as acting independently, in which case the total polarization factor is given by a sum of the four contributions:

$$\alpha_i=\alpha_{i,e}+\alpha_{i,i}+\alpha_{i,o}+\alpha_{i,s}\ , \qquad (12)$$

where the second subscript indicates the contributions from the different mechanisms. Often, since the characteristic frequencies are so different for the different mechanisms, only one of the contributions will have a strong frequency dependence in any particular range of frequencies and the other mechanisms can be considered to provide a frequency-independent background.

The relative permittivity of a material can now be calculated using the sum of the individual contributions to the polarization factor and the Clausius-Mossotti relation. The relative permittivity typically has a frequency dependence similar to the frequency dependence of the contributing polarization factors, represented in Fig. 3. The real component of the relative permittivity is larger at low frequencies (usually called the static dielectric constant, ϵ_0) than at high frequencies (usually called the optical dielectric constant, ϵ_∞) and will vary rapidly only over a relatively narrow range around the characteristic frequency. At frequencies well beyond the ultraviolet, the relative permittivity would drop even further as even electronic polarization processes cannot track the applied field at these frequencies.

At frequencies below the ultraviolet, many materials exhibit a frequency-independent contribution to the polarization from electronic polarization processes and a frequency-dependent contribution to the polarization from ionic polarization processes. The relative permittivity in this case is given by

$$\epsilon_r(\omega)=\epsilon_\infty+\frac{\epsilon_\infty-\epsilon_0}{\omega^2/\omega_T^2-1}\ , \qquad (13)$$

where

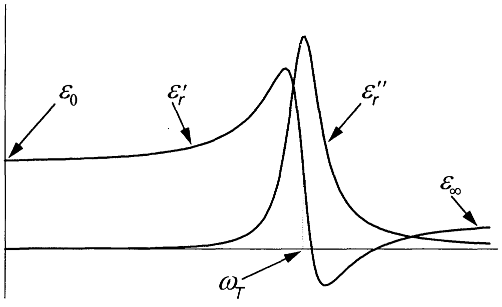

FIG. 4. Real and imaginary components of the relative permittivity typical of an ionic contribution to the polarization.

$$\omega_T^2=(\omega_i^2+j\gamma_i\omega)\left(\frac{\epsilon_\infty+2}{\epsilon_0+2}\right). \tag{14}$$

The real and imaginary components are shown in Fig. 4, where the change in sign of the real component just above ω_T is typical of an ionic contribution to the polarization.

Qualitatively different behavior characterizes the dipole orientation polarization mechanism, where the relative permittivity is given by

$$\epsilon_r(\omega)=\epsilon_\infty+(\epsilon_0-\epsilon_\infty)/(1+j\beta) \tag{15}$$

with

$$\beta=[(\epsilon_0+2)/(\epsilon_\infty+2)]\omega\tau\,. \tag{16}$$

Here $\epsilon'_r(\omega)$ decreases monotonically from ϵ_0 at low frequencies to ϵ_∞ at high frequencies, mimicking the frequency dependence of the orientation polarization factor shown in Fig. 3. In this case, a plot of $\epsilon''_r(\omega)$ as a function of $\epsilon'_r(\omega)$ has the particularly simple form of a circle, as indicated in Fig. 5. This type of graphical representation, called a Cole-Cole diagram, can be used to determine the relaxation time, τ. The procedure involves connecting a point $(\epsilon'_r(\omega),\ \epsilon''_r(\omega))$ at any particular frequency with either the high-frequency limit $(\epsilon_\infty,0)$ or the low-frequency limit $(\epsilon_0,0)$, as indicated by the straight dotted lines in Fig. 5. β may be estimated from the slope of either line and the relaxation time is then given by Eq. (16). Cole-Cole diagrams are useful in identifying relaxation-type polarization behavior, such as is typical of dipole orientation polarization, since other mechanisms appear more complex and qualitatively distinct when represented in this manner, as suggested in Fig. 6.

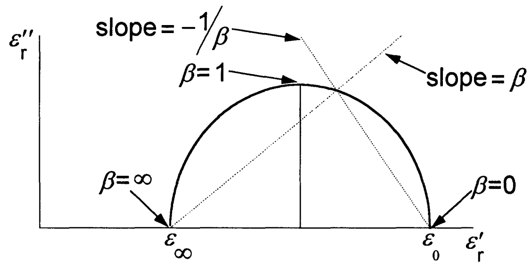

FIG. 5. Cole-Cole diagram for an ideal relaxation-time mechanism.

1.1.4 Piezoelectricity. Piezoelectric materials exhibit two characteristic effects: polarization in response to applied mechanical stress, and mechanical deformation in response to an applied electric field. Both effects are linear and change sign when the applied stress (mechanical or electrical) changes sign. A crystal with a center of symmetry cannot be piezoelectric, since mechanical stress alone will not disturb the balance among the dipole moments within a unit cell. Crystals with a center of symmetry will mechanically deform in an applied electric field, but the deformation will be proportional to the square of the applied electric field. This effect, also called electrostriction, is independent of the sign of the applied field and is usually quite small in magnitude.

Piezoelectricity is possible in any noncentrosymmetric crystal (which includes all the pyroelectric materials discussed below), as illustrated in Fig. 7. The Curie brothers (1880) discovered piezoelectricity in quartz, tourmaline $\{Na(Mg,Fe,Mn,Li,Al)_3Al_6[Si_6O_{18}](BO_3)_3(OH,F)_4\}$, and Rochelle salt. More recently (see PIEZOELECTRIC DEVICES) there has been great interest in organic materials such as polyvinylidene fluoride (PVDF).

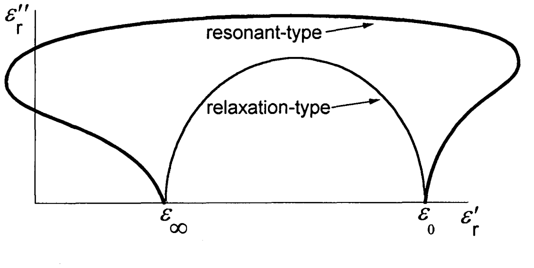

FIG. 6. Cole-Cole diagram illustrating qualitatively distinct behavior for different polarization mechanisms.

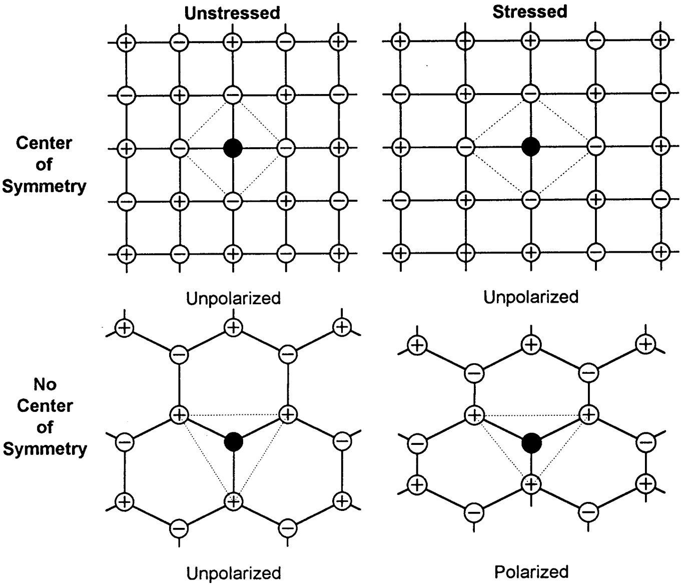

FIG. 7. Crystals with a center of symmetry are not polarized, even under stress. Piezoelectrics, without a center of symmetry, polarize under stress.

1.1.5 Pyroelectricity. Certain materials are called pyroelectric because they appear to generate a spontaneous polarization when heated (or cooled). In fact, polarization is always present internally in these materials, but is ordinarily masked by neutralizing charges collecting on the exposed surfaces. A net polarization is temporarily observed with temperature changes until the surface charges can reequilibrate with the temperature-dependent internal polarization. The observation of an internal polarization implies severe constraints on the symmetry of the crystal: there can be no mirror planes perpendicular to the axis of polarization and no rotational symmetry except along an axis parallel to the polarization axis.

1.1.6 Ferroelectricity. A material that is nonpyroelectric above a certain temperature T_C (the Curie temperature) and pyroelectric below T_C is called a ferroelectric. Just below T_C the spontaneous polarization is usually small and may be readily reversed in direction by an applied field opposing the original polarization, as shown by the characteristic hysteresis loop in Fig. 8. This hysteretic behavior in the polarization and the ability to reverse the polarization by an applied field is sometimes taken as the defining property of a ferroelectric. The term ferroelectric is in analogy to similar behavior observed in the magnetization of ferromagnetic materials.

The origin of ferroelectricity lies in the interaction between the local polarization and the macroscopic electric field. Solving Eqs. (9) and (10) for the total polarization yields

$$P = \frac{\Sigma_i N_i \alpha_i}{1-(1/3\epsilon_0)\Sigma_i N_i \alpha_i} E. \tag{17}$$

The orientational contribution to the polarization, $\alpha_{i,o}$, typically increases as $1/T$ as the temperature decreases, leading eventually to a zero in the denominator of Eq. (17) at some temperature, implying spontaneous polarization. Here, the local field produced by a dipole has a sufficiently strong effect on neighboring dipoles that all of the dipoles prefer to orient in the same direction, even in the absence of

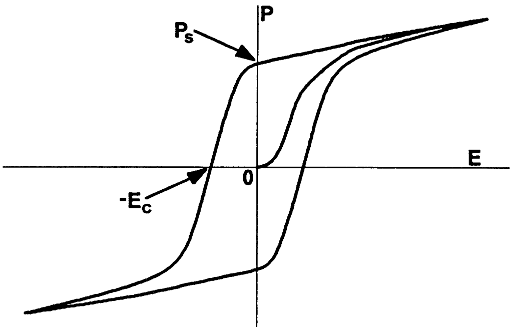

FIG. 8. The ferroelectric hysteresis loop indicating the spontaneous polarization (P_s) and coercive force ($-E_c$) required to reduce P_s to zero.

an applied field. This critical temperature is the Curie temperature T_C, and the dielectric susceptibility takes the form

$$\chi \equiv \epsilon_r - 1 = C/(T - T_C), \qquad (18)$$

where C is a constant, again in close analogy to the magnetic susceptibility of a ferromagnet.

The dipole moments that can be induced by applied fields or stress above T_C become permanent below T_C. The mechanisms responsible for ferroelectricity vary from material to material and will be discussed in the materials section below. Generally, however, ferroelectricity results from a lowering of the symmetry of the crystal lattice, similar to that suggested in Fig. 7 except that an applied stress is no longer required to maintain the polarized state. Blinc and Žekš (1974) list over 300 known inorganic ferroelectric compounds (not counting solid solutions), and Fousek (1991) estimates that over 50 families of liquid-crystal ferroelectrics are now known. A few representative materials exhibiting a variety of properties are listed in Table 1.

1.1.7 Lattice Dynamics and Soft Modes. The permanent polarization in the low-temperature form of a ferroelectric represents a modification of the lattice compared to the more symmetric, high-temperature form of the material. The lattice modification can be examined with experiments such as x-ray or neutron diffraction that are sensitive to the atomic positions. Cochran (1959) and Anderson (1959) introduced the concept that ferroelectricity results from an instability of one of the normal lattice vibrational modes. The characteristic frequency of the so-called soft mode, referring to the unstable lattice vibration, decreases on approach to the Curie temperature, T_C, and the restoring force tending to return the displaced atoms to their normal positions approaches zero. The soft mode then freezes in and the atoms become permanently displaced, resulting in the ferroelectric state.

While a detailed discussion of soft modes is well beyond the scope of this article, it is important to emphasize the close connection between the stability of the lattice with respect to distortion and the occurrence of ferroelectricity. Much of the study of ferroelectrics has been directed toward a detailed understanding of the occurrence, symmetry characteristics, and energetics of soft modes. Blinc and Zĕkš (1974) provide a review of theoretical and experimental techniques in the study of soft modes. Articles in this encyclopedia on phonons and lattice vibrations may also be of interest in this regard.

1.1.8 Antiferroelectric and More Complex Order. While individual dipoles orient in the same direction in a ferroelectric (at least within a single domain), this is by no means the only possible arrangement of dipoles. The first soft-phonon mode to freeze into a static displacement may have a periodicity identical to the original lattice unit cell or a simple multiple of the unit cell, or may even be incommensurate with the original lattice. In an antiferroelectric material, for example, there are two sets of dipole moments, each in a regular arrangement and alternating in direction. In this case there is no net polarization as one set of dipoles precisely cancels the other. $PbZrO_3$, the first known antiferroelec-

[b] Lower T_C.

tric, was identified by Kittel (1951), who also coined the term.

$Gd_2(MoO_4)_3$ has been found to be a ferroelectric, but the transition to the ferroelectric state is not associated with any observable dielectric anomaly and the substance is called an "improper" ferroelectric since the spontaneous polarization does not alter the symmetry of the crystal. Other and increasingly subtle types of dipole ordering are now recognized, in both homogeneous and inhomogeneous materials, and have been reviewed by Fousek (1991).

1.2 Magnetism

Magnetite (Fe_3O_4) may have been used as a compass by the Chinese as early as 2500 B.C., and magnetic materials continue to play an important role today as inductor cores, magnetic recording media, and permanent magnets for use in motors, generators, loudspeakers, and much more. Insulating magnetic materials are preferred to electrically conducting magnetic materials for high-frequency applications because the absence of induced eddy currents, which reduces power losses, makes them especially important for the manufacture of inductors.

The magnetic behavior of materials is no less varied than the electrical behavior described in the preceding sections. A more complete discussion is provided in the articles on magnetism and magnetic devices, but in broad terms the magnetic field H, the magnetic induction B, magnetic permeability μ, and magnetic susceptibility χ_m parallel the roles of the electric field E, the displacement field D, the permittivity ϵ, and the electric susceptibility χ already described. Caution must be exercised in pressing the analogies too far, however, because the physical origin of local magnetic-dipole moments is quite distinct from the origin of local electric-dipole moments, as will be described in the following sections.

1.2.1 Diamagnetism. Insulators composed of ions with all electronic shells filled are typically diamagnetic, and the total diamagnetic susceptibility may be reliably estimated from the contributions of the individual ions. The effect of an applied magnetic field, in this case, has been described as inducing a microscopic current in the orbital electrons about each atom. According to Lenz's law, the induced currents produce a weak magnetic field tending to cancel the applied magnetic field. A complete description of this behavior requires a quantum-mechanical treatment, but the effect is called diamagnetism. Under certain conditions superconducting materials exhibit "perfect diamagnetism," where the induced currents completely cancel the applied field and prevent the penetration of magnetic field to the interior of the superconductor. Diamagnetism arising from the orbital motion of electrons within an atom is about a million times weaker than perfect diamagnetism and is temperature independent. Although typical of most insulators, this weak diamagnetism is of little technological interest.

1.2.2 Paramagnetism. Paramagnetism refers to an induced magnetic field in the same direction as the applied field, which is to say, a positive magnetic susceptibility. Paramagnetism occurs in insulators composed of ions with partially filled $3d$ (Ni, Fe, Mn, etc.) or $4f$ (Sm, Gd, Dy, etc.) shells, representing first-row transition-metal ions and the lanthanides, respectively. The electrons occupying an incompletely filled shell experience electron-electron Coulomb interactions as well as an interaction between the electron spin and the orbital motion. These two interactions tend to keep the electron spins aligned, with the result that the ion has a permanent magnetic-dipole moment. The magnetic response of a solid composed of such ions will depend on temperature following Curie's law, analogous to Eq. (18), where the decrease in the susceptibility at high temperatures reflects the inability of an applied field to overcome the increased thermal agitation of the local moments.

1.2.3 Ferromagnetism. When in close proximity, the magnetic field produced by one localized magnetic moment may directly influence the orientation of the magnetic moment of a neighboring ion. In this case, the localized moments no longer behave entirely independently, and large numbers of moments may spontaneously orient in the same direction. This behavior is called ferromagnetism [Fig. 9(a)], and the temperature at which ferromagnetic order sets in will depend on the strength of the interaction between

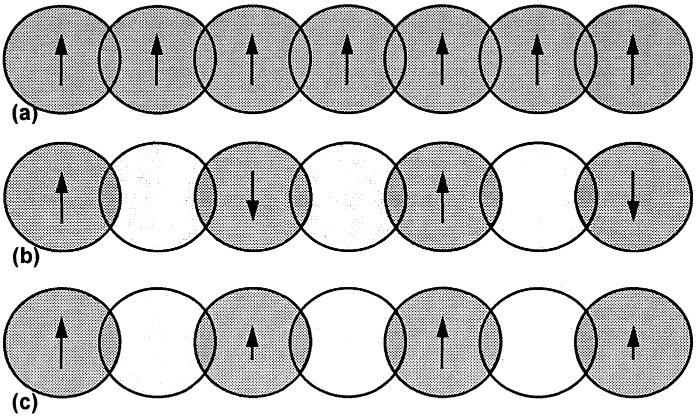

FIG. 9. (a) Direct exchange, local moments directly overlap leading to ferromagnetic order; (b) superexchange, local moments interact via an intermediate nonmagnetic ion leading to antiferromagnetic order; and (c) superexchange leading to ferrimagnetic order.

local moments. Above the ordering temperature, such materials exhibit paramagnetic behavior.

1.2.4 Antiferromagnetism and More Complex Order. In many crystal structures, local magnetic moments are separated by nonmagnetic ions, as illustrated in Fig. 9(b). Since the direct interaction between local moments decreases rapidly with increasing distance, the nonmagnetic ion can mediate a magnetic interaction that is stronger than the direct interaction. This type of interaction is called superexchange and is typically negative in sign, leading to the alternating spin-up, spin-down arrangement known as antiferromagnetism, as suggested in Fig. 9(b). An antiferromagnet exhibits no net magnetization, and the magnetic susceptibility, which peaks in a cusp at the antiferromagnetic ordering temperature, need not reach extremely large values. Complex crystal structures with more than one type of magnetic ion may exhibit a wide variety of magnetic ordering behavior with the magnetic moment varying in magnitude, as suggested by Fig. 9(c), or direction from one crystallographic site to another.

1.3 Thermal Properties

The heat capacity of insulators is remarkably well behaved, and even relatively simple models based on the statistical mechanics of phonons provides a quite accurate description. At high temperatures, each possible vibrational mode of an insulator is equally excited and the heat capacity approaches the temperature-independent Dulong-Petit value of $3k$ for each atom in the crystal. At low temperatures, the lattice vibrations decrease rapidly and the heat capacity varies as T^3 with relatively minor and well-understood deviations, except for materials with special considerations such as phase transitions.

Metals are typically good thermal conductors because of the ability of free electrons to conduct heat as well as electricity. The thermal conductivity of insulators is somewhat more complex, as discussed in more detail in Thermal Conduction in Solids, and can be either large or small depending on the material. Essentially, the heat carried by phonons in an insulator can be estimated from a knowledge of how fast and how far a phonon moves between scattering events. The thermal conductivity may be expressed as

$$\lambda=\tfrac{1}{3}Cv_sl, \qquad (19)$$

where C is the heat capacity per unit volume, v_s is the speed of sound, and l is the phonon mean free path. The speed of sound typically reflects the bond strength, and high–melting-point materials tend to have a high sound velocity and, therefore, high thermal conductivity. If there is only one atom per unit cell, all the phonon modes are acoustic modes with relatively high propagation velocities. As the crystal structure becomes more complex, the unit cell grows, and more phonon modes become optical in character with very low propagation velocity. Thus, the more complex the crystal structure, the lower the thermal conductivity is expected to be. Amorphous materials, such as fused silica, may be considered the limiting case in regard to structural complexity, and indeed these materials have among the lowest thermal conductivity values known.

In materials relatively free of defects, phonons may propagate a long distance before scattering, and in this case the long mean free path leads to a high thermal conductivity. Classic examples are diamond and aluminum nitride, which have thermal conductivity values greater than metals. Even if no other defects are present, the phonons themselves may be thought of as deviations from the ideal crystal structure and phonon-phonon scattering is often the limiting factor. At high temperatures, phonon-phonon scattering leads to a $1/T$ temperature dependence. At low temperatures, as phonon-phonon scattering decreases, the phonon mean free path becomes larger until the walls of the specimen prevent further propagation. Eventually, the thermal conductivity decreases as T^3 with decreasing temperature, reflecting the temperature dependence of the heat capacity discussed above.

2. INSULATING MATERIALS

Electrically insulating materials are far too common to enumerate in any complete way, but some appreciation of the trends and patterns may be achieved by a brief survey. Some of the more important materials will be discussed, as well as the connection between the structure of the materials and their properties.

2.1 Elemental Insulators

The rare gases, hydrogen, nitrogen, oxygen, and fluorine and chlorine are insulating gases under standard conditions and remain insulators even when they condense to liquids and finally solids at sufficiently low temperatures. Bromine is an insulating liquid and iodine and astatine are insulating solids under standard conditions. The common, stable form of selenium has infinite helical chains and is, like tellurium, semiconducting, but Se_8 polymorphs are red insulators similar to solid S_8, which is a very poor electrical conductor. Arsenic is a semimetal, and the electrical conductivity of phosphorus varies greatly among the four known allotropes, but the volatility and reactivity of these elements severely limit their use as solid insulators. Boron, the only refractory nonmetallic element other than carbon, occurs in two distinct crystal structures (the α and β forms), both of which are semiconductors with band gaps around 1.5 to 2.0 eV.

Carbon, in the diamond crystal structure shown in Fig. 10, is expected to become increasingly important since the development of diamondlike thin films. The diamond crystal structure may be described as two identical, interpenetrating face-centered-cubic (fcc) lattices. The second fcc lattice is displaced from the first by a translation along a diagonal of the cube by a distance of $\frac{1}{4}$ of the length of the diagonal. With its tightly bound electrons and strong covalent bonds, diamond is uniquely suited for many applications. The electrical properties of diamond are dominated by the very large band gap of 5.4 eV, which leads to electrical conductivity values as low as 10^{-13} S m^{-1}, although doping can increase this value to 10^{0} S m^{-1} or more. The strong bonds and small mass of carbon lead to sound velocity and thermal conductivity values among the highest known. For more information the reader is referred to DIAMOND AND DIAMONDLIKE CARBON.

Other forms of carbon are not electrical insulators. Graphite, for example, consists of two-dimensional sheets of hexagonally bonded carbon with only weak bonding between the sheets. Graphite is typically a fairly good electrical conductor, with conductivity values on the order of 10^5 S m^{-1}. Thus, by changing the crystal structure from the diamond arrangement to the graphite arrangement the

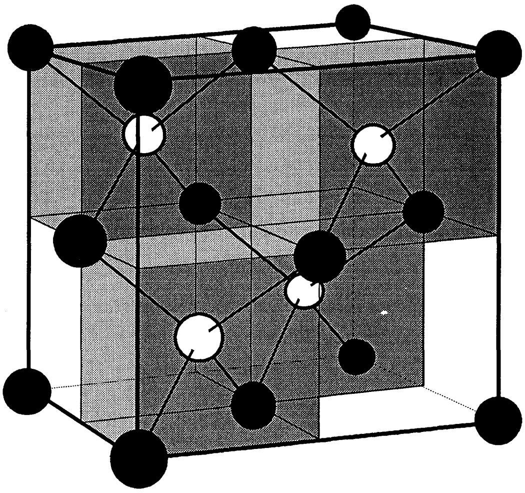

FIG. 10. The sphalerite (or zinc-blende) crystal structure. Also, the diamond crystal structure when the solid and open circles represent the same atom.

Table 2. Selected covalent insulators.

Structure type	Compound
Diamond	C

Wurtzite	BP, AgI, SiC, ZnS, BN, GaN, AlN, ZnO, BeO
Hexagonal	α-Si_3N_4, β-Si_3N_4, SiO_2

conductivity can increase by 18 orders of magnitude, which emphasizes the role of structure in determining the electrical properties of solids.

All of the remaining elements are semiconductors, semimetals, or true metals. Thus, among the elements, solid electrical insulators are relatively rare.

2.2 Binary Compound Insulators

2.2.1 Covalent Insulators. Many covalently bonded compounds are semiconductors, but some important insulators found in this group are listed in Table 2. The first group includes those compounds that share the same basic structure as diamond, except that the two interpenetrating sublattices shown in Fig. 10 are occupied by different atoms. This is the sphalerite (or zinc-blende) structure type, and Table 2 lists a number of common insulators with this structure. The sphalerite structure is symmetric about each atom in the unit cell and therefore is neither pyroelectric nor piezoelectric.

Other covalent insulators form in the wurtzite structure, which can be considered as two interpenetrating close-packed hexagonal lattices. As in the sphalerite structures, each atom is tetrahedrally coordinated with four atoms of the opposite type. BN can be found in the zinc-blende or wurtzite forms, as well as in a graphitelike hexagonal structure, all of which are good insulators. SiC forms in a large number of closely related structures composed of sphalerite and wurtzite layers, and although it has interesting semiconducting properties, all SiC polytypes may be considered insulators if sufficiently pure. The ease with which the covalent bond is polarized generally increases with atomic number, which can lead to somewhat larger static dielectric constants than expected for a nonpolarizable bond, but qualitatively the permittivity behaves very much as expected on the basis of the ionic polarization mechanism described in Figs. 2, 3, and 4.

2.2.2 Ionic Insulators. The ionic crystal structures for sodium chloride (NaCl) and cesium chloride (CsCl) are shown in Fig. 11. Under ordinary conditions, all of the alkali halides form in the NaCl-type structure, except CsCl, CsBr, and CsI, which form in the CsCl-type structure. Both are high-symmetry structures, exhibit no piezoelectric or pyroelectric effects, and have dielectric behavior in good accord with the ionic polarization mechanism described above. In Table 3 note the distinctly greater polarizability of the CsCl-type compounds compared to the trends among the NaCl-type as indicated by the relatively larger static dielectric constants ϵ_0 of the former compounds. This indicates that even closely related crystal structures with similar bonding can exhibit distinct properties.

2.2.3 Binary Oxides and Other Binary Insulators. Although both insulators and conductors can be found in almost any family of materials, many binary chalcogenides (especially oxides and sulfides) and pnictides

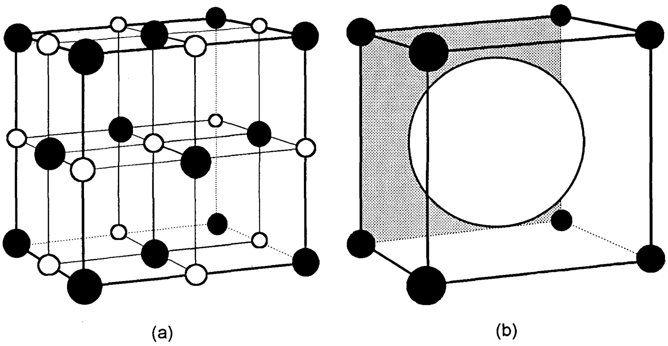

FIG. 11. (a) Sodium chloride and (b) CsCl crystal structure types.

(including nitrides and phosphides) and practically all halides are typically good electrical insulators. These compounds are neither purely covalent nor purely ionic, and while many are insulators, they tend to have relatively high symmetry crystal structures and fairly ordinary dielectric properties.

Most of the binary oxides are insulators, and materials such as alumina (Al_2O_3), magnesia (MgO), and beryllia (BeO) see widespread use for their dielectric properties. $3d$ transition-metal oxides such as Fe_3O_4 and CrO_2 are typically magnetic and exhibit the characteristic phenomena of saturation and hysteresis so important for magnetic recording applications. Many other $3d$ oxides such as MnO, FeO, and CrO are antiferromagnets, and in most cases the superexchange mechanism is responsible for the magnetic order.

Practically all the binary carbides and most of the borides not listed above, however, have at most relatively small band-gap energies and are semiconductors, and many, in fact, are metallic compounds. Only a handful of binary compounds (such as FeS, Bi_2S_3, WO_3 and possibly a few others) are ferroelectrics. Indeed, the scarcity of ferroelectric behavior among binary compounds left the impression for many years that ferroelectricity was rather rare, an impression later dispelled by studies of more complex materials. Finally, SiO_2 in its various forms deserves special attention and is discussed in dedicated articles on GLASSES and QUARTZ.

[a] CsCl structure type.

2.3 Multinary Compound Insulators

As increasingly complex materials have come under investigation, new types of behavior have been observed and characterized. Often, these new behaviors have no precedent among the binary compounds or among the elements. As far as ordinary dielectric properties are concerned, polystyrene, polyethylene, Mylar, Teflon, and similar materials are not qualitatively superior to or even especially distinct from the classic binary compounds discussed above. Still, modern plastics and polymers are often vastly preferred in dielectric applications for cost, packaging, or other practical considerations.

Many of the more complex materials exhibit effects completely unobserved in the binary compounds. Table 4, for example, provides an overview of the ferroelectric materials now known to exist. Typically, as each class of materials has been developed, new theoretical concepts have been required as well.

2.3.1 Rochelle Salts and Other Order/Disorder Systems. The earliest known ferroelectrics were the Rochelle salts (also called Seignette salts), such as $NaKC_4H_4O_6 \cdot 4H_2O$ (Valasek, 1920, 1921). The orientation polarization mechanism is vividly demonstrated in these materials in that the hydrogen bonding is sufficiently weak to allow a type of hindered rotation of the water molecules. The orientation of one water molecule influences the preferred orientation of others nearby, and as the temperature is lowered through the Curie temperature, the water molecules tend to order with respect to each other, establishing a net polarization.

An interesting feature of the Rochelle salts is the presence of two critical temperatures, as indicated in Table 1. Above the upper transition temperature and below the lower temperature, two different sublattices of water mol-

ecules are equally polarized, but in opposite directions resulting in no net polarization. Between the two transition temperatures the two sublattices are still polarized in opposite directions, but the polarizations do not exactly cancel. Fairly detailed models, which may be described as a competition between two distinct relaxation times rather than the single relaxation time assumed in Fig. 3, have been developed to describe the Rochelle salts and their heavy-water analogs (Blinc and Žekš, 1974).

Materials systems with related order-disorder transitions generally involve hydrogen bonding. Examples include the heavily studied potassium dihydrogen phosphate (KH_2PO_4 or KDP) type system, sulfates, selenites, nitrites, triglycine sulfate (TGS), formates, colemanite, alums, and more. These systems have been rather extensively studied and are reasonably well described by relaxation-time, order/disorder models.

2.3.2 Perovskites and Displacive Transitions. Figure 12 shows the typical perovskite crystal structure in the high-temperature, cubic phase. The oxygen atoms in the centers of the cube faces have two titanium nearest neighbors (atoms) along an axis perpendicular to the cube face, but there are no titanium atoms in the cube faces at all. Although the overall lattice is cubic, the oxygen atoms do not experience full cubic symmetry

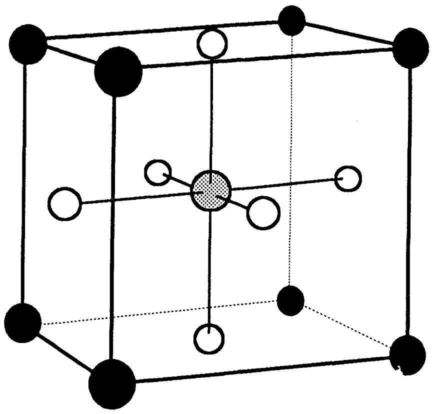

FIG. 12. The perovskite crystal structure for $BaTiO_3$. Ba atoms are at the cube corners, a Ti atom is at the cube center, and O atoms are at the centers of the cube faces. Note that each oxygen atom has only two titanium nearest neighbors, which is the origin of the ferroelectric behavior instability.

and can displace within the plane much more easily than in a direction perpendicular to the plane.

It is this asymmetric movement of the oxygen atoms that leads to an instability in the lattice, a rather clear example of a soft-mode instability. And indeed, upon cooling the unit cell distorts to a tetragonal structure and a net polarization develops along the direction of a cube edge, as shown in Fig. 13. On further cooling, the unit cell distorts again, this time along a diagonal in the face of the cube, and finally at still lower temperatures a rhombohedral distortion sets in, with a net polarization along a full cube diagonal.

The perovskites are called displacive ferroelectrics, since the mechanism involves a permanent displacement of atoms. Above the Curie temperature the resonant frequency (from Fig. 3) goes to zero as

$$\omega_i^2 \propto T - T_C , \tag{20}$$

a typical soft-mode signature.

2.3.3 Bronzes, Pyrochlores, and Nonmagnetic Oxides.

The metal oxides (niobates, manganites, tungsten bronzes, pyrochlores, molybdates, vanadates, and some others) listed in Table 4 undergo displacive transitions upon cooling and exhibit resonant behavior in the dielectric properties characteristic of an ionic soft mode, as with the perovskites. The theory of these ferroelectric materials can be said to be reasonably mature. Important for some time as commercial ceramics (see Table 5), many of these oxides continue to be the subject of research in the form of thin films, composites, and layered structures (see MATERIAL PROPERTIES OF CERAMICS).

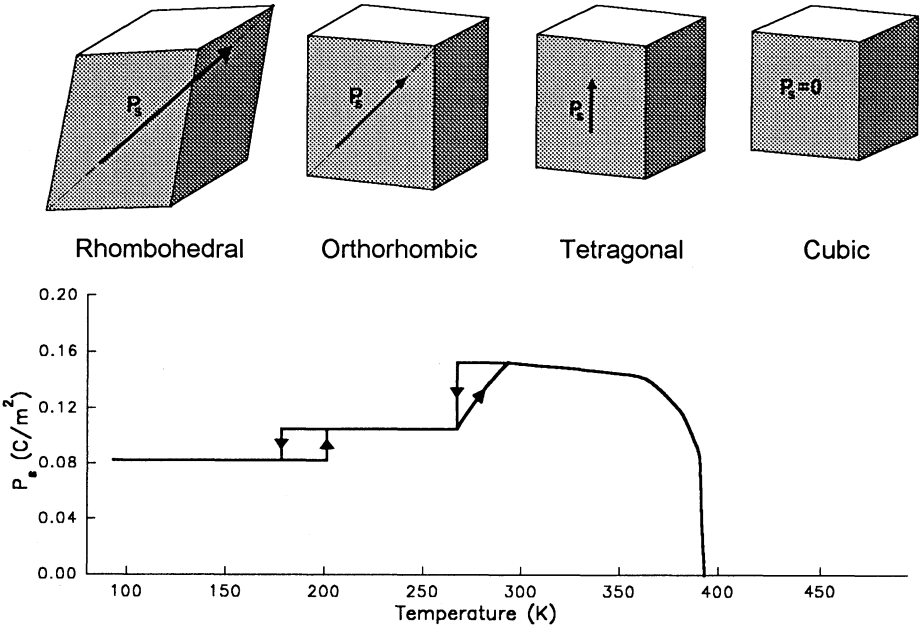

FIG. 13. Projection of the spontaneous polarization of $BaTiO_3$ onto one edge of the unit cell (modified from Merz, 1949).

2.3.4 Ferrites: Spinels and Garnets. The term ferrite is typically used to refer to ferrimagnetic oxides. These materials are hard, brittle, and poor electrical conductors widely used in inductors, particularly at high frequencies. An important family of ferrites are the spinels with the chemical formula MFe_2O_4, where the iron is trivalent and M denotes one of the divalent ions Mg^{2+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, or Cd^{2+}. Spinels have a cubic crystal structure containing 8 chemical formula units with 32 oxygen sites per unit cell. The metal ions occupy one of two types of sites within the unit cell, designated A and B, and are coordinated by either four or six nearest-neighbor oxygen ions, respectively. Thus, there are two types of magnetic moments, corresponding to the Fe^{3+} ions or the divalent metal ions, and ferrimagnetic behavior due to the superexchange mechanism dominates the magnetic properties. There are two structural variants, called normal and inverse spinels, depending on whether the divalent ions occupy A sites or B sites, respectively, and real materials are typically mixtures of both structural variants.

The garnets, with chemical formula $3M_2O_3 \cdot 2Fe_2O_3 \cdot 3Fe_2O_3$, have 160 atoms per unit cell and three distinct types of crystallographic sites occupied by magnetic ions. In these materials M represents one of the trivalent rare-earth elements; perhaps the best known example is yttrium iron garnet, abbreviated YIG, which is notable for particularly low magnetic losses at high frequencies.

Table 5. Oxides often used in insulating ceramics (modified from von Hippel, 1954).

Kaolinite	$Al_2(OH)_4Si_2O_5$
Quartz	SiO_2
Feldspar	$K_xNa_{1-x}[Al \cdot Si_3]O_8$
Mullite	$Al_6Si_2O_{13}$
Cordierite	$Mg_2Al_2Si_5O_{15}$
Alumina (corundum)	Al_2O_3
Steatite (talc)	$Mg_3 \cdot (OH)_2 \cdot Si_4O_{10}$
Clinoenstatite	$MgSiO_3$
Forsterite	Mg_2SiO_4
Zircon	$ZrSiO_4$
Spodumene	$Li_2Al_2Si_4O_{12}$
Wollastonite	$CaSiO_3$
Rutile	TiO_2
Barium titanate	$BaTiO_3$
Sodium tantalate	$NaTaO_3$
Sodium niobate	$NaNbO_3$
Cadmium niobate	$Cd_2Nb_2O_7$
Magnetite	Fe_3O_4
Spinel	$MgAl_2O_4$
Ferrite spinel	$Ni_xZn_{1-x}Al_2O_4$

2.3.5 Organics. Plastics, polymers, and organic materials of many types have become increasingly important for a variety of applications, from packaging to textiles (see Polymers, Material Properties of). Organic chemistry techniques applied to ferroelectric materials have led to the development of novel structures with unique properties. A few examples follow.

Polyvinylidene fluoride (PVDF) is an organic polymer that can be prepared from solvents in the form of thin films. As prepared, PVDF crystallizes in a nonpolar α phase, which upon stretching transforms to a ferroelectric β phase. Mixtures of PVDF and trifluoroethylene (and other copolymers) will crystallize directly in the ferroelectric phase without further mechanical treatment, and the Curie temperature can be adjusted in the range of 330 K to 400 K. PVDF and related materials may be inexpensively prepared in thin layers ($< 10\ \mu m$) and have therefore received considerable attention for various piezoelectric and pyroelectric applications, particularly those requiring rapid response times (Gerhard-Multhaupt *et al.*, 1987).

Liquid crystals represent a second family of organic insulators with particularly interesting ferroelectric properties. Liquid-crystal ferroelectrics typically consist of relatively long, rodlike molecules which "crystallize" in regular layers, as suggested in Fig. 14. These layered phases, called smectic phases, come in a variety of types enumerated alphabetically, as in SmA for the smectic A-type arrangement and so on. The arrangement depicted in Fig. 14 is the SmC arrangement, indicating that the long axes of the molecules are not quite in the direction normal to the planes, but are tilted somewhat. Within the layers, however, the molecules have no long-range order and behave essentially as a liquid, but the molecules remain essentially parallel and from plane to plane behave much like a crystal.

If the molecules in a smectic-C type phase are also chiral, meaning that the molecule has distinct right-handed and left-handed versions, then the liquid crystal will exhibit ferroelectric properties. Liquid-crystal ferroelectrics have become increasingly important for their potential in low-cost flat-panel displays,

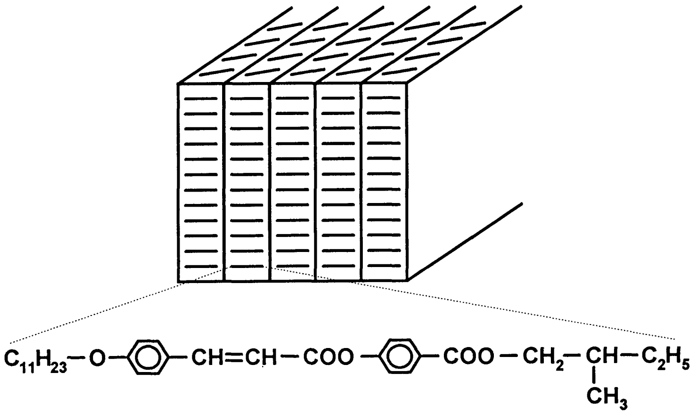

FIG. 14. Typical ferroelectric liquid crystal molecule, shown in the smectic-C arrangement.

and most of the new ferroelectric materials identified recently are liquid crystals (Fousek, 1991). For a more detailed discussion of liquid crystals, see LIQUID CRYSTALS, STRUCTURE OF.

Finally, the Langmuir-Blodgett technique is another powerful method for preparing organic thin-film structures with well-defined symmetry (Roberts, 1985). Typically, molecules with a hydrophilic head and a hydrophobic tail are dissolved in an organic solvent and spread on a water surface, and the solvent is evaporated. Monomolecular layers of the film-forming material can then be collected on a solid substrate by repeated passes through the water surface. A pyroelectric material can be produced by depositing alternating layers of fatty acids and amines, as shown in Fig. 15.

3. SUMMARY

The list of insulating materials has not been exhausted here. Rubbers, elastomers, plastics, polyvinyl chloride (PVC), gases, liquids, most minerals, glasses, and more have been nearly excluded. But the basic polarization mechanisms described (electronic, ionic, orientational, and space charges) provide a sound foundation for understanding the major insulating properties of a wide variety of materials. The principles of crystal structure and symmetry in allowing or forbidding various kinds of electric dipole ordering will also play a key role, regardless of the material or application in question.

The theoretical understanding of the classical insulating materials is quite mature and provides a firm foundation for further developments. The advent of liquid-crystal ferroelectrics and the ability to design and manufacture new structures nearly at will is sure to have an impact on future sensor, imaging, memory, and video technologies.

GLOSSARY

Critical Temperature: Typically a cusp or other sharp feature in the temperature dependence of an observable property, representing an abrupt change in the order among physical objects such as ions, electric dipoles, or magnetic dipoles.

Dielectric: A material that internally redistributes charges in response to an applied electric field.

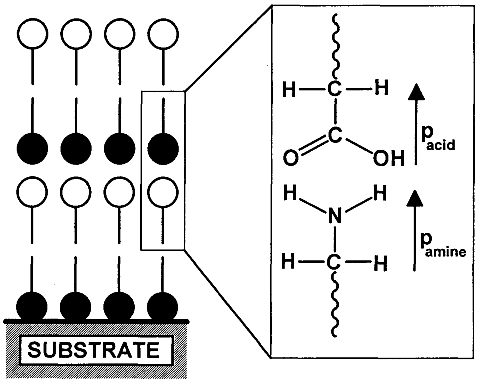

FIG. 15. Langmuir-Blodgett film of alternate acid/amine layers to produce a pyroelectric (redrawn from Roberts, 1985).

Phonon: A single lattice vibration mode representing physical displacement of atoms or ions about their equilibrium positions.

Polarization: The electric-dipole moment induced in a dielectric by an applied electric field.

Soft Mode: An unstable lattice vibration requiring little or no energy to displace atoms or ions from their equilibrium positions.

INTRODUCTION

Particle beams are characterized as intense if their self-fields are sufficiently strong to dominate their behavior. Such beams can be controlled with guiding magnetic fields, but they can also propagate freely in a variety of ways. They are characterized by the strength parameter ν/γ. The fundamental scale for intense beams is the Alfvén current

$$I_A = \frac{4\pi\epsilon_0 m_0 c^2}{e}\beta\gamma, \qquad (1)$$

where m_0 is the electron mass and the relativistic factor $\gamma^2 = (1-\beta^2)^{-1}$; $\beta = v/c$, and v is the particle velocity. In practical units

$$I_A = 17\beta\gamma \text{ kA}. \qquad (2)$$

The current of a beam can be written in terms of the Alfvén current as

$$I/I_A = \nu/\gamma, \qquad (3)$$

where ν is the Budker parameter, defined as the product of the number N of beam particles per unit length and the classical electron radius:

$$\nu = Ne^2/4\pi\epsilon_0 m_0 c^2. \qquad (4)$$

For $\nu/\gamma \ll 1$, electron trajectories are roughly sinusoidal and propagation is possible. Such a propagating beam has a characteristic "betatron wavelength" that is the characteristic oscillation length of the electron about the axis as it propagates. The betatron wavelength for a beam of radius a is

$$\lambda_\beta = a\gamma/\nu. \qquad (5)$$

As beam intensity is increased, a point is reached where the Larmor radius of beam electrons in the magnetic field of the current is about equal to the beam radius. Beam electrons turn completely around and flow stops. This limit occurs at $I \sim I_A$ for a uniform radial current distribution. So when $\nu/\gamma \approx 1$, self-fields strongly influence beam motion.

Intense particle beams were first developed in the 1960s when pulsed electrical systems producing tens of kiloamperes of electron current at megavolt energies succeeded in propagating beams at about the Alfvén current. Since that time, vigorous efforts have produced beams with megampere currents at several megavolts with typical pulse duration of 100 ns. Electrical beam impedance is low, $< 100\ \Omega$, and can be $< 1\ \Omega$. The large energy per pulse, as high as a megajoule, gives this technology many applications from nuclear effects simulation to inertial-confinement fusion, high-power microwave generation, and x-ray production. In this article we first discuss methods of intense-beam acceleration, then electron- and ion-beam emission, followed by beam propagation and, finally, the applications of intense beams.

1. METHODS OF GENERATION

1.1 Acceleration Techniques

Intense beams can be produced by a variety of means, usually involving a voltage-multiplying Marx generator that pulse-charges a liquid dielectric intermediate line in a time scale of about a microsecond (Fig. 1). The Marx generator works by charging capacitors in parallel to a high voltage (~100 kV), switching them into a series arrangement, and discharging them into a load (see Miller, 1982). Firing a gas- or liquid-insulated intermediate switch then allows the voltage pulse from the intermediate line to be applied to the pulse-forming line. This line determines the output pulse duration: when the output switch fires, a wave propagates along the pulse-forming line, reflects at the end, and returns. Therefore the output pulse is twice the transit time of the line, typically 100 ns. There is a prepulse switch in some machines that fires early in the pulse, preventing any early voltage transients from reaching the output. Finally, the pulse passes through an insulator and enters a vacuum diode consisting of electrodes from which particles, usually electrons or protons, are accelerated across the potential difference and extracted as an intense beam. Intense electron beams were first generated in the 1960s, and intense ion beams appeared in the 1970s. Figure 2 shows the historical development of intense-beam generators. Machines approaching 100 TW have been built, consisting of tens of modules, each of a few terawatts each.

An important variant of the Marx generator–pulse-forming line–diode approach to beam generation is the linear induction accelerator (LIA). This technique is essentially a transformer distributed in vacuum and allows substantial downsizing of the pulsed power system. The LIA is in fact a series of one-to-one pulse transformers, each threaded by an electron beam or a solid cathode. In the latter mode it is called a voltage adder (Fig. 3). Each of the *N* transformer sections generates an

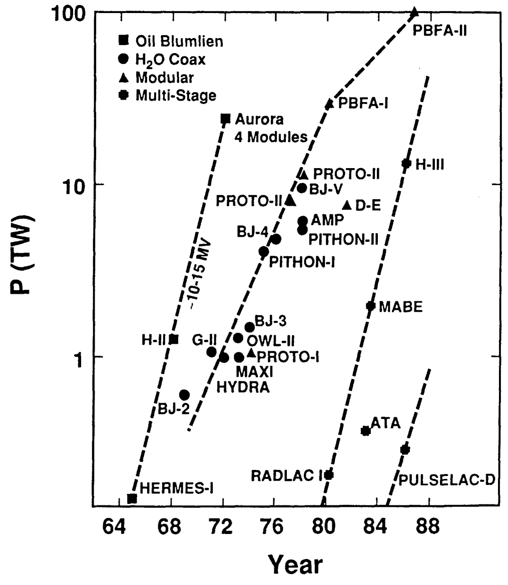

FIG. 2. Evolution of pulsed-power drivers of intense particle beams in the United States. The Blumlein is a type of pulse-forming line. Multistage devices accelerate beams incrementally; the LIA is of this type.

increment of voltage, *V*, on the cathode or beam so that the peak voltage *NV* occurs at the tip of the cathode or on the exiting electron beam. Its principal virtue is that the required accelerating voltage is distributed among a number of pulse-forming subsystems so that the full voltage appears only on the beam or at a beam-emitting diode. LIAs are useful for short pulses, < 100 ns. Greater output voltage can be obtained by adding more cavities since the system is fundamentally modular. While diode machines are limited to voltages of a few MeV, LIAs have reached 50 MeV. For example, Hermes III is a very large voltage adder built from modules (Fig. 4). This is in contrast to the diode machines, with which much higher currents (megamperes) can be generated. The disadvantages of the LIA are

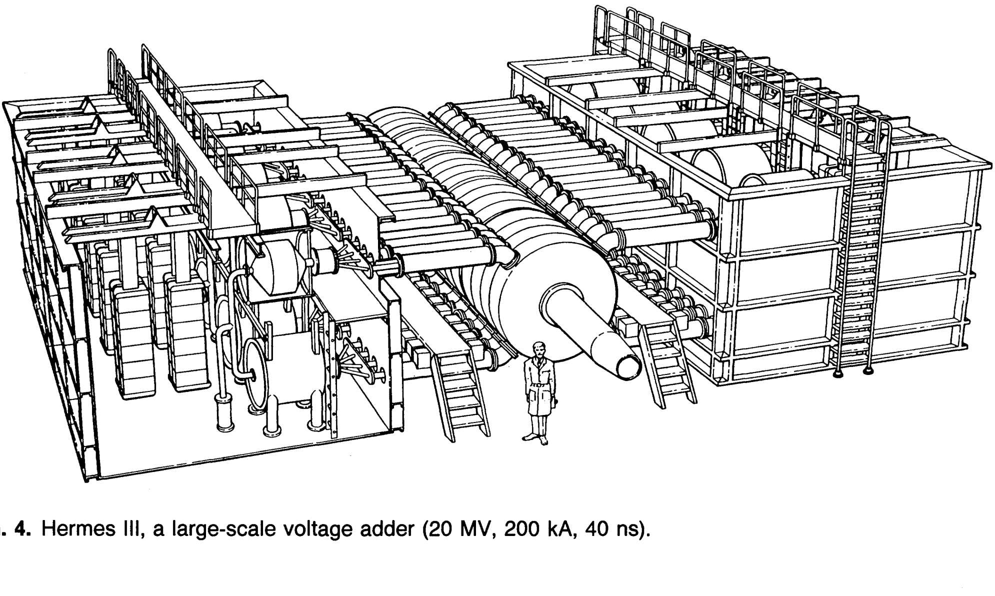

FIG. 4. Hermes III, a large-scale voltage adder (20 MV, 200 kA, 40 ns).

that it is expensive and complex compared to the diode machines.

Table 1 shows representative high-power beam-generation machines as of 1992. Most of these devices can generate intense particle beams for a wide variety of applications. For a discussion of these machines and those in Fig. 2, see Smith (1991).

1.2 Electron Emitters

The high currents needed make the electron source a vital factor in intense-particle-beam generators. We cover beam emission here; extraction and propagation are treated in Sec. 2. The most common electron sources are based on the following emitting phenomena, in order of decreasing emission current density: explosive emission, nonexplosive field emission, thermionic emission, and photoemission. In addition to the capacity for emitting at high current density, the attractiveness of each option depends on the requirements for "quality" of emission, as measured by spreads in the electron velocities and energies, ruggedness, and lifetime.

The most commonly used electron sources in present pulsed devices are based on the process of explosive emission. Applied average electric fields in excess of roughly 100 kV/cm at the emitting surface are further enhanced by the presence of naturally occurring micropoints. The enhanced fields lead to the flow of large field-emission currents through these micropoints, which rapidly heat and explode to form plasma flares within a few nanoseconds. Individual flares then expand and merge in 5–20 ns to form a uniform electron emitter capable of providing current densities of 10^7–10^8 A/m^2. The microscopic points are regenerated from one shot to the next, so that these sources can be reused. Explosive emission sources can be made from a wide variety of materials, including aluminum, graphite, stainless steel, and cloth emitters such as velvet. They produce the highest current densities of all options, are quite rugged, can tolerate poor vacuum conditions (the operationally limiting factor is arcing at $\sim 10^{-2}$ Pa), and have reasonable lifetimes. Undesirable features of explosive emission sources include the spotty character of the emission process at early times before the flares merge and the expansion of the dense plasma from which the electrons are drawn. This expansion causes the emitting surface to move with time, a phenomenon known as gap closure, which over the course of a long pulse will short out the accelerating voltage and terminate electron emission.

Field-emission sources use macroscopic points or grooves on a surface to get enhanced electric fields and produce nonexplosive field emission. Arrays of tungsten needles, grooved graphite, and polymer-metallic matrices are examples of emitters of this type; common velvet and cloth also make excellent field emitters. Current densities ranging from 10^6 to 10^7 A/cm^2 are achievable. Their advantages include operating at field levels below those required for explosive emission and avoidance of expanding plasma at the emitting surface. A disadvantage of these sources relative to explosive emission sources is the lower peak current density achievable; source lifetime is low.

Thermionic emission is based on heating an emitting surface to allow electrons to overcome the work function and escape the surface. No expanding surface plasma is required, and long-pulse to continuous electron beams can be produced. The most common thermionic emitter types are pure materials such as tungsten and LaB$_6$; oxide cathodes

Table 1. Representative intense beam generators, from Smith (1991).

	Pulse Power	Pulse energy	Duration (ns)	Voltage	Current
		Pulse Line Machines			
PBFA-II	70 TW	2.8 MJ	40	12 MV	5.8 MA

KALIF	1.5 TW	60 kJ	60	1.7 MV	1.3 MA
		Linear Induction Accelerators			
ATA	0.25 TW	10 kJ	40	50 MV	5 kA
Hermes III	16 TW	0.64 MJ	40	20 MV	0.8 MA

such as BaO; dispenser cathodes (tungsten impregnated with a mix of oxides such as BaO:CaO:Al_2O_3); cermet cathodes; and thorium-based cathodes. Thermionic emitters have the advantages of producing current densities up to 10^6 A/m^2 for a long or continuous pulses (lower than that for explosive and field emitters), and have good uniformity, long lifetime, and high beam quality. Disadvantages are the need for a cathode heater and susceptibility to poisoning at pressures above about 10^{-5} Pa.

In photoemission sources, the work-function energy for electron emission from materials such as GaAs and Cs_3Sb is supplied by laser illumination. These sources have the useful feature that electron emission can be turned on and off coincident with the laser pulse. Modulating the laser has the effect of producing a beam that is effectively bunched. Furthermore, because the electron emission is "cold," with very little excess energy over that required for emission, random thermal motions of the electrons imparted in thermionic sources can be eliminated. Current densities as high as 2×10^6 A/m^2 have been produced. The disadvantages of photoemitters are the possibility of plasma formation at the surface if the laser intensity is sufficiently high, the complication of adding a laser to the system, and the requirement for vacuums as low as 10^{-8} Pa.

Ion beams are produced by extraction of ions from cathode plasma; see Sec. 1.4.

1.3 Accelerating Diodes

The design of accelerating structures to produce electron or ion beams of high quality usually involves computer simulation in order to shape properly the electrodes and magnetic fields (if a field is used). See Septier (1983). Nevertheless, the basic features of diodes are illustrated by two idealized models. First is the Child-Langmuir diode in parallel planar geometry, which applies when the self-magnetic-field of the beam is small. The second is the pinched-flow model, parapotential flow, valid when the self-magnetic-field of the beam strongly influences the particle trajectories in the accelerating region. At nonrelativistic voltages below 500 kV, provided we can ignore the self-magnetic-field of the beam, the beam current density J depends on the diode voltage V according to the Child-Langmuir law. For an anode–cathode gap d, the law takes the form (in commonly used units)

$$J=(2.33\ \mathrm{kA\ MV^{-3/2}})\,V^{3/2}/d^2. \tag{6}$$

This expression is also based on the assumption that the cathode can supply enough current to be space-charge limited, in which case the electric field at the cathode is zero and the current is a maximum. The relativistically correct version of the Child-Langmuir law is complex, but for 500 kV and above the following approximate expression is quite accurate:

$$J=\frac{(2.71\ \mathrm{kA})}{d^2}\left[\left(1+\frac{V}{0.511\ \mathrm{MV}}\right)^{1/2}-0.847\right]^2. \tag{7}$$

Note the identical scaling with the anode–cathode gap spacing in both cases. The voltage scaling is quite different, however, with the familiar $V^{3/2}$ scaling at low voltages, while at high voltages $J\sim V$.

In real diodes of the Child-Langmuir type, several phenomena left out of this analysis can be important. First, the azimuthal self-magnetic-field of the beam causes electron beams to pinch at high currents due to the force $F_r=v_zB_0$. The critical beam current above which beam pinching occurs is estimated by equating the Larmor radius for an electron at the edge of the beam with the anode–cathode gap:

$$I_c=8.5(r_c/d)\gamma\ \mathrm{kA}, \tag{8}$$

where r_c is the cathode radius. Pinching leads to a very different flow pattern, the parapotential flow (Fig. 5). For $I>I_c$ electron flow is derived from a model in which electrons move along conical equipotentials, for which the parapotential current is,

$$I_P=I_c\ln[\gamma+(\gamma^2-1)^{1/2}]. \tag{9}$$

In order to extract the electron beam, the anode must be a screen or foil thin enough (i.e., much less than one electron range) that the electrons can pass through without undue angular scattering. The foil becomes a stress point in the design, since it will have a limited lifetime. Also, beam heating of the anode can create an anode plasma, which contributes to gap closure. Finally, the conducting anode

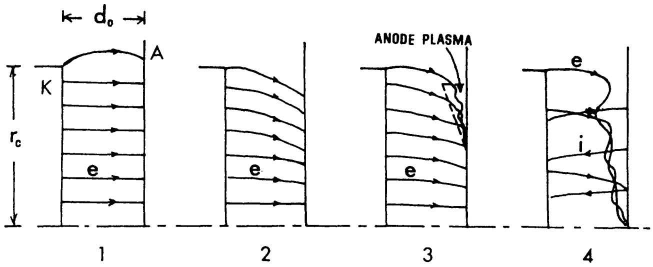

FIG. 5. Evolution of charge flow in an intense pinched electron-beam diode. (1) Child-Langmuir electron flow at low voltage; (2) electron flow at high voltage; (3) anode-plasma–induced collapsing electron ring; (4) electron and ion trajectories in pinched diode (parapotential flow).

will locally short-circuit the radial electric field of the beam, which disturbs the beam electron trajectories and introduces further spread in the transverse velocities of the electrons. Gap closure has the effect of making the diode gap a time-dependent quantity: $d=d_0 - v_p t$, where closure velocities are typically greater than 100 m/μs.

A means of avoiding the problems associated with foil or mesh anodes is to use a foil-less diode.* An example of such a diode is shown in Fig. 6. A strong magnetic field guides the electrons, preventing them from striking the wall so that they can be extracted down a drift tube. Foil-less diodes produce hollow electron beams, since emission at the outer edge of the cathode screens the smaller-radius portion of the cathode from the anode potential. The exact relation between current and voltage in these diodes depends on the details of the diode configuration. See Humphries (1990).

Just as with Child-Langmuir diodes, plasma expansion from the cathode is a problem with foil-less diodes. Plasma expansion both along and across the magnetic field can occur. Expansion along the field is faster, by roughly an order of magnitude, than cross-field expansion.

1.4 Ion-Beam Diodes

Intense ion beams at powers greater than a terawatt can be generated by megavolt-level voltages applied between two electrodes in vacuum if the electron flow in the diode is suppressed by using magnetic insulation. A magnetic field is supplied perpendicular to the electron path and to the electrodes so that it prevents electrons from crossing the gap. An anode plasma provides the ions that, being less affected by the magnetic field because of their greater mass, are accelerated by the electric field toward the cathode. The magnetic field in an ion diode serves two functions: it insulates the diode so that ions can be extracted, and it also traps electrons. The accumulated space charge of the electrons causes enhancement of the ion flux beyond the Child-Langmuir limit.

There are several ion diode types, depending upon how the field is generated and what geometry is chosen. One of the simplest types is the pinch reflex diode, which uses no static magnetic field. The flow develops as in Fig. 5. The electrons at first flow straight across the gap, then begin to pinch. They heat the anode, which begins to emit ions. Their space charge cancels that of the electrons, altering their flow. The result is the complex trajectories shown in the fourth part of Fig. 5. Since electrons move radially inward, the scale length for them is r_c. The ions cross directly, so their scale is d. This has the net result that the ion current is enhanced by roughly d/r_c

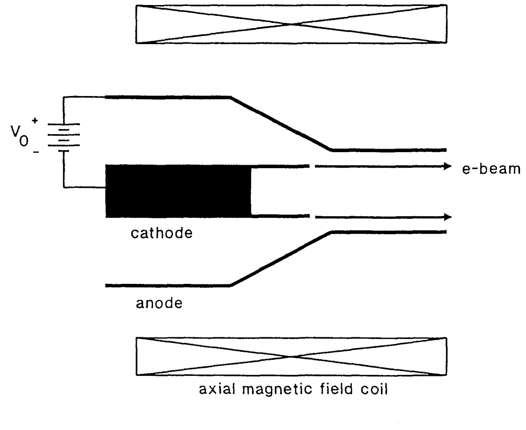

FIG. 6. Schematic of a foil-less diode.

---

*Diodes of this type are also commonly called *magnetically insulated diodes* in the Soviet literature.

relative to the Child-Langmuir diode. Therefore for large-aspect-ratio diodes ($r_c/d > 10$), large ion currents (~ 100 kA) can occur for megavolt applied voltages.

The pinch reflex diode has been largely superseded by applied-B-field diodes in which an external coil provides the insulating field, i.e., the magnetic field that must be applied to keep electrons drawn into the gap by the voltage from striking the anode. The two most common geometries are shown in Fig. 7. In Fig. 7(a), both anode and cathode are "barrel shaped," i.e., a structure symmetric about the center line. The ions cross the cathode and are focused in the center of the diode. The extractor diode, Fig. 7(b), is used in order to separate the target from the diode.

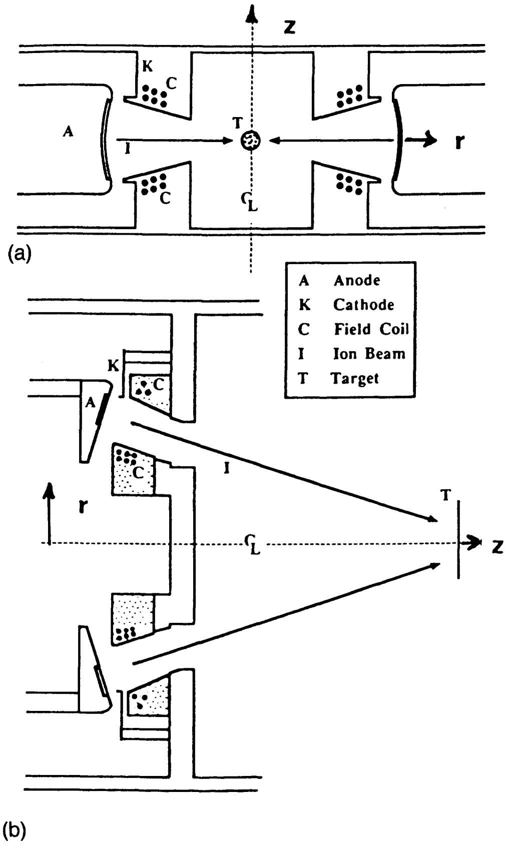

FIG. 7. Two forms of ion diodes used in inertial-confinement fusion studies. Above: barrel diode; below: extractor diode.

2. PROPAGATING INTENSE BEAMS

2.1 Beams in Gas and Plasma

Intense particle beams have self-fields sufficiently strong to dominate their behavior. Once a beam leaves the accelerator, its ability to travel a distance depends on canceling in some way the repulsive electrostatic force due to the charge of the beam electrons and the attractive magnetic force that arises from the beam current. In vacuum, the electrostatic force dominates, and the beam rapidly expands radially. Electron repulsion can be countered by supplying neutralizing ions from preexisting plasmas, by direct ionization of gas by beam electrons or by laser beam, or by applying a longitudinal magnetic guide field. In principle, fractional space-charge neutralization sufficient to provide force balance is possible, but in practice propagating beams very quickly become space-charge neutralized. When electrostatic fields have been eliminated by one or more of the above means, the magnetic force determines particle orbits.

There are three ways of exceeding the Alfvén limiting current. The naturally occurring method is "current neutralization," which arises from the tendency of plasma or any conductor to resist sudden changes in magnetic field. A fast-rising beam current induces an opposing axial electric field that drives a partially canceling return current in the plasma. The resulting net current (beam minus plasma current) determines electron orbits, so that v/γ is replaced by $(v/\gamma)_{\text{net}}$. For highly conducting plasma, the net current can be reduced to such a low value that beam electrons are not contained and expand to the boundaries of the chamber.

The second method of propagation is to employ a radially nonuniform current distribution. For example, a beam with most of the current flowing in a shell near the edge will propagate with $v/\gamma > 1$ by turning beam electrons only in the outer shell. Alternatively, in the Bennett distribution, the current density is peaked on the axis. It can be shown that v/γ is proportional to the ratio of the magnetic field energy within the beam to its kinetic energy. Nonuniform beam distributions reduce the magnetic energy, increasing the allowable current that can be propagated.

The third method, application of a longitudinal magnetic guide field, will prevent electrons from turning in their self-field, allowing propagation. The energy density of the field must be at least as great as that of the beam.

In recent years, experiments have demonstrated an electrostatic propagation aid. A laser ionizes a channel through a background gas. When the head of an electron beam passes, the electrons are expelled, leaving a background of ions. The remainder of the beam has its charge neutralized by the ions, so the beam propagates along the channel.

For further discussion of the above phenomena, see Humphries (1990).

2.2 Beams in Drift Tubes

A case of interest in many accelerators and beam-transport systems is the propagation of beams through metal pipes called drift tubes, usually in vacuum. Primary issues are space-charge depression of the energy of the beam electrons, limiting currents, beam equilibria, and beam quality.

Space-charge depression is a reduction of kinetic energy of the beam electrons by the self-electric-field arising from the beam space charge. Compare this to the ideal case of a low-current beam in which space-charge effects are negligible. In this case, the potential within the drift tube will be the same as the anode potential of the walls, and the kinetic energy of a beam electron will be given by the full diode voltage: $E_K = (\gamma - 1)mc^2 = eV_0$.

For an intense beam with significant space charge, the potential within the beam will be reduced from the anode potential by an amount determined by the beam space-charge density. Far from the diode region, the potential in the drift tube will be solely a function of radius, so that space-charge depression introduces shear (or radial variation) into the axial drift velocity of the electrons. As the beam current increases, the electrons are increasingly slowed down, until at some point a maximum current, known as the space-charge-limiting current, is achieved. One commonly occurring case is a thin annular beam drifting along a strong guiding magnetic field, for which the space-charge-limiting (SCL) current is

$$I_{\mathrm{SCL}} = (8.5\ \mathrm{kA})\,\frac{(\gamma^{2/3} - 1)^{3/2}}{1 + r_0/a}, \tag{10}$$

where a is the radius of the beam and r_0 is the radius of the drift tube wall. Note that I_{SCL} scales as $V_0^{3/2}$ at low voltages, and as V_0 at large voltages, similar to the Child-Langmuir diode.

For example, if a beam of 5 kA is injected at 425 keV with $a = 1.9$ cm and $r_0 = 2.4$ cm, then $I_{\mathrm{SCL}} = 12.6$ kA. The kinetic energy at injection is 340 keV, and the electrostatic potential energy is 85 keV, which is 20% of the total injected energy.

Electric and magnetic forces between the pipe wall and the beam can provide equilibrium in some cases. There is an induced image charge on the conducting wall. If the length of the beam pulse is shorter than the time it takes for magnetic field to penetrate the metal, there can be no magnetic beam-generated field outside the pipe, and therefore a return current exists on the wall equal and opposite to that of the beam. The image charges on the wall attract the beam and the return current repels it. If the beam is in the center of a cylindrical pipe, the image charges and currents are symmetric and no net force occurs on the beam. If the beam is off-center in the pipe, the beam shifts toward the outer wall and the repulsive force increases. An equilibrium ensues in which the force from the image charge balances the centripetal force. However, the beam can be destabilized if it encounters too abrupt a bend.

We have only touched on the large subject of beam instabilities. Many of the applications use instabilities to extract energy from beams in useful forms. For further discussion of beam instabilities and the above phenomena, see Humphries (1990) and Lawson (1988).

3. APPLICATIONS OF INTENSE PARTICLE BEAMS

The principal applications of intense particle beams are discussed here. The most studied applications are the topics described below. There is much interest today in industrial processes that could involve intense beams, but none of these has received sufficient attention in the research community to date.

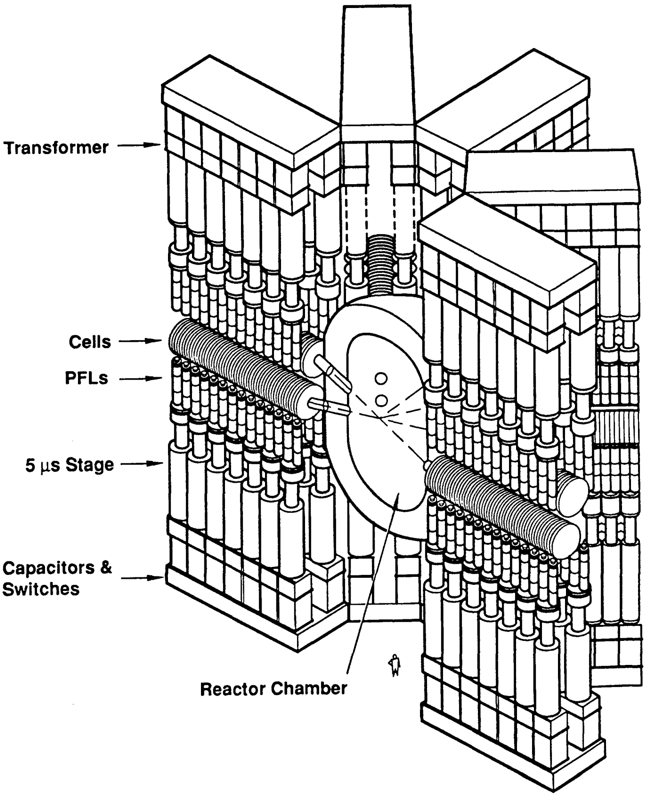

FIG. 8. LIBRA concept for a light-ion fusion reactor (30-MV, 4-MJ, 9-ns driver; 16 modules, 28 cells/module). A voltage adder injects beams into a reactor chamber. Note scale of human figure. PFL is pulse-forming line.

3.1 Inertial Fusion

Inertial fusion, as distinct from magnetically confined fusion techniques, centers around the rapid heating and compression of a small deuterium–tritium target at solid densities. The technique is called inertial-confinement fusion (ICF) because inertia of the target prevents its disassembly before fusion can occur (see FUSION, INERTIAL CONFINEMENT). Lasers and particle beams have been suggested for the driver. There are two approaches involving intense particle beams: one uses light ions and the other heavy ions.

The challenge of inertial fusion with particle beams is great. The particle-beam driver must deliver about 4 MJ of energy to the target, cost less than $100 per joule delivered, operate at an efficiency of at least 10%, avoid preheat of the fuel, and focus the beam to a 1-cm-diam target at about 100 TW/cm^2 with good uniformity. Any nonexpendable portion of the reactor must be at least 3–5 m from the pellet and must be built to survive the explosion. It would operate repetitively, at a few shots per second, in an environment with nuclear products.

The deuterium–tritium fuel must be compressed to approximately a thousand times its liquid density, and a small region in the center must reach a temperature of 4 keV. Ablatively driven spherical implosions compress and heat the fuel, driving a high-gain target. The key element is the ion-beam-producing diode, which is the juncture between the electrical energy produced by the pulsed power system and the transport system that carries the beam through the reactor cavity to the target. Heavy-ion fusion and laser fusion both have relative isolation because the transport methods to the target are ballistic and optical focusing, respectively, which place far fewer constraints on the total system than does light-ion focusing. The greatest challenge of light-ion fusion is achieving 100-TW/cm^2 power densities. An aid to focusing is that light ions at the approximately 30 MeV required are nonrelativistic, so that the voltage can be ramped upward to bunch the ion beam as it transits to the pellet. This technique also is used in heavy-ion fusion.

Many electrical technologies will be used in developing light-ion fusion, ranging from present-day, single-module, TW proton accelerators to repetitive, multimodule, multibeam, few-hundred-TW, multimegajoule lithium-ion accelerators, which will be needed to develop the final reactor chamber. The approach now being considered for the final reactor is the voltage-adder technique extended to much higher voltages, while keeping the current high enough for magnetic insulation. A conceptual view of such an accelerator is shown in Fig. 8.

Current concepts for an ion-beam diode are challenging. For example, the laboratory microfusion facility shown in Fig. 9 is conceived as 12 Hermes-III scale modules, each producing a 40-ns ion beam in which energy ramps from 18 to 20 MeV and current ramps from 460 to 720 kA. In addition, there are 24 accelerators delivering an ion pulse that ranges from 26 to 32 MeV and current that ranges from 800 to 1200 kA. Each beam bunches during its 4-m drift to the target, after which the pulse duration is 15 ns. The 36 lithium beams deposit 20 MJ onto a 2-cm-diam target. Extraction ion diodes are used with ballistic transport followed by focusing using magnetic lenses (Fig. 10). The challenges of efficient, low-cost, repetitive operation are immense.

3.2 High-Power Microwaves

High-power microwaves (HPM) is one of the most vigorous areas for applications of intense particle beams. Applications for high-power microwaves vary from particle accelerators to modification of the atmosphere, fusion heating, laser pumping, and electronic warfare. They generally require peak powers varying from 100 MW to 10 GW and average powers from 1 kW to as much as 1 MW radiated power. The more intense powers are required for large-scale applications such as modification of the atmosphere. For example, microwaves at a power level of 1 GW can be beamed into the lower ionosphere around 70 km to enhance local ionization. The moving microwave beam quickly paints an ionizing region, and a low-frequency (< 100-MHz) signal is bounced over the horizon, allowing long-range radar detection. Another suggestion is that microwaves can break up atmospheric contaminants such as chlorofluorocarbon (CFC), which is causing destruction of the ozone. Of course, the power required to clean the atmosphere is enormous. For a survey of HPM applications, see Benford and Swegle (1992).

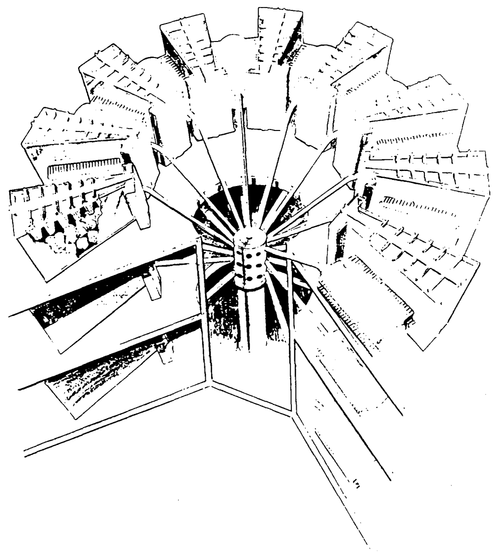

FIG. 9. Concept for a laboratory microfusion facility employing Hermes III–type technology.

Particle acceleration using rf fields has long been an application for conventional microwave devices. To achieve gradients of 100 MV/m requires raising the power or frequency. Typical values are > 100-MW sources operating above 10 GHz. Hundreds of such sources are necessary in order to drive next-generation accelerators.

The use of high voltages to produce relativistic electron beams has had several profound consequences for microwave generation. Very high power levels have been achieved. Figure 11 shows the peak power generated by a representative sample of high-power sources

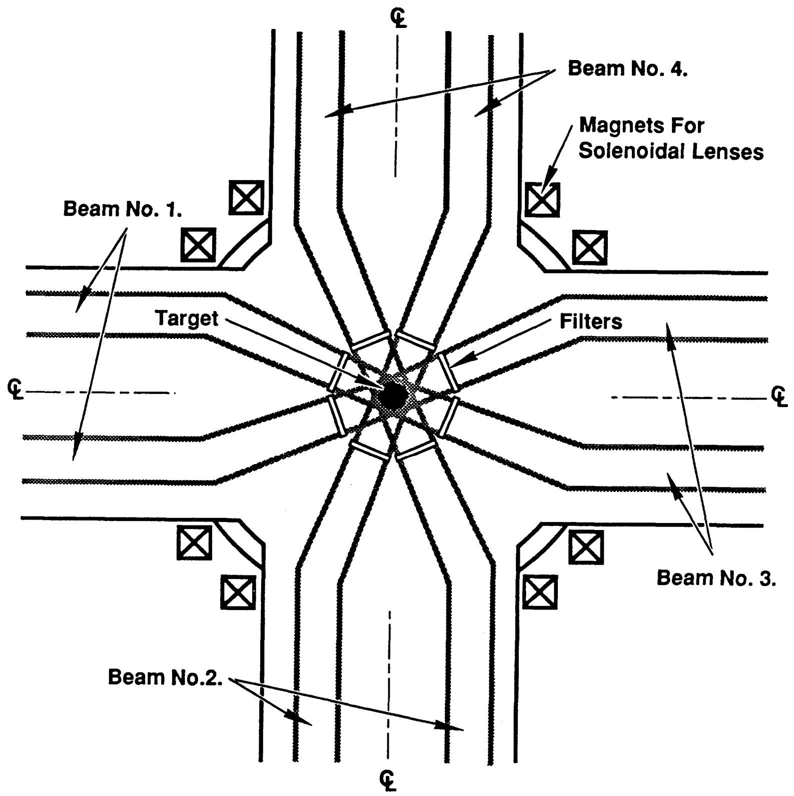

FIG. 10. Transport and focusing of multiple beams with ion lenses, filters, and overlap of beams on target.

as a function of the frequency. The factor P/λ^2 is a measure of the power density that can be produced. It appears that source power falls off roughly as f^{-2} at high frequencies; however, no clear trend emerges for the lower frequencies, below 10 GHz.

The limit on HPM source power is not known. Electrical pulses with power up to about 10 TW are available from a single pulse generator, and one can buy 1-TW generators commercially for a few million dollars. At a moderate extraction efficiency of 10%, one could therefore expect a peak power of 100 GW. Such a power will probably be achieved within the next decade. This will nevertheless require substantial improvements in the understanding of the limitations of specific devices and the overcoming of breakdown limits

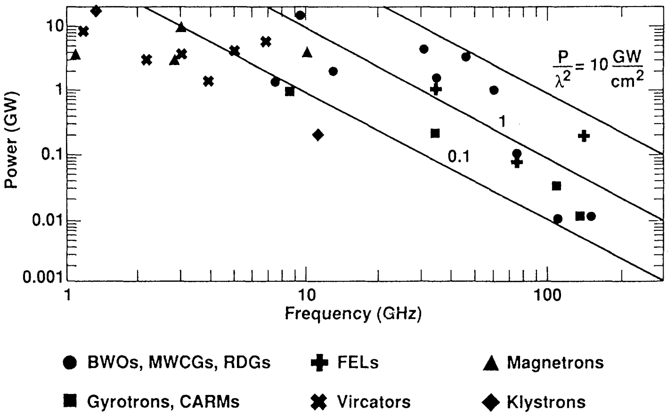

FIG. 11. Peak powers of pulsed high-power microwave sources.

and source-specific problems such as spurious mode generation.

Microwave sources can be classified into three basic types, as shown in Table 2:

1. O type: Devices in which the electrons drift parallel to an externally imposed magnetic field. This field helps to guide the intense beams used in HPM sources and, in some instances, plays an essential role in the microwave-generation process.
2. M type: Devices in which the electrons drift perpendicular to crossed electric and magnetic fields.
3. Space charge: Devices, possibly involving an applied magnetic field, in which the interaction producing microwaves is intrinsically traceable to intense space-charge interaction.

A consequence of the use of intense beams for HPM is the introduction of devices based explicitly on relativistic effects, such as the gyrotron. A second is stronger energy-, as opposed to velocity-, dependent tuning of the output frequencies in devices such as the free-electron laser (FEL) and cyclotron autoresonant maser (CARM). A third is the development of devices such as the virtual-cathode oscillator and the relativistic klystron that depend fundamentally on the very high beam currents that accompany high-voltage operation. Finally, a number of HPM sources are descendants of conventional microwave sources such as the magnetron, the backward-wave oscillator, and the traveling-wave tube. Nevertheless, in these devices, relativistic operation has brought increased power through the use of higher operating currents and stronger beam–field couplings within the interaction region.

An example of a space-charge device is the virtual-cathode oscillator, or vircator. An electron beam is generated in a diode with a thin foil anode that allows the beam to pass through to the drift space beyond. The maximum beam current that will pass through the drift region is the space-charge-limiting current I_{SCL}. One can ensure that the beam current exceeds this value by injecting the beam through a transmitting anode into a drift space of sufficiently large radius. In this event, a strong potential barrier will form at the head of the beam, from which a significant number of the beam electrons will be reflected back toward the anode. The reflection point for the electrons is known as the virtual cathode. Essentially, the excess space charge in the beam is rejected from the drift space. This situation is intrinsically different from other microwave-generation mechanisms. Instead of starting with a well defined initial beam state in which perturbations grow from small amplitudes at early times, in virtual-cathode formation there is a very fundamental breakdown of the beam state with the result that no beam equilibrium is possible. The position of the virtual cathode oscillates axially, shedding charge and behaving like a

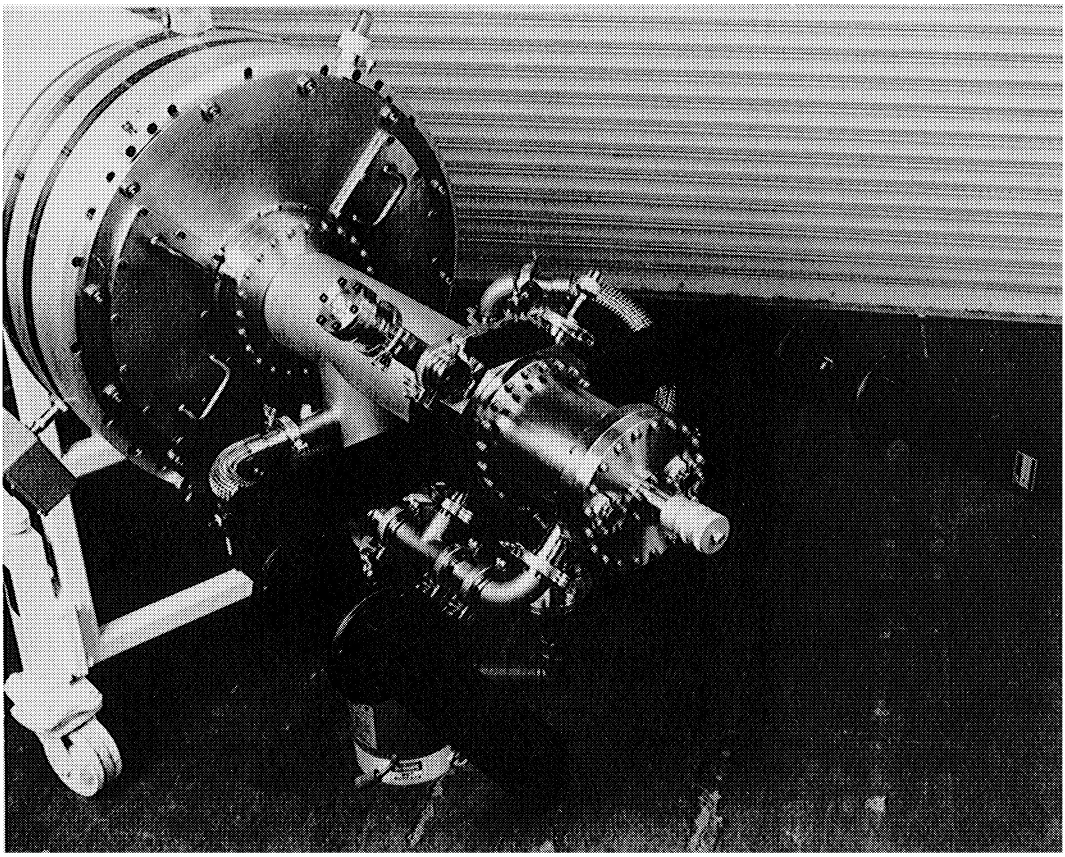

FIG. 12. Commercial vircator with tunable end wall and two extraction waveguides. Figure courtesy of Physics International Company.

relaxation oscillator. The motion of the space charge and potential well of the virtual cathode produces radiation at a frequency that is proportional to the square root of the beam current (of the order of the beam plasma frequency). The bandwidth of the vircator is quite large, though, and if the virtual cathode is formed in a resonant cavity, it will interact with the cavity modes to oscillate at a frequency tuned to a cavity mode. Figure 12 shows an advanced version of the vircator that is commercially available.

3.3 X-Ray Production

Intense beams allow production of very large fluences of x rays. At high voltages the efficiency of x-ray production can be large; for example, at 10 MeV x rays can be produced at about 10% efficiency in an optimized converter. Such converters contain a high–atomic-number material with a thickness of about a quarter of the electron range. Because the beam is intense, additional low–atomic-number material may be necessary to contain the impulse generated by the deposition of the beam. Efficiency is roughly proportional to voltage in this range, and therefore power will be proportional to the product of current and voltage squared. However, relativistic narrowing of the radiation cone enhances the radiated power in the forward direction so that power on target is more sensitive to voltage. At energies above 5 MeV, x-radiation power scales roughly as $V^{2.8}$. For example, at 10 MeV and 300 kA, x radiation can be generated at 0.3 TW and produce radiated energies of order 10 kJ. From such converters the mean x-ray energy is about a third of the energy of the accelerating potential of the electrons.

In order to produce much lower-energy x rays, pulsed-power devices are used to drive linear z pinches that, when their collapse stagnates on axis, generate copious amounts ($\sim$10 kJ) of low-temperature x rays with energy of order of 1 keV.

3.4 Industrial Applications

Intense particle beams have been developed for a variety of applications, usually involving defense, such as nuclear x-ray simulation and directed-energy weapons. Nonmilitary applications of particle beams are at an early stage of development. Examples are radiation treatment of food and waste, x-ray lithography, and powering of industrial lasers. These applications have a common thread of requiring high average power as well as high peak power. This is because they are performing high-volume processing. Continuous operation at high repetition rates is required. The ratio of peak to average power, usually referred to as the duty factor, must be large in order to make a system economically viable. Intense particle beams have not been developed with average power above about 100 kW, which is a threshold value for an industrial process. Therefore successful industrial applications of intense particle beams will have two basic requirements. The first is that the process must itself require high peak power in order for intense beams to be applicable. The second, the high average power of any industrial process, will stress the technology of intense particle beams that have been developed for single-shot work or low average powers. The future utility of intense particle beams in the emerging area of industrial processing lies in the ability to develop high-average-power, high-peak-power devices.

GLOSSARY

Bennett Beam Equilibrium: Model in which particle density is peaked on the axis.

Image Charge: Fictional charge used to describe electric fields in a region by replacement of the actual problem with charges external to the region of interest.

Larmor Radius: Radius of the circular orbit of an electron in a magnetic field.

Linear Induction Accelerator: Means of generating particle beams using vacuum pulse transformers based on ferrite magnetic cores.

Marx Generator: Means of producing high voltages by charging a group of capacitors in parallel and then firing switches to connect them; they then discharge in series.

Return Current: Conduction current on conducting surfaces near the beam that allows the current to return to its point of origin.

Space-Charge Fields: Electric fields due to distribution of electrons.

Voltage Adder: A linear induction accelerator with a metal cathode threading it, allowing peak voltage to appear only at its tip.

INTRODUCTION

The interactions between solids and both energetic particles and ionizing radiation produce a wide range of phenomena and lead to numerous applications. These interactions form the basis of most detectors of particles and radiation. They also allow spectroscopies of the electronic structure of solids to be developed. In addition, various properties of the solid target can be altered, either by radiation damage or by the implantation of incident particles. In this article we describe and illustrate a number of these phenomena and applications. In Sec. 1 particles are discussed, including electrons, ions, and neutrons. In Sec. 2 electromagnetic radiation is discussed, including soft x rays, hard x rays, and γ rays.

1. PARTICLES

Several elementary particles and many ionized atoms can be formed into beams and directed onto a solid target. At high energies the interesting aspects of the collisions that occur have to do with the properties of elementary particles and the nuclei in the solid. Here we deal with lower energies where characteristics of the solid or the modification of its properties are the primary focus.

1.1 Electrons

Electrons are bound to the atoms out of which every solid is made. The outermost, or valence, electrons create the cohesive forces that bind the solid together (see COHESIVE ENERGY). These electrons are held within the solid by a binding energy of typically several electron volts (eV). An electron volt is the energy an electron gains or loses in passing through a potential difference of one volt. Valence electrons do not, however, all have the same total energy. They exist in distinct states having a range of energies. This range is referred to as the valence-band width, and varies from less than 1 eV to several eV in different solids. When an additional electron is injected into a solid the extent of its interaction with valence and core (very tightly bound) electrons depend on its own kinetic energy.

1.1.1 Low Energies. An electron in a solid with energy in the range of a few to several thousand eV interacts strongly with the valence electrons. Its electric field causes valence electrons to be excited to higher energy states. The energy gained by the valence electrons is lost by the moving electron, causing it to slow down rapidly. In a metal this rapid slowing down continues all the way to the Fermi energy, which is the lowest energy the extra electron can have. In an insulator or semiconductor the strong coupling to the va-

lence electrons continues until the kinetic energy of the electron is equal to the band gap measured from the bottom of the conduction band. Below this point it does not have enough energy to excite an electron across the band gap and can therefore no longer lose energy by this process.

Transitions like these in which one electron loses energy while another gains energy are called Auger excitations. In this energy range Auger collisions occur so frequently that they can be thought of as causing a viscous friction force. The average distance an electron moves between Auger collisions is called the mean free path and depends strongly on the kinetic energy of the electron. The minimum value of the mean free path is typically 3–4 Å and occurs for a kinetic energy of about 30 eV. The mean free path is also sometimes referred to as the escape depth, since in photoemission experiments the important information comes from electrons excited by ultraviolet photons that emerge from the solid without losing energy.

1.1.2 Intermediate Energies. As the kinetic energy of the electron rises above 30 eV, the mean free path increases, and continues to do so to higher energies. The strength of the coupling between the fast electron and those in the solid decreases, and inelastic collisions become less frequent. It then becomes possible to produce sample materials in the form of thin films such that only one collision occurs as the fast electron passes through the sample. This means that the energy and momentum lost by the fast electron are transferred entirely to a single excitation in the solid, making it possible to demonstrate the existence of and study the dynamics of electronic excitations in solids by this means.

As the incident electron moves rapidly through the solid, the electrons in the material feel a pulse of electric field as it moves past. When an electric field is applied to a solid, its response can be characterized by a dielectric function $\epsilon(q,\omega)$, Here q is the wave vector of the applied electric field, equal to $2\pi/\lambda$, where λ is its wavelength and ω is its frequency. When the fast electron scatters in the solid, creating such an electric field, in order to conserve energy and momentum it must give up energy $\hbar q$, where $\hbar$ is Planck's constant divided by 2π. The relation between the scattering cross section and the dielectric function is (Schnatterly, 1977)

$$\frac{d^2\sigma}{d\Omega\, d\omega}=\frac{\hbar\gamma^2}{(\pi e a)^2 n q^2}\,\mathrm{Im}\left(\frac{-1}{\epsilon(q,\omega)}\right), \tag{1}$$

where n is the number density of electrons in the sample, a is the Bohr radius, and γ is the relativistic mass enhancement factor. Since the dielectric function has roughly the same magnitude for different momentum transfers q, this shows that the cross section falls off approximately as $1/q^2$.

The above equation for the scattering cross section is of great importance for our understanding of the dielectric properties of solids. It says that we can determine $\epsilon(q,\omega)$ by measuring the scattering of fast electrons through a thin film of a given material. Actually, what is directly measured is not the dielectric function itself, but the imaginary part of its inverse. The real part of the inverse dielectric function can be obtained from the imaginary part using a Kramers–Kronig integral relation. This requires knowing the imaginary part over a wide energy range. In the limit that q becomes small, the dielectric function obtained in this way becomes equal to that measured optically. To evaluate the total cross section for scattering through all angles and losing all possible energies, the above equation must be integrated with respect to Ω and ω. Using a simple statistical model of atoms to do so results in (Schnatterly, 1977)

$$\sigma=8\pi\gamma^2 Z^{1/2}\left[k^2\ln\left(\frac{Z^{3/2}}{(\Delta E/2E)^2(ka)^2}\right)\right]^{-1}. \tag{2}$$

This total inelastic cross section allows mean free paths to be estimated as a function of atomic number Z and electron beam energy E with forward momentum $\hbar k$.

In addition to the inelastic scattering processes described above, elastic scattering of the fast electron can occur from the atoms in the solid, with no loss of energy and no excitation of electrons in the material. The elastic cross section remains nearly constant with q out to a few Å^{-1}, while the inelastic cross section starts at a larger value and decreases rapidly with increasing q.

An important property of the dielectric function is that it obeys an important integral relation known as the oscillator strength sum rule (see Wooten, 1972):

$$\int \epsilon_2(q,\omega)\omega\, d\omega=\frac{\pi}{2}\omega_p^2. \quad (3)$$

Here $\omega_p^2=4\pi ne^2/m$ is called the plasma frequency of the electrons with number density n. Since the dielectric function is defined in terms of the polarizability per unit volume of the solid (see **Glossary**), the oscillator strength is proportional to the number of electrons per unit volume. This sum rule is a great help in making sure that measured cross sections or dielectric functions have the correct overall magnitude.

1.1.2.1 Examples of Spectra for Various Solids. Figure 1 shows inelastic electron scattering data for LiF, an ionic insulator with a very large band gap. LiF is sometimes regarded as the simplest of the alkali halides, since Li and F have fewer electrons than the other alkali-metal or halogen atoms. Figure 1 shows scattering power plotted against excitation energy in eV for four values of q in both the (100) and (110) directions. The lowest energy peak, at about 14 eV, is due to an exciton, which is an electron in the conduction band bound to a hole, or missing electron, in the valence band. An exciton is similar to a hydrogen atom with the hole playing the role of the proton. The excitation spectrum of an exciton is similar to that of a hydrogen atom but with a different energy scale for each solid. The dominant feature in the spectra shown in Fig. 1 is a strong peak near 25 eV, which is due to a plasma excitation. This is a collective motion of all the valence electrons in LiF. As q is increased the plasma peak loses strength relative to the other features in the spectrum and splits into two partially resolved peaks. This splitting is due to the interaction with the periodic field of the ions of the crystal lattice. The other features in the spectra are due to interband transitions that also change shape and position with q.

The change in position and shape of these features with q provides dynamical information about the electronic properties of LiF. For example, note that the exciton energy increases as q is increased. Figure 2 shows a graph of this exciton energy plotted against q for both the (100) and (110) directions. The curvature of this graph for small q gives an effective mass for the exciton. In other words, if you could reach into the solid and push on the exciton, how much inertia would it have? Since mass is a measure of the inertia of an object, the greater the mass (i.e., the less the curvature shown in Fig. 2), the greater the inertia of the exciton.

This question has a more fascinating answer than one might at first expect. In classical physics, when two particles are bound together, their total inertia is unaffected. This is a fundamental conclusion coming directly from Newton's laws of motion. Here we have an electron and a hole bound together, but it turns out that their inertia is affected by the binding. Figure 3 shows a measurement of E_p, the exciton peak energy, versus the square

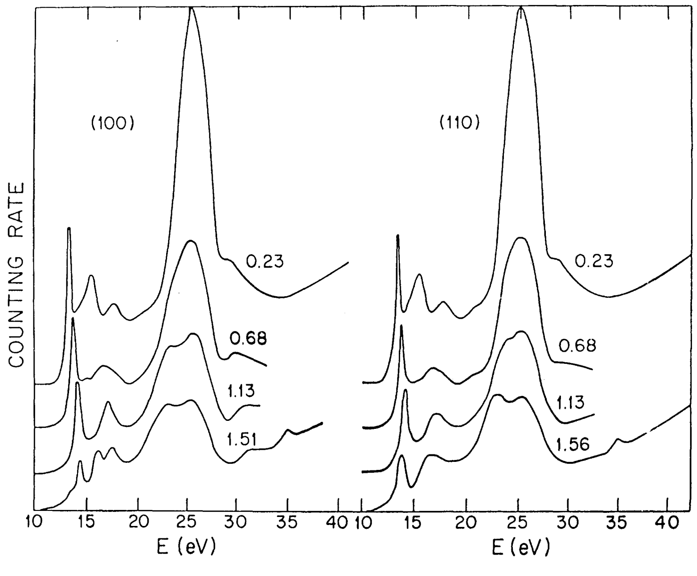

FIG. 1. Inelastic electron-scattering spectra for LiF. Momentum transfers in the (100) and (110) directions are given in Å^{-1} (Schnatterly, 1977).

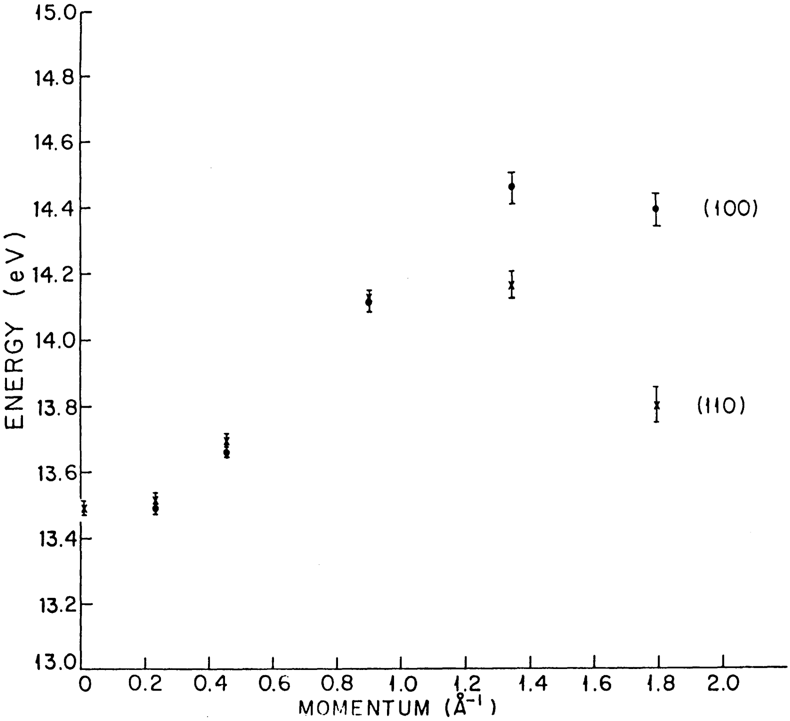

FIG. 2. Energy of the LiF valence exciton vs q for the (100) and (110) directions (Schnatterly, 1977).

of q for NaCl. The slope of this line gives a value for the mass of the exciton in this material. Plotted on the same graph is the energy to create an unbound electron and hole, E_g. The slope of this line is greater, indicating that the unbound electron–hole pair in NaCl is lighter than the bound pair. This is a quantum-mechanical effect due both to the wave nature of matter on the atomic scale, and to the fact that these electrons and holes are moving in a lattice with which they interact rather than in free space. This example stands in contrast to the other way that the mass of a system depends on its binding, namely special relativity. In that case the total mass of the composite system is decreased; here it is increased, and the effect is due to quantum mechanics, not relativity.

Figure 4 shows the real (dashed line) and imaginary (solid line) parts of the dielectric function for LiF plotted versus energy. These results were obtained from electron-scattering measurements, as described above, using a small momentum transfer q, and so they should agree with the results of optical experiments. In the 10–20-eV range are the exciton and valence excitations discussed above. At

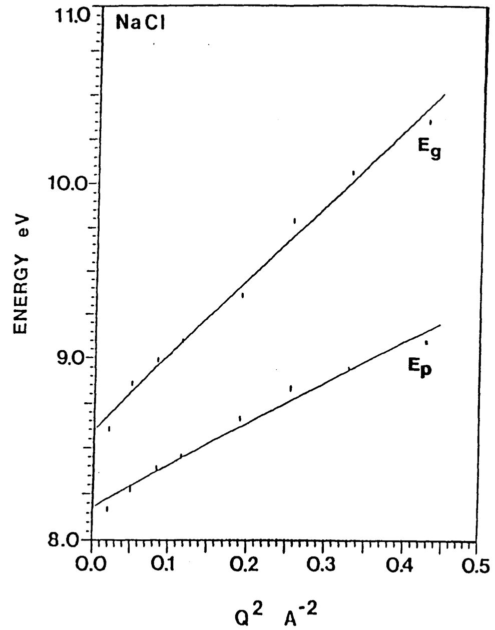

FIG. 3. E_g, the energy of an unbound electron–hole pair at threshold, and E_p, the energy of a bound electron–hole pair for NaCl vs q^2 (Schnatterly *et al.* (1988).

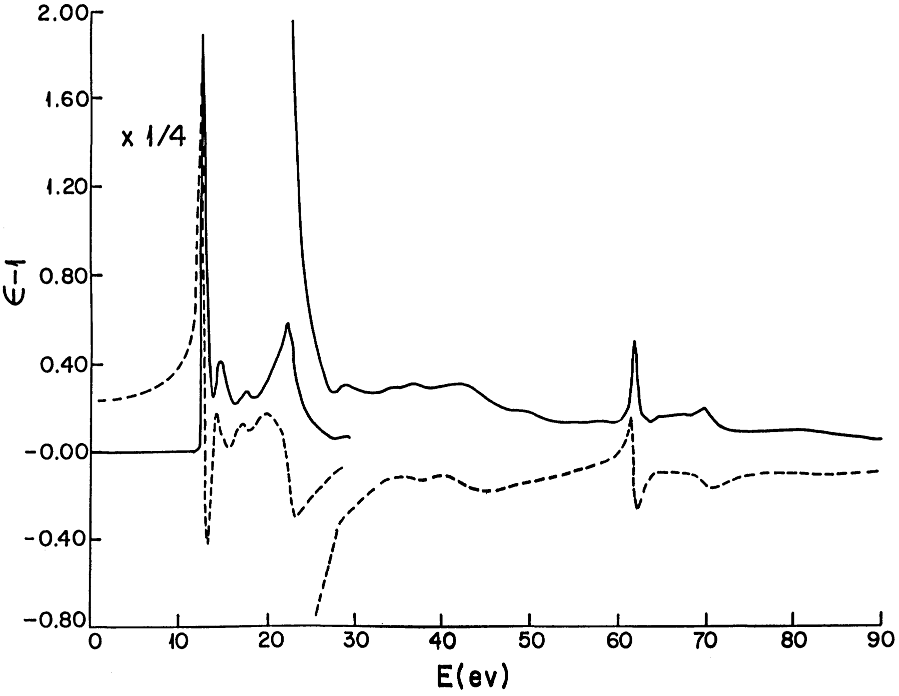

FIG. 4. $\epsilon - 1$ for small q vs E for LiF. The dashed line shows the real part and the solid line the imaginary part of the dielectric function (Schnatterly, 1977).

much higher energies, in the 60–70-eV range, is another set of features. These are due to the excitation of an electron out of the 1*s* core level of Li. The 1*s* level is the most tightly bound state on any atom. These electrons have a small-radius state and do not interact significantly with the other electrons in LiF. Core levels such as this play an important role in other spectroscopies of solids such as XPS (x-ray photoemission spectroscopy) and Auger experiments (see AUGER SPECTROSCOPY).

Simple metals such as Na and Al were the first kinds of materials studied by inelastic electron scattering. This is partly because some metals are easy to prepare in thin-film form by vacuum evaporation, and partly because the measured spectra were dominated by the plasma excitation, and so appeared simple to interpret. In simple metals the plasma peak stands out even more strongly than that for LiF above. Figure 5 shows an example for Al. The shoulder at 1.5 eV is an interband transition; at 7 eV is a surface plasma excitation; at 15 eV, and stronger by a factor of more than 100, is the bulk plasma excitation; at 30, 45, and 60 eV are multiples of this dominant feature in which electrons create two, three, and four plasma excitations. Beginning at 72 eV are features due to the 2*p* core of Al. All these excitations were measured with q small compared with the Fermi wave vector of Al.

The plasma excitation is a direct consequence of the strong tendency of electrons in solids to screen out applied electric fields. For metals this screening is complete for macroscopic fields at zero frequency. One of the important boundary conditions used in electrostatics is that there can be no electric field inside a metal. The highest frequency that the electrons in a metal can follow is the plasma frequency. Above that frequency metals become much more transparent to light; the reflectivity and absorption coefficient both drop sharply.

As the wavelength of an applied field decreases (the wave vector increases), the screening decreases even below the plasma frequency. It is in this regime that we need to understand the screening effect in order to develop quantitative models of the interactions between electrons as they move about inside a solid. The most direct way to study this experimentally is to measure the q dependence of the plasma excitation in simple met-

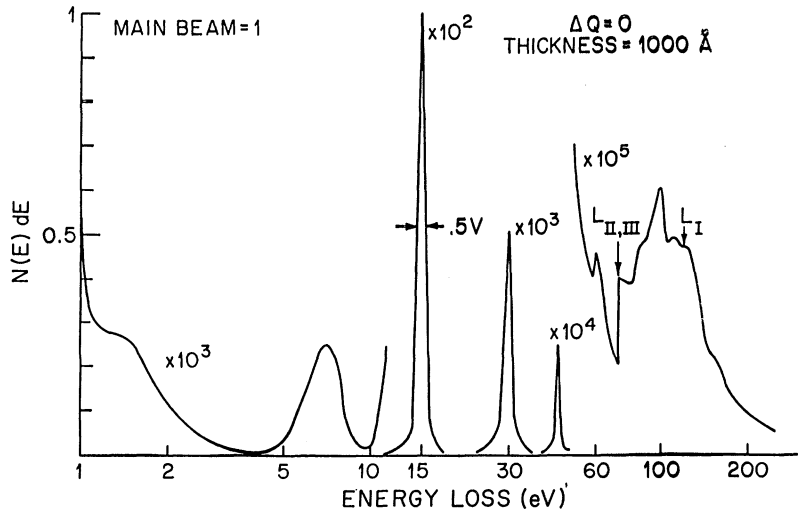

FIG. 5. Excitations in Al measured by inelastic electron scattering (Schnatterly, 1977).

als. As q is increased the plasma energy and the width of the peak both increase. Figure 6 shows the plasma energy of Al as a function of q. Figure 7 shows the width of the plasma peak in Al versus q. The peak width increases very rapidly for q greater than a cutoff wave vector q_c. In the simplest model, below this value the width is expected to be zero. Understanding the shape of this excitation in simple metals over a wide range of q values is a fundamental problem in condensed-matter physics. Much effort has been expended in developing models for this purpose (see Mahan, 1990).

Intermediate in terms of electronic properties between simple metals such as Al and good insulators like the alkali halides are the semiconductors. Excitons and interband transitions are much weaker in typical semiconductors than for good insulators. Plasma excitations in semiconductors often have widths for small q that are intermediate between those for metals and insulators. All atoms have core levels, and so semiconductors exhibit core spectra that often reveal information about the chemical state of the atom involved. Figure 8 shows the $2p$ core threshold for both Si and SiO_2. The threshold energy is shifted up in the oxide compared with the semiconductor and the shape is markedly different.

1.1.3 Radiation Damage. Electrons with energies below roughly 100 keV damage some materials rapidly and others not at all. In this energy range damage is caused by creation of electron–hole pairs in the solid. The number of electron–hole pairs created is roughly equal to the ionizing energy deposited divided by $2.8E_g$, where E_g is the band gap of the material. An electron excited out of the valence band of an insulator is a broken chemical bond. Whether the bond is reformed before a nearby atom moves from its normal lattice site is a question with no simple answer. Generally speaking, metals and covalent semiconductors do not damage rapidly, if at all, by

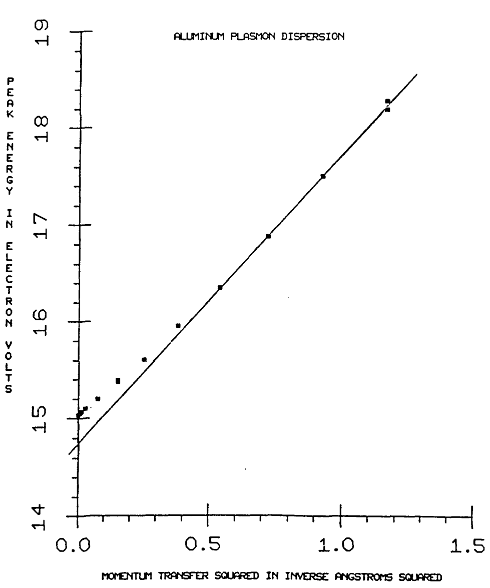

FIG. 6. Energy of the Al plasmon vs q^2.

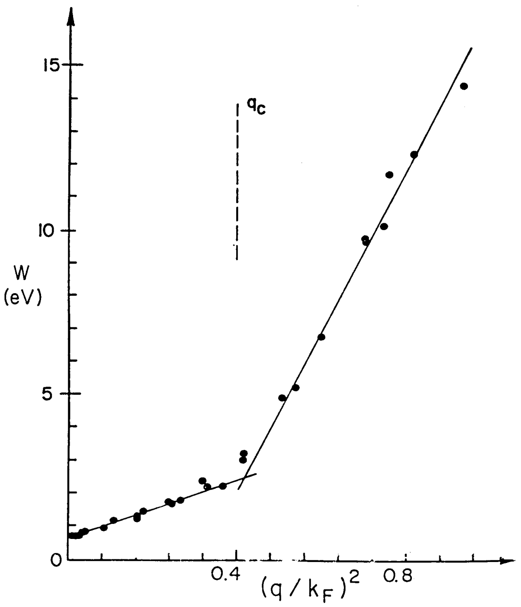

FIG. 7. Width of the Al plasmon vs q^2. q_c is the value of q below which the width should be zero according to the random-phase approximation (Schnatterly, 1977).

this mechanism. Ionic and organic materials are much more sensitive to damage by electron–hole pair excitation. In some materials two electron–hole pairs must be excited very near each other before damage occurs.

As the energy of an electron beam is increased, eventually the electrons have enough momentum to dislodge an atom from its lattice site by direct collision. Since the nucleus must be hit head-on, the cross section for this kind of damage is small. When an electron with energy E strikes an initially stationary atom of mass M, the maximum kinetic energy that can be transferred to the atom T_{max} is

$$T_{\text{max}}=2(E+2mc^2)E/Mc^2\ . \tag{4}$$

For each atom in a solid there is a threshold value of energy transferred to the atom, T_d, that will result in its being displaced from its normal lattice position. Values of T_d vary from 4 to 25 eV, with the value for a particular atom being typically about twice the bond energy for that atom. For example, for Si, T_d= 13 eV, which corresponds to 145 keV for the incident electron-beam energy.

Radiation damage effects in alkali halides are representative of those in insulators generally and have been extensively studied. The most readily produced atomic defect caused by electron–hole pair excitation in alkali halides is a negative-ion vacancy, which then traps an electron to produce a color center called an *F* center. The *F* center is an example on the atomic sale of a particle in a box. It is a direct consequence of the wave nature of matter that, as the box is made smaller, the energy of the electron in it increases. This also means that the energy difference between the ground and first excited states of the electron increases as the size of the box is reduced. The color associated with color centers comes from light being absorbed as the electron makes a transition between these two states. Changing the lattice constant of the crystal then changes the wavelength of light that is absorbed. This variation is described by the Mollwo–Ivey law: $\lambda_p = 703d^{1.84}$ where λ_p is the wavelength of the peak of the absorption band in Ångström units, and d is the lattice constant of the alkali halide in ångströms.

As the temperature is lowered, the *F*-center absorption peak shifts to shorter wavelengths and the width of the band decreases. The width is due to the interaction of the electron with the vibrations of the surrounding atoms, and the shift is due primarily to thermal contraction as the lattice constant becomes smaller at lower temperatures. The magnetic moment of the trapped electron allows *F* centers to be studied by electron paramagnetic resonance. *F* centers are a model system in solid-state physics, which have stimulated

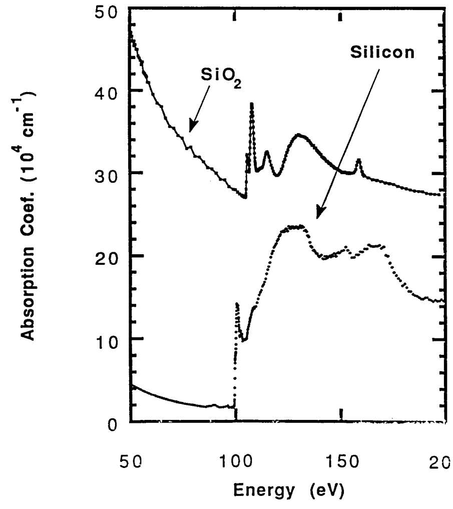

FIG. 8. Si 2*p* core threshold region for Si and SiO$_2$ (Husk *et al.*, 1991).

the development of new experimental techniques and theoretical concepts (see Fowler, 1968).

F centers interact with each other, and a kind of *F*-center chemistry occurs. Two *F* centers bound together form a new entity originally called the *M* center, which is the analog of the hydrogen molecule. Three and four *F* centers in nearest-neighbor positions also form stable aggregates. Higher concentrations of *F* centers are required to form these aggregate centers, which of course requires a greater dose of ionizing radiation. Eventually enough halogen atoms leave the crystal that alkali-metal particles are formed within the material. These particles also give rise to interesting optical effects since they scatter incident light strongly and in a manner that depends on wavelength.

Perhaps the most common material in the Earth's crust is SiO_2. It is also important in the semiconductor industry, since it is used to form insulating layers in Si integrated circuits. Exposure to ionizing radiation causes the formation of oxygen vacancies, creating the E_1' center, which absorbs light in the ultraviolet region of the spectrum. Defects such as this trap charge and cause inhomogeneities that interfere with the operation of high-density integrated circuits. (see Verweij and Wolters, 1983.)

Radiation damage produces defects in a number of insulators that can trap charge carriers and hold them for very long times, even millions of years. As such a material is heated, the trap lifetimes become rapidly shorter as a result of the Boltzmann factor, which describes the probability of thermally ionizing the trap. By observing the light emitted as the crystal is heated, the total number of defects caused by radiation can be determined. This technique is called thermoluminescence, and can be used to determine how long ago certain minerals were at elevated temperatures. The rate at which radiation produces traps can be measured for a given material. Then if the rate of cosmic-ray incidence or natural radioactivity is known, the material's thermoluminescent output indicates how long it has been subjected to the radiation at ambient temperatures. This is useful in geology (age since mineral formation) and anthropology (e.g., age of pottery).

Electrons with sufficiently high energies lose energy in solids primarily through bremsstrahlung. This is a scattering process in which the electron comes very close to the nucleus of an atom and is strongly accelerated. According to electromagnetic theory any accelerated charge must radiate. The radiation in this case is in the form of x rays. For example, in Pb, above about 10 MeV, the electron inelastic-scattering cross section is dominated by bremsstrahlung and is proportional to the energy to well above 1 GeV. This means that the energy lost by an energetic electron in a certain path length is proportional to the electron's energy, thus providing a method of measuring that energy.

As energetic electrons pass through Pb, or any other material, they generate x rays that propagate out in all directions from the path of the electron beam. This is called an electromagnetic shower. The x rays are scattered and eventually absorbed, creating electron–hole pairs. The number of pairs is proportional to the energy deposited in the material. Semiconductors allow the number of pairs to be measured by the current they generate in an electric field; phosphors (insulators doped with optically active charge traps) allow the number to be measured by the amount of light generated. In either case these interactions allow the energy of the electron to be determined through a variety of different experimental arrangements.

1.2 Ions

Ions incident on a solid surface cause many different physical and chemical processes to occur that are of both scientific and technological interest (see ION-BEAM MODIFICATION OF MATERIALS). Light ions of keV or more energy undergo a series of energy-loss collisions with both atoms and electrons, eventually stopping hundreds to thousands of atomic layers from the surface. Even for a monoenergetic beam of incident ions, there will be a distribution of penetration depths, approximately Gaussian in shape, due to the statistical nature of the collisions. This provides a means of doping the target material near the surface. Ion implantation, in contrast to chemical diffusion, allows a greater range of composition and concentration of dopant atoms because of the nonequilibrium nature of the process. The *p-n* junctions in many integrated circuits are formed using ion implantation.

Heavy ions with keV or more energy can create a collision cascade in which many hundreds of atoms in the target are displaced from their regular lattice sites. For example, 10-keV Bi ions incident on Si create amorphous tubes in which thousands of Si atoms along the flight path of a Bi ion have completely lost their local crystalline arrangement. These tube diameters are approximately 50 Å, and when the incident dose is sufficient for them to overlap, the entire surface region is amorphous.

Another process, important for surface studies, is sputtering (*q.v.*). Incident ions, often 3-keV Ar ions, deliver most of their energy very near the surface. Surface atoms, through multiple collisions with other target atoms, can be ejected into the vacuum. This provides a means of cleaning oxides and other contaminants from a surface. By using a mass spectrometer to identify the ejected ions, sputtering can be used to determine target composition as a function of depth. For some materials electron–hole pair excitation alone can cause sputtering without the need for direct momentum transfer from an incident ion.

In all of the above processes radiation damage plays a role. Often this is an undesirable aspect of the process, and it is desirable to anneal the damage away. Some fascinating things have been learned in studying these phenomena in semiconductors. If a heat pulse lasts less than about 1 ns and it contains sufficient energy, the result is to convert crystalline material to an amorphous structure. The heat pulse could come from a passing heavy ion, in which case it might last 10^{-11} s, or from a very short laser pulse. The physical origin of the lattice energy does not seem to matter. Longer heat pulses, usually produced by lasers, in the ns to μs regime, can produce local melting, followed by rapid crystal growth. Annealing can also be accomplished by the more conventional method of heating the entire target to an appropriate temperature.

In metals phenomena similar to those in semiconductors occur. Bulk radiation damage can be monitored by measuring the electrical resistivity of the metal. A metal with no structural disorder will have zero resistivity at a temperature of 0 K. A metal irradiated at low temperature and then warmed up while its resistivity is monitored reveals the temperatures at which various kinds of radiation damage anneal. Surprisingly, even for "hard" metals (e.g., Pt) annealing begins at very low temperatures, typically 10 K. X-ray diffraction and EXAFS (extended x-ray absorption fine structure) can also be used to monitor radiation damage.

For gas ions (e.g., H, He, Ar) incident on metals in the keV range an important phenomenon occurs at high dose levels. After the incident ions have been neutralized in the metal and have come to rest, they can usually diffuse around at room temperature. If the concentrations are high enough, they will aggregate to form bubbles. This often occurs for incident doses in the $(10^{16}\text{–}10^{17})/\text{cm}^2$ range. Bubbles cause blistering, which is an important source of degradation of thermonuclear fusion reactors. The densities of gas atoms or molecules in a bubble are comparable to those of the liquid, and yet the molecules are at room temperature, and so the pressures are very high. The bubbles near the surface eventually burst, causing a pockmarked appearance under a microscope and degraded vacuum and strength characteristics.

For incident ions in the MeV range deeper penetrations occur. For crystalline targets the depth of penetration is highly dependent on the target orientation relative to the incident beam direction. This is due to the occurrence in most crystal lattices of open regions within each unit cell, which line up with each other in particular directions in the lattice. If an incident ion beam is collimated and aimed along one of these directions, much of the beam penetrates considerably further than if the beam direction is changed by only 1° or 2°. This effect, referred to as channeling, can be observed by monitoring the fraction of backscattered ions as a function of target orientation. Channeling disappears completely for amorphous materials, and so it provides a means of monitoring the crystallinity of the surface of a target during experimentation or processing.

Energetic ions incident on thin targets will penetrate through and emerge from the other side, having lost some energy. The emerging ions often have lost a number of electrons and are in a highly excited state. Many excited-state lifetimes can be measured by monitoring the intensity of emitted light as a function of distance from the thin target. Experiments based on this technique are referred to as beam-foil spectroscopy. Another fascinating aspect of this kind of experiment is that electrons often emerge from the target having the same velocity as the ions, but not bound to them. These are referred to as convoy electrons. Convoy electrons are largely an atomic phenomenon, since their velocities are much greater than the Fermi velocity and they also occur in gases.

1.3 Neutrons

Neutrons interact with atoms in solids in a completely different manner than ions or electrons, since they have no charge. The cross sections for neutrons to scatter from atoms are about eight orders of magnitude smaller than those for keV ions or electrons, and so the mean free paths are that much longer. Thermal neutrons are available from research nuclear reactors in collimated beams that can be directed onto a sample. They have wavelengths of a few ångströms, comparable with the lattice constants of typical crystals. This means that thermal neutrons can be used to study crystal structures by diffraction, just as can x rays of a similar wavelength. A major difference is that the thermal-neutron scattering cross section varies irregularly from nucleus to nucleus in the periodic table, whereas the x-ray cross section varies as Z^2, where Z is the atomic number. This means that light elements are difficult to observe with x rays, while they may even dominate when observed with neutrons. Thermal neutrons also cause no radiation damage since they carry so little energy and momentum. Thermal neutrons are also used to study the vibrational energies of atoms in solids. For this they are uniquely suited, having both the correct momentum and energy for the task.

In addition to scattering directly from nuclei, neutrons possess a magnetic moment, which allows them to scatter from the magnetic moments of electrons in magnetic solids. In particular, antiferromagnetic materials, which have no net magnetization, could only be understood when thermal-neutron sources became available to study them after World War II.

Nuclear reactors also produce neutrons in the MeV energy range, which cause radiation damage by direct displacement of atoms from their regular lattice sites. Both point defects and collision cascades, in which a large number of atoms in a region are displaced, can occur. Samples can be irradiated by lowering them into the core region of a reactor and leaving them for a specific period of time. An interesting variation on this process is transmutation doping, in which the neutrons transmute one chemical element into another. For example, ^{30}Si, which has a natural abundance of about 3%, can be converted to P by absorbing a thermal neutron. This turns the Si into an *n*-type conductor with nearly perfect random placement of the P atoms and no introduced disorder. High-quality power diodes are doped in this way (see POWER ELECTRONICS).

2. ELECTROMAGNETIC RADIATION

The electromagnetic spectrum covers a wide range of wavelengths from radio waves to γ rays. The longer-wavelength regions are discussed in other articles in this Encyclopedia. Here we understand radiation to mean ionizing radiation, and begin with the soft–x-ray region.

2.1 Soft X Rays

X rays used for diffraction studies of solids have energies of 10 keV or more. Soft x rays have energies in the range of 20–30 eV to about 1000 eV. In this region of the spectrum man-made diffraction gratings can be used to resolve different wavelengths, but they must be used at grazing incidence to achieve reasonable reflectivities. Soft x rays are absorbed strongly by all solids, penetrating only 0.1–1 μm depending on wavelength.

Soft–x-ray absorption spectra exhibit sharp and detailed structure above the threshold energy for exciting an electron from a core level into empty states in the conduction band of the material being studied. Core spectra have sharp features in this energy range because these core levels have long lifetimes. At higher energies core states have shorter lifetimes, and in agreement with the energy uncertainty principle their spectra exhibit more broadening.

Core absorption spectra such as those shown in Fig. 8 reveal information about states available to electrons in the immediate vicinity of the atom being excited, in this case Si. As the figure shows, these states change significantly when the chemical state of the atom is altered. Spectra like those shown in Fig. 8 can be measured using soft x rays produced by a synchrotron, as well as by inelastic electron scattering, as was the case for the results shown in the figure.

Soft-x-ray emission spectra consist of soft x rays emitted by a sample after a core state has been ionized. An empty core state can be filled in two primary ways: A valence electron makes a transition into the core state while another valence electron is excited to higher energies. This is called an Auger transition, and typically dominates the process in this energy range. The second possibility is that a valence electron makes a transition into the core state and a soft x ray is emitted. The energy distribution of soft x rays then reveals the energy distribution of valence electrons since the core-state energy is fixed.

Figure 9 shows an example of soft-x-ray emission spectra for crystalline and amorphous Si. This is the inverse transition to that shown in Fig. 8. The energy position of the emission band is determined by the core-state binding energy, and thus will be different for each kind of atom. The shape of the spectrum is determined by the electronic structure of the valence band of the material. It is clear from Fig. 9 that crystalline Si has more structure than amorphous Si. The loss of long-range order in amorphous materials blurs the valence states of electrons, smearing out the structure in the density of states.

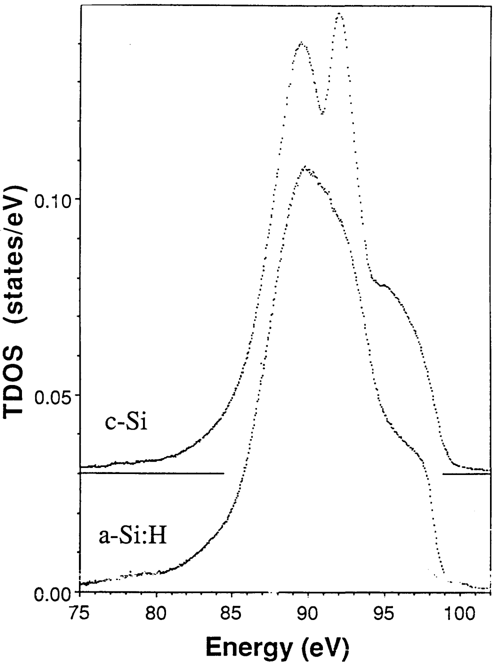

FIG. 9. Soft-x-ray emission of crystalline and amorphous Si due to transitions from the valence band to the $2p$ core level. The crystalline Si spectrum has been displaced upward by 0.03 units (Bruhwiler and Schnatterly, 1989).

Measurements such as these can be used as a check on our understanding of the valence electronic states in a material. This emission band in Si is due to transitions from valence states to the $2p$ core level. The dipole selection rule, which governs transitions such as these, requires that only s-like and d-like states in the valence band can contribute to the spectrum. The Si valence band is made up of $3s$ and $3p$ states, with a small contribution from $3d$ states. Since the $3p$ states are suppressed in this spectrum, it allows us to observe the smaller contribution of the $3d$ states, which is not possible in other spectroscopies such as photoemission, where the $3p$ states dominate.

Theoretical calculations of the shape of the Si emission spectrum of crystalline Si agree quite well with the result shown in Fig. 9. Calculations for amorphous Si have not yet been carried out.

Figure 9 also shows that some emission intensity remains at energies below the emission band. This is caused by a radiative–Auger transition in which both processes occur: A soft x ray is emitted and a valence electron is excited to higher energies, reducing the energy available to the soft x ray.

Figure 10 shows the emission spectrum of BN. This material has a layered structure, and its valence electrons have states either in the planes of the layers (σ states) or perpendicular to those planes (π states). This causes the emission spectrum to be anisotropic, allowing it to be separated into σ and π components as shown. The dashed line shows the radiative–Auger contribution for the π states. Also shown is a peak at about 192 eV in the π spectrum that is not part of the valence band. This is a core exciton, which for some materials contributes to the emission. Figure 9 shows a weak feature near 100 eV in the case of amorphous Si that is also due to a core exciton.

2.2 Hard X Rays

Higher-energy x rays are produced by both bremsstrahlung and transitions to core states. They are absorbed by matter predominantly by electron–hole pair creation. Structural studies in condensed-matter physics are greatly aided by x-ray diffraction, in which x rays scatter elastically from atoms, revealing their relative positions within a material.

Inelastic scattering of x rays in matter also occurs. In this case the incident x ray gives some of its energy and momentum to a single electron, emerging with a lower energy and longer wavelength. This process is known as Compton scattering and played an important role earlier in this century in verifying the reality of photons as the quanta of electromagnetic radiation. Compton showed that if λ_1 is the wavelength of the incident x ray, and λ_2 the wavelength of the scattered x ray,

$$\lambda_2 - \lambda_1 = (h/mc)(1 - \cos\theta) , \qquad (5)$$

where h is Planck's constant, m the mass of the electron, and c the speed of light. The combination h/mc is called the Compton wavelength of the electron and has the value 0.00243 nm.

Compton's formula above applies to electrons that have zero energy, either kinetic or potential, before interacting with the x ray. Electrons in solids have both. The interaction with the nucleus and the other atoms creates a binding energy, which can be very large for core states and is different for different atoms. Valence electrons have a range of kinetic energies as described above. This means that Compton's formula must be modified to include the effects of the initial energy and momentum of the electron. Measurements of inelastic x-ray scattering from solids then provide a means of probing these energies and momenta.

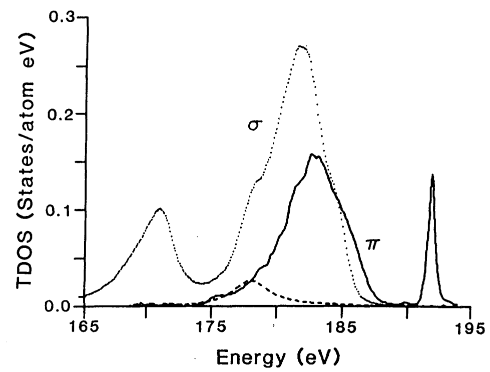

FIG. 10. Soft-x-ray emission spectrum of BN due to transitions from the valence band to the *B* 1s level (Mansour and Schnatterly, 1987).

The cross section for inelastic x-ray scattering from a solid has the same energy and momentum dependence as that for inelastic electron scattering, that is, it is proportional to the imaginary part of the inverse dielectric function. The coefficients multiplying the inverse dielectric function are completely different from those in Eq. (1) since the interaction of x rays with matter is different from that of charged particles. The size of the cross section is smaller than that for electrons by about 10 orders of magnitude. This means that macroscopic samples can be used as targets rather than the thin films used in electron scattering.

In principle, all the kinds of information described above obtainable about solids with electron scattering can also be found using x-ray scattering. In the past the counting rates in the measurements have been much lower, and the energy resolution obtainable has been worse, than that for electron scattering. As synchrotrons become more and more intense x-ray sources, this comparison will improve.

One interesting application of inelastic x-ray scattering derives from the fact that different atoms can be distinguished from one another because of their distinct electron energy levels. This makes it possible to scan an object, e.g., a package, to determine whether a given substance is present inside. With very sensitive x-ray detectors and a raster scanning source, the total radiation exposure is very low, and so this procedure can even be applied to human beings.

2.3 γ Rays

Higher-energy electromagnetic radiation is produced by nuclear transitions and collisions between elementary particles. As the energy increases, absorption of radiation by electron–hole pair creation decreases rapidly. Compton scattering becomes dominant typically above 0.1–1 MeV. At still higher energies, pair creation dominates the interaction of radiation with matter. At these energies, a photon near the nucleus of an atom can create an electron–positron pair. This requires a minimum of about 1 MeV, and the probability increases rapidly above that energy. For these and higher energies electromagnetic showers are produced by incident γ rays similar to those produced by energetic electrons.

Electron–hole pair creation, Compton scattering, and electron–positron pair creation are the three mechanisms by which γ rays interact with matter. These mechanisms underlie the production of detectors of γ rays, which can not only monitor their presence but also record their energies. In these detectors the following things must occur: first, the conversion of the γ-ray energy to kinetic energy of electrons by one of the above three mechanisms; second, the production of electron–hole pairs or excited molecular states by these electrons; and third, the collection and measurement of the charge carriers, or the light produced in the detector material.

Each γ ray then produces a pulse of either charge or light that can be measured. If the entire energy of the γ ray is deposited in the detector, then the size of the pulse is a measure of its energy.

Two such detectors will be described here briefly. NaI(Tl) is a scintillator material that has been used for years to detect x rays and γ rays. This consists of a crystal of NaI in which a small fraction of the Na atoms have been replaced with Tl atoms. The Tl impurities are optically active and can capture electrons and holes producing light. The cross section for stopping γ rays in a solid increases with atomic number, which is the reason the alkali iodide is used. These detectors are quite useful up to energies of several MeV. An important characteristic of these detectors is how much of the γ ray's energy is needed to produce each detected photon. For NaI(Tl) this is about 100 eV.

Ge is a semiconductor that is also widely used to detect γ rays. In pure Ge at low temperature no free carriers of charge exist within the material. Each of the four outer electrons of the Ge atom are contained in a valence band that cannot carry current. Above the top of the valence band is a gap region with no allowed electron states, followed by a conduction band. Only by exciting electrons into the conduction band can charge be carried through the Ge under the influence of an electric field. The gap region in Ge is about 0.7 eV wide.

A very pure crystal of Ge can be used as a γ-ray detector in the following way. An electric field is placed across the crystal, and the resulting current measured with an external circuit. Typically this is done at a temperature of 77 K, the boiling point of liquid nitrogen, so as to reduce the number of electrons thermally excited across the gap. When a γ-ray deposits energy in the Ge, many electron–hole pairs are created causing a pulse of current, which is measured. The average energy needed per created electron–hole pair is only about 3 eV.

The creation and detection of electron–hole pairs are statistical processes. This means that a beam of monoenergetic γ rays will produce pulses with a range of sizes. The energy resolution of the detector is determined by the width of this distribution of pulse sizes. This width increases approximately as the square root of the number of pairs detected. The γ-ray energy increases linearly with the number of pairs. This means that the relative resolution (energy divided by the uncertainty in energy) improves as the number of detected pairs increases. In this regard, Ge is a better detector than NaI(Tl), since more detectable events are created in Ge by the same energy γ ray than in NaI(Tl). In a typical detector, for example, a 1-MeV γ ray can be detected with a pulse width of about 1.6 keV.

Energy-sensitive detectors such as these are used in numerous applications involving radioactivity. For example, a company producing a radioactive source of ^{201}Tl, which is used in medical imaging, must specify not only how much activity there is from this isotope, but also how much is present due to impurities. Using a Ge detector, it is possible to detect impurity radionuclides down to the 0.001% activity level.

An important method used to identify the various chemical elements present in a sample of material is neutron-activation analysis. The sample is placed in a nuclear reactor, where it is subjected to a thermal neutron flux of up to 10^{14} cm^{-2} s^{-1} for perhaps a few days. The neutrons react with the nuclei present in the sample, changing them to new nuclides, many of which will be unstable and will emit radiation. γ-ray emitters are particularly valuable in this application because the cross sections for their production vary by large factors between radionuclides, making it easier to distinguish them. An important prerequisite for this to work well is either a low neutron cross section for the matrix material and a high cross section for the trace element of interest, or a large difference in half-lives of the produced radionuclides. Some elements, in particular the light ones, cannot be detected by neutron-activation analysis, since their nuclei do not become active under neutron exposure. This is an advantage in looking for trace elements in organic and geological materials, since the activation of the matrix (i.e., H, C, N, O, Si, P, S, and Ca) is negligible. For example, rare-earth elements can be detected in rock samples at the level of nanograms per gram. A Ge detector is a good choice for this application.

GLOSSARY

Auger Transition: A relaxation process in an atom, molecule, or solid in which one electron moves to an empty state with lower energy and another takes the energy gained in being excited to a higher energy state.

Band Gap: An energy region for which no electron states exist within a solid. The band gap most widely referred to is that just above the valence band.

Bremsstrahlung: The production of electromagnetic radiation, especially x rays, by the acceleration of an incident electron by the electric field of an atomic nucleus.

Channeling: Deep penetration of a beam of incident ions into a crystal when the direction of the beam is aligned along certain crystallographic axes.

Collision Cascade: The displacement of hundreds of atoms in a crystal by a single incident heavy ion with sufficient energy.

Compton Scattering: The scattering of an x ray by an electron with negligible initial energy.

Core Electron: An electron tightly bound to an atom in a small orbit so that in a molecule or solid it does not interact strongly with electrons on other atoms.

Dielectric Function: A coefficient describing the electric polarization of a solid, usually defined by $\epsilon E = E + 4\pi P$, where ϵ is the dielectric function, E the electric field, and P the induced dipole moment per unit volume. ϵ varies with q and ω where q is the wave vector and ω the frequency of the applied field.

Electron Volt: The energy an electron gains or loses upon passing through a potential difference of 1 V.

Exciton: An electron and a hole bound to each other in a semiconductor or insulator.

F Center: A negative-ion vacancy in an ionic solid that has trapped an electron.

Hole: A missing electron in a distinct state in an atom or solid. The hole behaves like a positively charged particle.

Ion Implantation: The process of adding atoms to a solid by exposing it to a beam of energetic ions.

Kramers–Kronig Relation: An integral equation relating the real and imaginary parts of the dielectric function. This allows the complex dielectric function to be evaluated if some measured property (reflectivity, inelastic electron scattering cross section) is known over a wide energy range.

Mean Free Path: Average distance between collisions for a particle moving in a medium (e.g., an electron in a solid).

Neutron-Activation Analysis: A test procedure for identifying chemical elements in a sample by exposing it to thermal neutrons in a reactor. This converts many elements to a radioactive form that can then be identified by their emissions.

Plasma Excitation: An excitation in solid in which a large number of electrons, e.g., all the valence electrons, move coherently together at a characteristic frequency (the plasma frequency) in response to an applied field.

Sputtering: The removal of surface atoms from a solid by bombarding with energetic ions, often Ar.

Thermoluminescence: Emission of light by a material as it is being gradually heated. The increasing temperature causes electrons and holes to be released from traps; as they recombine light is emitted.

Transmutation Doping: A method of doping Si in which one of the Si isotopes is transmuted to P by exposure to thermal neutrons in a reactor.

Valence Electrons: The outermost electrons on an atom, which form the chemical bonds that hold molecules and solids together.

INTRODUCTION

Intercalation compounds in general are formed by the insertion of atomic or molecular layers of a guest chemical species, called the intercalate, between layers of a host material. Intercalation compounds have received a great deal of attention from the physics, chemistry, and materials science communities because the intercalation process leads to the synthesis of new classes of materials, modifying the properties of both the host material and the guest species. In this article, the structure and properties of intercalation compounds are reviewed. These materials are of special interest because of their potential both for practical applications and for the study of novel physical phenomena. Shown in Fig. 1 are several schematic examples of layered intercalation compounds, with the basic structural unit of the host material ranging from a thin monolayer to a thick multilayer unit. In each case, the addition of the intercalant has little effect on the basic structural unit of the host material.

1. STRUCTURAL ORGANIZATION

To allow insertion of entire layers of guest species, the host material is usually a layered material, with very strong in-plane bonding and very weak interplanar bonding. There are many examples of host materials that support intercalation (see Fig. 1), including graphite (Dresselhaus, 1984; Dresselhaus and Dresselhaus, 1981; Solin, 1982, 1984; Kamimura, 1987), which has been studied most extensively; transition-metal dichalcogenides (Gamble and Geballe, 1976; Liang, 1987); some silicates and metal chlorides (Gamble and Geballe, 1974); some clays (Wada *et al.*, 1987; Newman, 1987); and some polymers and gels (Aldebert *et al.*, 1982). Intercalation modifies the properties of the host materials, giving rise to materials that are more conducting, more anisotropic, magnetic, or capable of storing large concentrations of hydrogen, to give some examples. Correspondingly, intercalation results in the modification of the intercalate, often changing the chemical reactivity drastically because of the bonding between the intercalate and the host material.

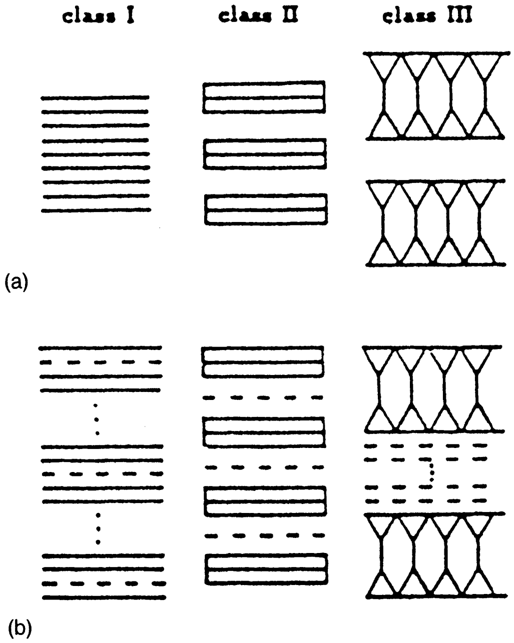

FIG. 1. Schematic classification of (a) pristine layered host materials and (b) the intercalated forms of (a). In (b) the dashed (solid) lines represent guest (host) layers. Three classes of intercalation compounds are shown, class I having the lowest layer rigidity and class III having the greatest rigidity for the host material (Solin, 1984).

1.1 Layer Stacking Arrangements

In discussing the structural organization of intercalation compounds it is necessary to comment on the structure of the host material and of the intercalate prior to intercalation, the effect of intercalation on these structures, and the structure of the entire intercalation compound. In this subsection, the layer stacking arrangements are discussed. First, host materials have their own specific structures prior to intercalation. In general, the basic structural unit of the host material is unaltered in the intercalation process. For example, the graphite host material is a layered compound with *ABAB* stacking and four atoms per unit cell (see GRAPHITE). After an intercalate layer has been inserted, the same intralayer atomic arrangements persist, and the same interlayer correlations between adjacent host layers are maintained within the basic structural unit of the intercalation compound, but the host-layer stacking sequence across basic structural units will in general be different if an intercalate layer is introduced between two layers of the host material.

Likewise the transition-metal dichalcogenide host material shown in Fig. 2 consists of a trilayer containing two chalcogenide monolayers *X* between which a transition-metal monolayer is sandwiched. This strongly bound trilayer unit maintains its structure as an intercalate layer is introduced in the van der Waals gap between the trilayer sandwiches, as indicated in Fig. 2. Similarly, the large, strongly bonded silicate basic structural unit also remains unaltered as the intercalate is inserted between silicate basic structural units as shown in Fig. 3. The intercalate may enter every available van der Waals gap (or intercalate gallery) between basic structural units of the host material in the case of a saturated intercalation compound with the maximum intercalate concentration. For more dilute intercalation compounds, only a fraction of the available van der Waals gaps are occupied by intercalate guest species. For those basic structural units of the host material connected by unoccupied van der Waals gaps, the stacking sequence remains un-

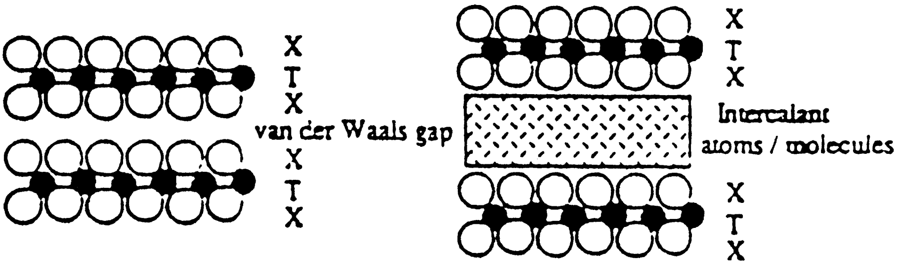

FIG. 2. Schematic representation of the trilayer transition-metal dichalcogenide TX_2 sandwiches and the interlayer van der Waals gap before and after addition of an intercalation complex (Liang, 1987) between layers of TX_2, where *T* denotes the transition-metal layer (usually from groups IV, V, and VI in the periodic table) and *X* is the chalcogenide layer (i.e., S, Se, or Te).

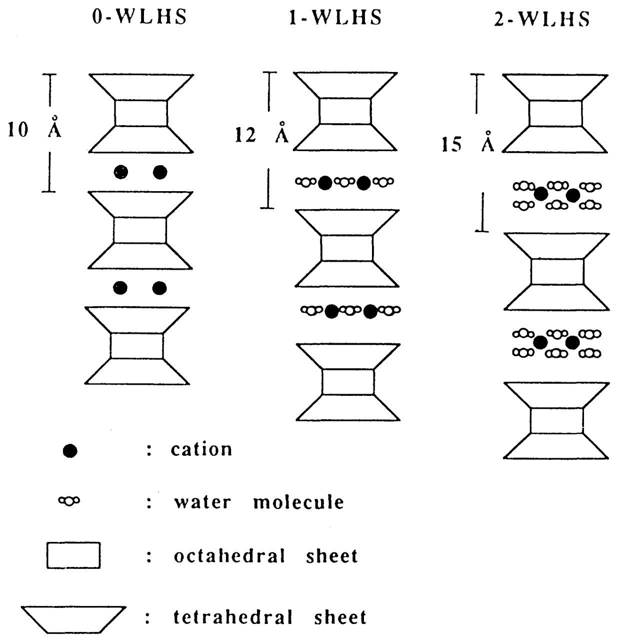

FIG. 3. Schematic representation of the vermiculite clay structure for zero-, one-, and two-water-layer hydration states (WLHS). Typical values for the *c*-axis repeat distance are indicated.

changed relative to the bulk host material prior to intercalation. The structure of the intercalate layer and of the resulting intercalation compound is more complex and is discussed in Sec. 2.2.

A special feature of intercalation compounds is the staging phenomenon, by which a constant number of layers of a host material are sandwiched between sequential intercalate layers, as shown in Fig. 4. The staging phenomenon thus gives rise to a periodic array of intercalate sheets [a one-dimensional (1D) superlattice normal to the layer planes] that can independently undergo 2D order–disorder and structural phase transitions within the layer planes (see Sec. 2.4). Staging allows control of the separation between sequential intercalate layers, thereby providing a means for control of the magnitude of the intercalate interplanar interactions. This control is exploited in studies of a variety of 2D phenomena including quasi-2D magnetism. The two layers of the host material between which the intercalated layer is sandwiched are called the *bounding* layers, while the layers of the host material with host layers on either side are called *interior* layers. Of all the host materials, graphite forms intercalation compounds (GICs) exhibiting the highest degree of staging fidelity.

Whereas intercalation normally refers to the insertion of complete atomic layers of guest species into a layered host material, the term intercalation is also used to denote the insertion of lines of atoms into host materials. For example, the high-T_c superconductor $YBa_2Cu_3O_7$ has chains of oxygen and copper (Cu2) atoms where the stoichiometry is CuO, and planes of the Cu and O species (Cu1) where the stoichiometry is CuO_2. The insertion of oxygen atoms into the chain planes, which contain available sites for O atoms, has also been called intercalation. It should be noted, however, that in the highly anisotropic high-T_c superconductors of the bismuth-based oxide series Bi-Sr-Ca-Cu-O [$Bi_2Sr_2CuO_x$ (2:2:0:1), $Bi_2Sr_2CaCu_2O_x$ (2:2:1:2), and $Bi_2Sr_2Ca_2Cu_3O_x$ (2:2:2:3)], layered intercalation compounds have been synthesized with the indicated basic structural units for the host material, using planes of iodine for the intercalate (Xiang *et al.*, 1991).

In some cases, such as fullerenes, the molecules of the host material are bound to each other by weak van der Waals forces, allowing the guest species to enter interstitial tetrahedral or octahedral sites. In this case the host material has been ordered crystals of C_{60} or C_{70} molecules, and the intercalate species

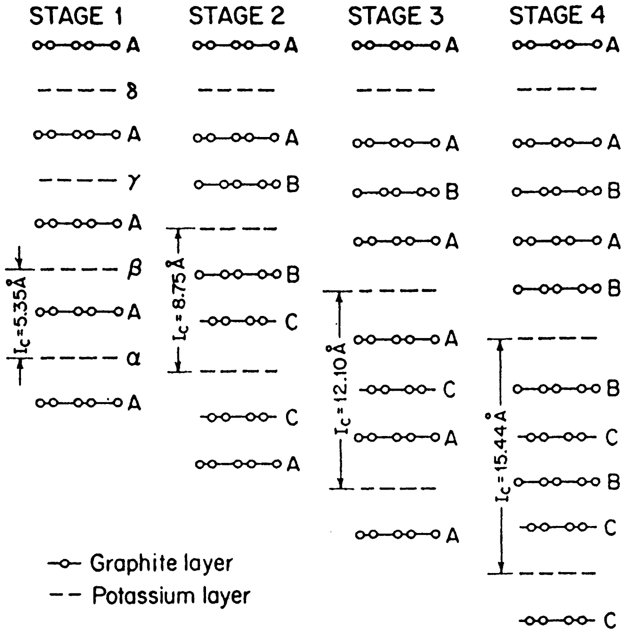

FIG. 4. Schematic diagram illustrating the staging phenomenon in certain layered intercalation compounds for stages $1 \geqslant n \geqslant 4$. In this figure the potassium intercalate layers are indicated by dashed lines and the host graphite layers by solid lines connecting open circles, and indicating schematically a projection of the carbon atom positions. For each stage, the distance I_c between adjacent intercalate layers is indicated.

have been various alkali metals (Na, K, Rb, Cs) and alkaline-earth metals (Ca, Ba) (see FULLERENES).

1.2 Requirements for Intercalation

The occurrence of the intercalation process in layered materials generally requires sufficient chemical activity to

1. transfer charge from the intercalate to the adjacent host layers in order to provide the electrostatic attraction between the intercalate and the host layers that is necessary for their mutual bonding, and
2. supply the elastic energy necessary to separate adjacent layers of the host material to accommodate the intercalate.

The insertion of isolated intercalate molecules into a layered host material introduces large local strains. These strains are greatly reduced by the insertion of a second similar intercalate molecule nearby. Thus both elastic forces and normal chemical bonding forces in solids give rise to an attractive in-plane intercalate-intercalate interaction, so that once nucleation of an intercalate layer is initiated, the subsequent growth of the intercalate layer is rapid, exploiting the enhanced in-plane diffusion coefficients of layered materials. In the case of intercalation compounds where the intercalate seeks specific sites (such as intercalated fullerenes) or specific atomic rows (such as certain cuprate compounds), the intercalation-induced change in lattice constant of the host material is quite small. In contrast, the repeat distance of a layered intercalation compound can be much larger than the basic structural unit of the host material, as discussed in Sec. 2.3.

A variety of chemical and structural considerations determine the facility with which a particular intercalate enters a given host material (Hérold, 1979). For example, graphite is a host material that is easily intercalated, forming intercalation compounds with several hundred chemical species. Although nature has synthesized intercalation compounds in the form of clays and minerals over geological time periods, and scientists have synthesized intercalation compounds for over 150 years (Schafhäutl, 1840), it is only recently that methods have been perfected to the point that one can prepare materials with specific structures and properties (Dresselhaus and Dresselhaus, 1981; Solin, 1982; Zabel and Solin, 1990). In the case of clay intercalation compounds, which are also layered materials, intercalation results from ion exchange between a guest ion and an ion in the host material. During this ion exchange process no charge transfer occurs.

A host material with very strong intraplanar binding and very weak interplanar binding provides a necessary condition for intercalation in layered compounds but not a sufficient condition. For example, BN has essentially the same crystal structure and lattice constants as graphite (see Table 1). However, guest species enter into graphite easily but do not enter BN easily. The major difference between the graphite and BN host materials is the semimetallic electronic structure of graphite with a 40-meV band overlap, while BN is an insulator with a band gap of 4.5 eV. Therefore graphite has a relatively high density of states near the Fermi level E_F to facilitate the charge transfer that provides the electrostatic attraction between the intercalate layer and the two adjacent graphite bounding layers. On the other hand, the wide-gap insulator BN does not have available states near E_F to facilitate charge transfer, so that the weak electrostatic interaction may account for the poor intercalation properties of BN host materials.

For a given host material, some species can easily be intercalated and other species cannot. With the exception of the clays where intercalation occurs by ion exchange, a strong electrostatic interaction and a large amount of charge transfer favors intercalation, while the separation of two sequential layers of the host materials to accept the intercalate layer requires the expenditure of elastic energy. The competition between the electrostatic process and the elastic process determines which species will intercalate easily and for which stages the intercalation process is favorable. Thus for the graphite intercalation compounds (GICs) with molecular bromine (denoted by Br_2-GIC), the stage-1 compound is energetically unfavorable while the stability of higher-stage compounds is favorable. As another example, alkali-metal–GICs can usually be prepared for many stages, though the formation of Na-GICs is energetically unfavorable except for high-stage ($n \geqslant 6$) compounds.

Table 1. A comparison between the crystalline and electronic properties of graphite and boron nitride.

Property	Graphite	BN
In-plane lattice constant	2.46 Å	2.49 Å
c-axis lattice constant	3.35 Å	3.33 Å
c-axis layer stacking	*ABAB*	*ABAB*
Electronic structure	Semimetallic	Insulating
Band gap (overlap)	−0.040 eV	4.5 eV

It is experimentally found that transition-metal dichalcogenide and fullerene host materials can be intercalated relatively easily with donor species, but not by acceptor intercalates. The intercalates that can be readily inserted into transition-metal dichalcogenides include metal atoms (such as alkali metals Li, Na, K, Rb, noble metals such as Ag, and polyvalent metals such as Ca, In, Sn, Pb), organic molecules (such as amines, pyridine, ammonia and hydrazine), and 3*d* transition metals (such as V, Cr, Fe, Co, Ni). Clays also permit a large number of species to be inserted into their van der Waals gap.

When an intercalation compound is energetically stable, it can often be prepared by a variety of techniques, such as vapor transport, liquid-phase growth, growth from solution, or electrochemical techniques (Hérold, 1979). Of these various possibilities, electrochemical techniques offer perhaps the greatest number of possibilities for preparing exotic intercalation compounds (Brec, 1987; Besenhard *et al.*, 1983), while vapor transport often results in materials with the greatest staging fidelity (Hérold, 1979).

While energetics determine whether or not an intercalation compound is formed, kinetic considerations are important for determining the time necessary to form a given compound. One of the most intriguing of the kinetic considerations concerns the transition from one stage to another as the intercalation process proceeds. The model due to Daumas and Hérold, which minimizes mass transport (see Fig. 5), provides a simple explanation for a staging transition from stage n to stage $n-1$ (Hérold, 1979), such as is commonly observed for graphite intercalation compounds. *In situ* x-ray (00l) diffraction or *in situ* Raman-scattering studies of the staging transition provide detailed information on the staging kinetics (Suematsu *et al.*, 1988). In such an *in situ* study, the intercalate species in the gas phase is brought into contact with the host material, which is held at constant temperature, and x-ray spectra are taken every few minutes to monitor the sample stage. The results presented in Fig. 6 for the K-GIC system show a stepwise dependence of the stage index on vapor pressure, with little evidence for multiple-stage coexistence.

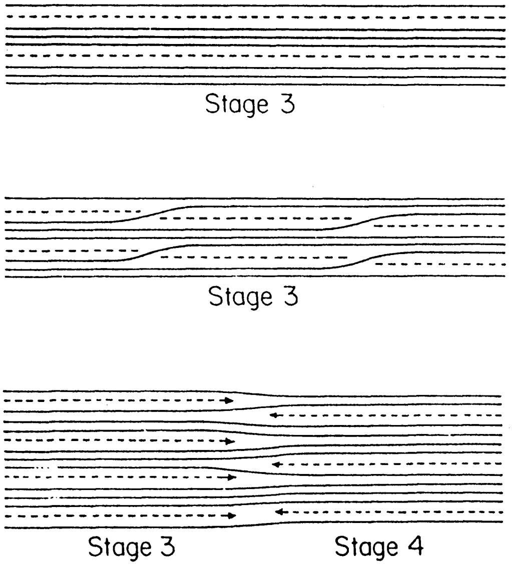

FIG. 5. (a) Single-domain model for a stage-3 compound with every third layer occupied by the intercalate species. (b) Daumas–Hérold domain model for a stage-3 compound with intercalate contained between all graphite planes. (c) Interchange of fourth- and third-stage regions as might occur during a stage transformation.

1.3 Classification According to Rigidity

The layered host materials that can be intercalated are conveniently classified according to their rigidity (Solin, 1984). For the class-I host materials, such as graphite and BN (see Fig. 1), the host material has a basic structural unit that is one monolayer thick (i.e., 3.35 Å for graphite), thereby giving rise to a relatively thin basic structural unit and to relatively flexible materials. A single isolated layer of the graphite structure is called a graphene layer. The basic structural unit of the host material for the transition-metal dichalcogenide intercalation compounds, which are examples of class-II compounds, consists of a trilayer (*XMX*), where *M* denotes the transition-metal layer flanked on either side by a chalcogen layer (see Fig. 2). This trilayer structural unit is intermediate between class I and class III with regard to layer rigidity. Other examples of host materials in the class-II category are the group III–VI (III: Ga, In; VI: S, Se) layered compound semiconductors, where the metal (*M*) and chalcogenide (*X*) layers are arranged in the sequence *XMMX* to form a four-layer slab with strong covalent bonding between each of the four layers and weak van der Waals bonding between these slabs (Julien *et al.*, 1986). Examples of the rigid class-III materials are the silicate clays, where the basic structural unit is typically ~10 Å thick, or thicker when the waters of hydration are included, as shown in Fig. 3 (Wada *et al.*, 1987).

In general, the less rigid the host material, the more likely that it can support the staging phenomenon, which depends also on the competition between the electrostatic and elastic interactions. Of the various host materials, graphite exhibits the highest degree of staging periodicity. Though some transition-metal dichalcogenide intercalation compounds exhibit evidence for staging, this occurs only for low-stage (i.e., $n=1,2$) compounds, and these compounds characteristically have low staging fidelity. Clay intercalation compounds (CICs), which show the largest layer rigidity, do not generally show any evidence for staging, except for stage-1 compounds. On the other hand, clay host materials permit the intercalation of multiple sequential intercalate layers (see Fig. 1), in contrast to the graphite and transition-metal dichalcogenide host materials, which only permit intercalation of a single intercalate unit (either a monolayer or a trilayer unit, as discussed in Sec. 1.4).

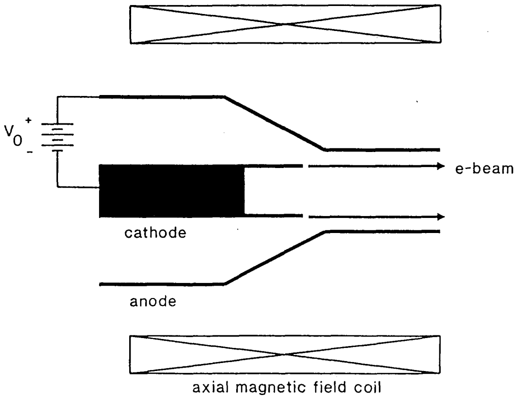

FIG. 6. *In situ* x-ray study of staging transitions (where T_G, the graphite temperature, is 400.1 °C). The kinetics of the staging process in K-GICs is obtained from the time dependence of (00*l*) reflections for transitions from a stage-7 compound to a stage-3 compound (Suematsu *et al.*, 1988).

1.4 Classification of the Intercalate Layers

There are several possible structural arrangements for the intercalate layers. The most common are binary compounds for which the intercalate is a single chemical species, such as an alkali metal, a halogen, or a metal chloride. In some cases, such as the alkali metals or halogens, the intercalate layer consists of a single atomic layer, sandwiched between the basic structural units of the host material. In other cases, such as transition-metal chlorides, the intercalate basic structural unit is a trilayer sandwich. For example, $FeCl_3$ forms a trilayer sandwich of Cl-Fe-Cl constituent layers. Not all compound intercalates form multilayer sandwiches; for example, $AuCl_3$ forms a monolayer intercalate.

A great deal of attention has also been given to the study of ternary intercalation compounds, which are formed by the insertion of a second intercalate species into a binary intercalation compound. Some common examples include the insertion of a second intercalate species into an alkali-metal graphite intercalation compound. Examples of intercalate species that intercalate into alkali-metal GICs include metal intercalates such as Ag and Tl, inorganics such as hydrogen or NH_3, and organic constituents such as benzene (C_6H_6) or tetrahydrofuran (THF) (Zabel and Solin, 1990). In general, the structural arrangement for these ternary intercalation compounds is that of the basic structural unit(s) of the host material, followed by an intercalate trilayer of *MNM* in which *M* refers to an alkali-metal layer and *N* refers to the new ternary constituent, subsequently added to the original binary intercalation compound. The classification of the ternary compounds is complicated by three issues. First, some of the ternary compounds, such as potassium hydride graphite intercalation compounds (KH-GICs), can also be prepared by direct intercalation; independent of whether KH-GICs are prepared sequentially or directly, they are classified as ternary compounds. (Here the intercalate contains two species, potassium and hydrogen.) Second, two-component metal alloy intercalates are said to form ternary intercalation compounds, even though the intercalate is inserted into the host material directly, and the intercalate occupies a single atomic layer as a random-alloy monolayer. The third complication in the ternary classification arises from the possibility of preparing bi-intercalation compounds where the two intercalate constituents are located in different van der Waals gaps or intercalate galleries. Further examples of the various types of binary and ternary systems are given later in this section.

For either binary or ternary intercalation compounds, the separation of two host layers d_s between which the intercalate is sandwiched can vary over wide ranges. In general d_s depends on the size of the guest species. The wide variation of d_s is most clearly seen in the GICs. One example of a GIC where d_s deviates only slightly from that of the unintercalated host material is the case of the Li donor intercalate in graphite where $d_s = 3.70$ Å and $\tilde{c}_0 = 3.35$ Å is the thickness of the basic structural unit of a single graphene sheet. In the opposite limit, d_s can be greater than $3\tilde{c}_0$ for trilayered intercalates into graphite such as transition-metal chlorides (see Table 2) (Dresselhaus and Dresselhaus, 1981; Solin, 1982). Ternary compounds such as KHg-GICs tend to have large d_s values as indicated in Table 2.

The separation between specific intercalate layers can be further increased by the synthe-

Table 2. Intercalate sandwich thickness d_s for several graphite intercalation compounds (GICs) showing that the repeat distance I_c for a low-stage GIC can be varied over a wide range by proper choice of intercalate.

Intercalate	d_s (Å)

sis of bi-intercalation compounds (Zabel and Solin, 1990). Bi-intercalation compounds contain two different intercalants that assume special ordered arrangements. Layered bi-intercalation compounds with intercalants M_1 and M_2 can be prepared, forming the layered sequence $M_2CM_1CM_2$ where C denotes carbon (a single graphene sheet). One synthesis route for such bi-intercalation compounds can be the intercalation of species M_2 into a stage-2 M_1-GIC. For example, in a bi-intercalation metal chloride compound, the separation between sequential M_1 layers is close to 20 Å. Such compounds are of particular interest for the synthesis of quasi-2D magnetic systems, and in this connection the compound $CoCl_2$-$GaCl_3$-GIC has been synthesized and studied magnetically (see Sec. 4).

More generally, ternary intercalation compounds provide a mechanism whereby more than one intercalate species can be introduced into a host material (Solin and Zabel, 1988). As mentioned above, aside from the bi-intercalation compounds, there are basically two different categories of ternary compounds: intercalates introduced as alloys, and intercalates introduced sequentially. An example of an intercalate alloy system is K_xRb_{1-x}, which intercalates into graphite as a substitutional random alloy on each intercalate monolayer (Solin and Zabel, 1988). Such substitutional alloy systems offer very interesting possibilities for studying the physics of quasi two-dimensional random alloys. Intercalate alloys can also be introduced into nonlayered host materials, such as fullerenes. For the case where the two intercalate species have nearly the same size, the two intercalate species enter the fullerene lattice randomly in either octahedral or tetrahedral sites, while for cases like Na_xCs_{1-x}, where the two species have very different radii, the Na ions tend to favor the smaller tetrahedral sites and the larger Cs ions strongly favor the octahedral sites, so that an ordered compound of stoichiometry Na_2CsC_{60} can be prepared.

The more widely studied classes of ternary compounds comprise the sequentially intercalated compounds (Solin and Zabel, 1988), which allow the intercalation of species M_2 that could not itself be intercalated into the host material. In such cases, the prior intercalation of species M_1, often an alkali metal, permits subsequent intercalation of species M_2. Examples of such ternary compounds formed with M_1 as an alkali-metal species include as the M_2 species tetrahydrofuran (THF), an organic species; NH_3, an inorganic species; and the metallic species Hg and Tl, which form superconducting ternary GICs (see Sec. 5). In the case of the hydrogen ternary compounds, both chemisorbed and physisorbed compounds are possible, where the structure of the chemisorbed compound is similar to that for the ionic KHg-GICs (see Fig. 7), while the physisorbed compound can be prepared from stage-2 K-GICs and is important for high-density hydrogen storage applications. Because of the large differences in the amount of physisorption of the various isotopic hydrogen species (tritium $> D_2 > H_2$), the physisorbed hydrogenated K-GICs offer important possibilities for isotope separation applications (Terai and Takahashi, 1981).

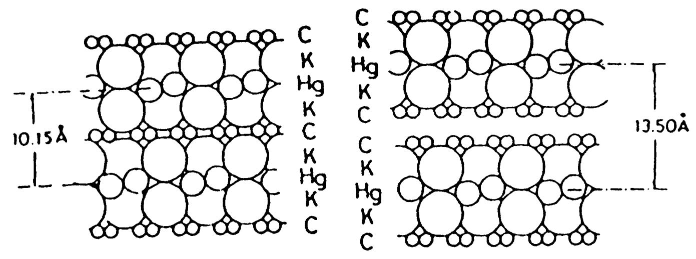
In the above discussion of the intercalate layer, it was assumed that the guest species in the intercalate layer is the same as the guest species prior to intercalation. This is not always the case. For compounds such as the $SbCl_5$-GICs, the intercalation process results in a chemical reaction called disproportionation, giving rise to different species in the intercalate layer, as, for example, the species $SbCl_3$, $SbCl_6^-$, $SbCl_5$, and $SbCl_4^-$ relative to the parent intercalate species $SbCl_5$ prior to intercalation (Zabel and Solin, 1990).

2. STRUCTURAL CHARACTERIZATION

In Sec. 1, the general structural organization and classification of intercalation compounds was summarized. In this section, the structural ordering along the *c* axis normal to the layer planes and in the *a-b* layer planes is reviewed. Interlayer correlations and phase transitions in intercalation compounds are also discussed.

2.1 *c*-Axis Ordering

The dominant ordering along the *c* axis is the staging periodicity, discussed in Sec. 1.2, and characterized by the stage index *n* and the staging fidelity, denoted by the average length of the stage-*n* material (both in-plane and along the *c* axis), and by the amount of each minority stage *n′*, expressed as a percentage of the sample volume. The simplest method



(a) stage 1 C_4KHg

(c) stage 1 C_4KHg

(d) stage 2 C_8KHg

FIG. 7. (a),(b) The layer stacking order of the ternary KHg-GICs for stages 1 (C_4KHg) and 2 (C_8KHg), respectively, where the ideal chemical formulas are also given. (c),(d) A schematic diagram for the reaction process for stage-1 and stage-2 compounds, respectively.

for determining the stage index and information on the staging fidelity of an intercalation compound is the measurement of ($00l$) x-ray diffraction patterns. High-resolution transmission electron microscopy (TEM) studies of lattice fringe images provide a powerful technique for showing detailed aspects of the ordered lattice planes. Since the intercalate often has elements of higher atomic weight than the host material (e.g., carbon), the intercalate layer scatters the TEM electrons more effectively, thereby giving clear contrast between the intercalate and the light host materials. Such measurements show that many host materials exhibit some short-range staging correlations. For a few hosts, especially those with low rigidity (see Sec. 1.4), long-range staging is observed. For the case of graphite intercalation compounds, high-resolution TEM lattice fringe images show that a high degree of staging perfection (over a scale of ~100 Å) can be achieved under favorable circumstances (Zabel and Solin, 1990). For GICs, the c-axis repeat distance I_c between sequential intercalate layers follows the simple relation $I_c = d_s + (n-1)\tilde{c}_0$, where $\tilde{c}_0$ is the interlayer separation in pristine graphite, or the thickness of a single graphene sheet. The validity of this simple relation indicates that, to first order, GICs can be considered as a linear superposition of graphite and intercalate layers. Similar results are obtained in some cases for other host materials. Graphite intercalation compounds are, however, of particular interest with regard to staging because they can be synthesized with stages up to $n \sim 10$ and because of their relatively high degree of staging fidelity (Hérold, 1979; Zabel and Solin, 1990).

TEM studies also provide information about the coupling between the host material and intercalate at their interface. Some compounds such as $CuCl_2$-GICs show sharp interfaces with weak coupling between the intercalate and the graphite host, while K-GICs and F-GICs show very wavy fringes, indicating a strong interlayer coupling. In the case of F-GICs the coupling is so strong that the intercalate layers become puckered as covalent bonding is initiated between the fluorine intercalate and the graphite host material.

The basic structural units of the transition-metal dichalcogenide crystals TX_2 (see Fig. 2) also show *c*-axis ordering both before and after intercalation. The arrangements of atoms within a sheet and the stacking of the atomic TX_2 sheets are now described. Each sheet consists of atoms in a hexagonally close-packed network as shown in Fig. 8(a), which also identifies the three inequivalent close-packed sites *A*, *B*, and *C*. Two types of coordination structure are possible, and either one or both can form the basic structural units of the TX_2 crystal. In the *trigonal prismatic coordination*, the sandwich of *X-T-X* follows the ...*AbA*... sequence, as in Fig. 8(b), and in the octahedral coordination, the ...*AbC*... sequence, as in Fig. 8(c). Here capital letters are used to denote the chalcogen positions and lower-case letters for the metal atoms. In an ideal structure, the distance between chalcogen atoms across the sandwich is the same as that in the plane, which is also equal to the *a* and *b* lattice constants as well as the distance between metal atoms (in plane).

In addition to the two *intrasandwich* octahedral and trigonal prismatic coordination arrangements, there are many variations for *intersandwich* packings, and a large number of polytypes are known. The six most common polytypes for transition-metal chalcogenides are shown in Fig. 9. The nomenclature that identifies these polytypes specifies the number of trilayer sandwiches contained in the unit cell perpendicular to the plane of the layers, and the overall symmetry (trigonal, hexagonal, or rhombohedral) of the structure. Lower-case subscripts are sometimes further required to distinguish polytypes otherwise similarly labeled (e.g., $2H_a$ and $2H_b$). Thus the simplest polytype with octahedral coordination, labeled $1T$, has trigonal symmetry and a repeat distance, perpendicular to the layers, of one trilayer sandwich. The simplest trigonal prismatic coordination polytypes contain two trilayer sandwiches, and are designated $2H_a$ and $2H_b$ (see Fig. 9). The $2H_a$ structure is adopted by metallic group-V materials such as NbS_2 and stacks the metal atoms directly above each other along the *c* axis, while in the $2H_b$ structure, adopted by semiconducting group-VI materials such as MoS_2, the metal atoms are staggered. Octahedral interstitial sites between sandwiches are also shown in Fig. 9 in parentheses, and are the vacant sites into which intercalate atoms or molecules may enter. The crystallographic axes for the *T* and *H* structures are labeled by

a(*x*,*y*) parallel and *c*(*z*) perpendicular to the layers. Typical values are 3–4 Å for the *a* lattice parameter, and 6 Å for the sandwich repeat distance along the *c* axis.

In addition to the octahedral interstitial sites shown in Fig. 9, there are also tetrahedrally coordinated intersandwich sites that lie immediately below and above the chalcogen atoms and are displaced from the symmetric plane between the trilayer sandwiches. These are shown as the "a" and "b" sites in Fig. 10. Octahedral interstitial sites are usually favored in the intercalation of alkali metals, Li, Na, etc., and the 3*d* transition metals, and the maximum intercalate uptake *M* gives a limiting stoichiometry of MTX_2. Tetrahedral site occupation is found in intercalation complexes formed with silver and copper, and with hydrazine; in this case the limiting stoichiometry is M_2TX_2. Li ions in VSe_2 can occupy both octahedral sites, forming $LiVSe_2$, and tetrahedral sites, as in Li_2VSe_2. Transition-metal dichalcogenide hosts are especially interesting for the possibility of introducing very large spacers between the TX_2 trilayers, as, for example, the insertion of *n*-octadecylamine into $TaSe_2$ leading to a separation of nearly 60 Å between sequential Ta layers in the layered structure of the intercalation compound.

2.2 In-Plane Ordering

Not only can intercalation compounds show long-range staging fidelity with regard to their *c*-axis ordering (1D superlattice), but intercalation compounds also show various in-plane orderings, which are of interest in their own right and bear importantly on the observed properties of this class of materials. The two major classes of in-plane structures are the commensurate and the incommensurate arrangements of the intercalate layers with respect to the adjacent host layers. In the commensurate structures (see Fig. 11), the intercalate atoms are in registry with the adjacent host, forming intercalate unit cells with areas that can be multiples of the areas of

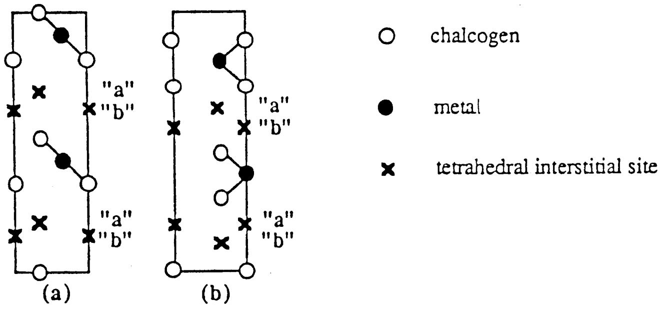

FIG. 10. Tetrahedral intersandwich sites *x* in the (a) 1*T* and (b) $2H_b$ TX_2 polytype structures.

the 2D unit cell of the host material. The following are common examples of commensurate structures that occur in GICs: $(\sqrt{3}\times\sqrt{3})R30°$, $(2\times 2)R0°$, $(\sqrt{7}\times\sqrt{7})R19.1°$, and $(\sqrt{3}\times 2)R(30°,0°)$, where the notation lists the lengths and angles of the intercalate basis vectors relative to those for the graphite lattice, and angular redundancies are not repeated. Commensurate structures are found in a wide variety of model GIC systems (see Table 3), including stage-1 binary donor compounds, such as C_6Li, C_6Eu, C_8K; coplanar molecular acceptor compounds, such as $C_{7n}Br_2$ for stages $n \geqslant 2$; triple-layer sandwich acceptors, such as the $SbCl_5$-GICs; and triple-layer sandwich donor ternary systems, such as KHg-GICs and KH-GICs (Zabel and Solin, 1990).

The formation of commensurate in-plane structures has a close analogy to the growth of semiconductor strained-layer superlattices by the molecular beam epitaxy (*q.v.*) (MBE) method or by metal-organochemical vapor deposition [see CVD (CHEMICAL VAPOR DEPOSITION)] (Dresselhaus, 1987). Because the intercalate layer in an intercalation compound is so thin (a single monolayer or a single trilayer sandwich), commensurate in-plane structures can be formed without the need for misfit dislocations to relieve local strains.

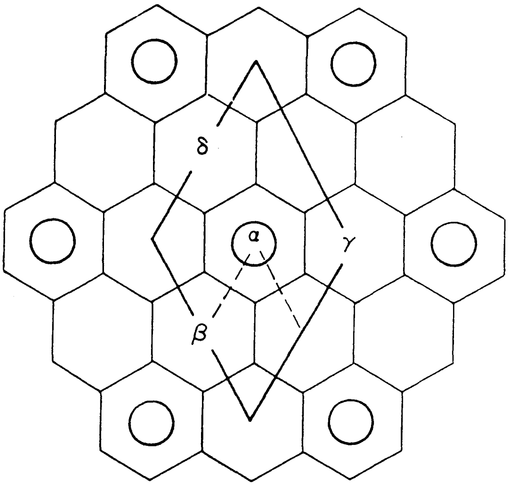

FIG. 11. Schematic diagram of an in-plane unit cell for the commensurate $(2\times 2)R0°$ structure. Carbon atoms from the host material are located at the corners of the hexagons on one layer and the intercalate species are shown as the large open circles, which are located on the adjacent layer. In this diagram the intercalate and graphite layers are projected onto a single plane. For this structure there are four equivalent intercalate sites, labeled α, β, γ, δ. On a given intercalate layer only one of these sites is occupied. The dashed lines represent the in-plane unit cell for pristine graphite. For the first-stage C_8K and C_8Rb, the intercalate on consecutive layers is arranged on sequential α, β, γ, δ sites.

Table 3. Structure of common commensurate GICs.

Intercalate	Stage	Formula[a]	Structure[b]
Li	1	C_6Li	$(\sqrt{3}\times\sqrt{3})R30°$
Eu	1	C_6Eu	$(\sqrt{3}\times\sqrt{3})R30°$
K	1	C_8K	$(2\times 2)R0°$
Br_2	$\geqslant 2$	$C_{7n}Br_2$	$(7\times\sqrt{3})R(0°,30°)$
$SbCl_5$	$\geqslant 1$	$C_{14n}SbCl_5$	$(\sqrt{7}\times\sqrt{7})R19.1°$
KHg	1	C_4KHg	$(2\times 2)R0°$
KH	1	C_4KH	$(2\times 2)\mathrm{R}0°$

[a] The nominal chemical formula for a stage-n compound.

[b] The notation for the 2D superlattice refers to the length scaling and the angle of rotation of the unit vectors for the intercalated superlattice relative to graphite.

The lowest energy state for an intercalate atom is obtained by placing it over (or below) the center of a graphite hexagon, thereby achieving the greatest packing density (Dresselhaus and Dresselhaus, 1981; Hérold, 1979). A close-packed in-plane configuration for the intercalate maximizes its chemical bonding and minimizes the strain energy introduced into the adjacent graphite layers from insertion of the intercalate. When both registry with the graphite hexagons and close packing of the intercalate layers can be simultaneously satisfied on a long-range basis, commensurate intercalate layers are favored. Otherwise, the close-packed configuration of the intercalate layer implied by chemical binding considerations prevails and an incommensurate solid forms. In many cases, the in-plane intercalate lattice constant for incommensurate interlayer stacking is close to that of the parent material. Examples of intercalates forming incommensurate GICs are transition-metal chlorides and bromides (Vogel and Hérold, 1977; Hérold *et al.*, 1983), some of which have especially interesting magnetic properties, as discussed in Sec. 4.

Intercalate registration (the tendency for an intercalate atom to be located in a position of minimum energy with respect to the adjacent graphite layers) affects the structural ordering of GICs in many ways besides the formation of commensurate GICs, as discussed above. For the case of incommensurate GICs, local registration of the intercalate with respect to the graphite layers leads to *orientational* alignment of the intercalate, as evidenced by the spot patterns observed by (*hk*0) diffraction spectra for many incommensurate GICs. In addition, many incommensurate intercalates (e.g., transition-metal chlorides) tend to form intercalate islands (~100 Å in diameter) to minimize the number of intercalate atoms not in registry with the graphite host material (Dresselhaus, 1987).

2.3 Interlayer Correlations

Not only is there intercalate ordering within the intercalate layer, but there is also 3D stacking order of intercalate layers with respect to one another. A clear example of this phenomenon is observed in stage-1 alkali-metal–GICs (Dresselhaus and Dresselhaus, 1981). Because the intercalate unit cells can be much larger than that for the host, there will be several equivalent sites for the intercalate atoms in a commensurate GIC. For example, for a $(2\times2)R0^\circ$ in-plane lattice (see Fig. 11), there will be four equivalent intercalate sites, labeled α, β, γ, δ. But once one of these sites is occupied by an intercalate atom (e.g., an α site), then the intercalate atoms on the same layer (within a single domain) will also tend to occupy the same type of site (an α site), thereby giving the maximum packing density for the intercalate (Dresselhaus and Dresselhaus, 1981). Because of the local strain introduced by placing an intercalate atom on site α, the intercalate atom on the adjacent intercalate layers will be less likely to be located on an α site than on a non-α site. This interlayer exclusion argument implies that when there is sufficient intercalate-intercalate interlayer correlation mediated by the intervening graphite layers, interlayer stacking order will result. A number of low-stage binary GICs and ternary GICs have been reported to exhibit interlayer stacking correlation effects (Solin and Zabel, 1988). Even when there is no long-range interplanar stacking order, there is often short-range interplanar correlation based on the interplanar intercalate exclusion argument given above. Because the interplanar intercalate-intercalate interaction energy is small, thermal excitation at room temperature is often sufficient to destroy interplanar intercalate correlation, thereby producing quasi-2D intercalate layers, uncorrelated in the *c* direction.

2.4 Intercalate Phase Transitions

In general, the host material and intercalate materials have different melting points. Thus unusual phase transitions can be observed, as one of the constituents melts while the other remains solid. Such behavior is, for example, observed in GICs, since graphite does not undergo structural phase transitions up to very high temperatures (~4000°C). Examples of such phase transitions are order–disorder transitions in the intercalate layer, as occur in the HNO_3-GIC system (Dresselhaus and Dresselhaus, 1981). The disordered intercalate phase often exhibits the characteristics of a lattice gas, whereby each intercalate atom is fluidlike in the intercalate layer, but has a high probability of being in registry with the adjacent graphite layers. Such effects are observed in high-resolution x-ray diffraction measurements (Zabel and Solin, 1990) of high-stage ($n>2$) alkali-metal GICs. Intercalate melting is a closely related phenomenon and has been observed for a variety of intercalates (Dresselhaus and Dresselhaus, 1981).

For some GICs, two or more intercalate orderings have approximately the same free energy, leading to multiphase coexistence, with domain walls that are either more dense (heavy walls) or less dense (light walls) than the ordered domains. An ordered array of domain walls may occur, giving rise to modulated structures, as occur in many high-stage ($n>2$) alkali-metal GICs (Zabel and Solin, 1990). Heavy and light walls also arise at the boundary between regions of different site occupation in a commensurate in-plane superlattice [e.g., the boundary between an α domain and a β domain in the same intercalate layer of a $(\sqrt{3}\times\sqrt{3})R30^\circ$ superlattice]. These phenomena have been widely studied for adsorbed rare-gas phases on graphite (Zabel and Solin, 1990).

A particularly interesting example of a modulated in-plane structure in GICs is the stripe domain phase (Zabel and Solin, 1990), which has been observed in a stage-4 Br_2-GIC with nominal stoichiometry $C_{28}Br_2$. This intercalation compound has a commensurate $(7\times\sqrt{3})R(0^\circ,30^\circ)$ in-plane structure with

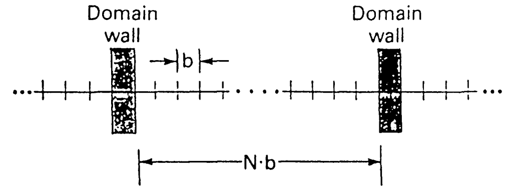

FIG. 12. Schematic diagram of a stripe domain phase. The intercalate lattice remains commensurate except in the domain wall where a phase slip occurs every *N* unit cells.

a rectangular unit cell containing four Br_2 molecules. The driving mechanism for this phase transition is the differential thermal expansion between the graphite basal plane, which has essentially zero thermal expansion, and that for a bromine layer, which has a normal thermal expansion coefficient. For the Br_2-GIC system, the coupling between the graphite and intercalate layers is sufficiently large so that the structure remains commensurate over a large temperature range. At a temperature $T_c=69$ °C, a phase transition occurs whereby the graphite and bromine layers retain long-range registry along the $\sqrt{3}$ direction, but form a stripe domain phase along the seven-fold direction. As the temperature increases above T_c, the average bromine lattice constant along the seven-fold direction increases, though the graphite and bromine remain locally commensurate over a domain containing N unit cells (see Fig. 12). These domains are arranged in a periodic array with lattice constant $Nb+\tau$, where τ is the thickness of the domain wall, and $\tau=2b/7$ where $b=7a_0$ and a_0 is the graphite in-plane lattice constant. The domain wall is also called a misfit dislocation in the terminology of the strained-layer superlattice. This stripe domain phase is one example of a more general discommensuration phenomenon, which features local commensurate behavior but long-range incommensurate behavior. Discommensuration effects are also observed in high-stage alkali-metal–GICs (Zabel and Solin, 1990).

3. ELECTRONIC PROPERTIES

In accordance with the structural ordering discussed above is the periodicity in the charge distribution perpendicular to the layer planes, which arises from the charge transfer associated with the intercalation process. In general, charge transfer is the driving mechanism for intercalation and is responsible for the observed transport and electronic properties of intercalation compounds. In this section the concept of charge transfer is discussed and the transport and electronic properties that result from charge transfer are also reviewed.

3.1 Charge-Transfer Phenomena

To illustrate the charge-transfer concept in a general intercalation compound, let us consider the charge transfer from an alkali metal to a host material such as graphite in a graphite intercalation compound (see Fig. 13). Let us suppose that each alkali-metal atom contains one nearly free electron. If this electron is donated to the graphite layers, the alkali-metal layers become positively charged, thereby attracting the negative charges in the graphite layers. Thus the majority of the electrons transferred to the graphite will be located in the graphite bounding layers adjacent to the intercalate layers, as shown in Fig. 13. Lower concentrations of transferred charge will be available for the graphite interior layers that are surrounded only by graphite layers (Dresselhaus, 1984). Calculations of the charge distribution in the graphite layers

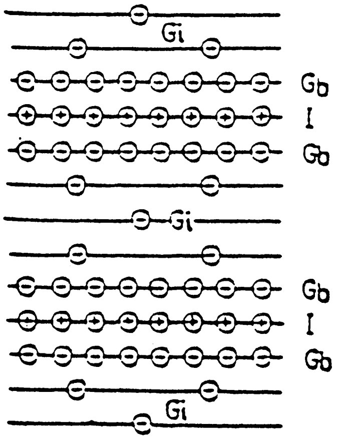

FIG. 13. Schematic representation of charge transfer in graphite intercalation compounds, showing the intercalate layer (*I*) for a donor compound transferring electrons to the graphite bounding (G_b) layer, with a small amount of charge also transferred to the graphite interior (G_i) layers.

show that the graphite bounding layers effectively screen the graphite interior layers from the intercalate layers with a power-law dependence of z^{-4} relative to the position of the intercalate layer. The charge-transfer concept for alkali-metal intercalation into other host materials is similar.

Since the carrier concentration in graphite is very low ($\sim 2\times 10^{-4}$ carrier/C atom at room temperature and $\sim 6\times 10^{-5}$ carrier/C atom at low temperature), the charge transferred to the graphite layers through intercalation causes a major increase in the mobile carrier concentration in the graphite layers. An estimate of three orders of magnitude increase in carrier concentration follows from assuming a charge transfer of one carrier per intercalate unit to the graphite layers and assuming an intercalate concentration one order of magnitude smaller than that for graphite. Since the mobility of pristine graphite is relatively high (13 000 cm^2/V s at 300 K), intercalation compounds with very high in-plane electrical conductivity can be synthesized. On the other hand, the conductivity in the intercalate layers is expected to be low because of the low mobility of ions generally, and the low density and low mobility of electrons (or holes) in the intercalate layers. Thus electrical transport in the basal planes of GICs is mainly by graphitic π-band electrons and holes. Intercalation with donors raises the Fermi level so that conduction is predominantly by electrons, while intercalation with acceptors lowers the Fermi level, giving rise to conduction by holes (Dresselhaus and Dresselhaus, 1981).

Because of the high electron affinity of the transition-metal dichalcogenides and fullerenes, these materials lead only to donor intercalation compounds. Charge transfer in the donor transition-metal dichalcogenide compounds is especially interesting, since TX_2 compounds containing a group-IV transition metal, such as ZrS_2, are semiconducting, so that, for example, intercalation with an alkali metal can partially fill the d_{z^2} level, making the material conducting. On the other hand, if the transition metal T is a group-V element such as Nb, the TX_2 compound is metallic; however, if sufficient charge is transferred, a filling of the d_{z^2} band may occur, resulting in a semiconductor. These various possibilities are considered in Fig. 14.

The current that flows during the electrochemical intercalation process provides one direct measure of the charge transfer in intercalation compounds. In principle, magneto-oscillatory Fermi-surface experiments should also yield accurate values of the charge transfer. This has been demonstrated by very careful magneto-oscillatory measurements made on several well-characterized alkali-metal–GICs and a very few acceptor GIC materials. Because of the difficulty of these experiments, it is not likely with present techniques that Fermi-surface studies will become a widespread characterization tool for charge transfer in GICs.

Charge transfer in ternary GICs is of particular interest. For example, the addition of Hg or H to the first-stage compound C_8K reduces the electron concentration in the graphite layers by a back-donation process, while the Hg or H layers become negatively charged. This can be more easily understood by referring to Fig. 7 where the trilayer structure of the intercalate sandwich for a ternary compound (such as KHg-GIC) is shown. Here the Hg or H layers behave somewhat like an acceptor intercalate, though residing in an otherwise donor compound. It is believed that the Hg conduction band gains electrons but remains partially occupied in order to support

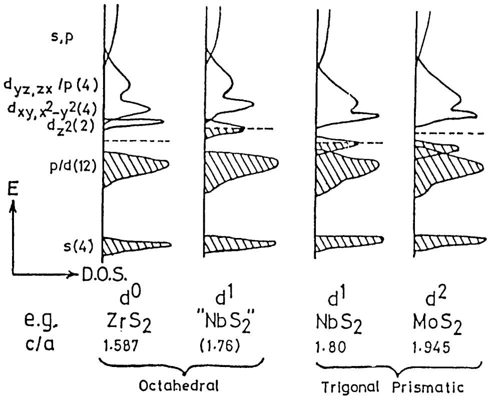

FIG. 14. Schematic density-of-states diagrams for groups IV, V, and VI transition-metal dichalcogenides. The numbers in parentheses following the atomic orbital notation indicate the number of states per formula unit that can be accommodated in each band. The compounds used as examples are taken from metals of the same row of the periodic table. NbS_2 does not actually crystallize in the octahedral form, and the second diagram represents an extrapolated hypothetical band diagram (Liang, 1987).

superconductivity in the KHg ternary compounds as discussed in Sec. 5.

3.2 Transport Properties

Because of the large increase in carrier concentration that often accompanies intercalation, large increases in the in-plane conductivity σ_a is often observed in intercalation compounds. For semiconducting group-IV or group-VI transition-metal dichalcogenides, the change in conductivity can be many orders of magnitude, since the material prior to intercalation has such a low electrical conductivity. For the GIC host material, the room-temperature in-plane conductivity can with suitable intercalates (e.g., AsF_5) become comparable to that of the best room-temperature conductors. Because of this potential for practical applications, most transport studies on intercalation compounds have been done on GICs. For most GICs, in-plane conductivity increases approaching an order of magnitude are frequently observed. Some exceptions to this general behavior are found in high-concentration F-GICs, where the intercalation process itself leads to disorder, the formation of covalent bonding, and a reduction in σ_a.

Not only is the electrical conductivity of layered intercalation compounds very high in the basal planes, but it is also highly anisotropic. The most anisotropic intercalation compounds are the GICs, a result in part of the anisotropy of the host material. The conductivity of pristine graphite in the *c* direction is between 3 and 4 orders of magnitude lower than that in the basal plane, depending on the temperature (Dresselhaus, 1987). Since intercalation with acceptors tends to introduce intercalate layers containing molecular species with very low electrical conductivity, the electrical anisotropy of graphite is increased by intercalation with acceptors, reaching values of σ_a/σ_c in the range 10^6–10^7 (McRae and Marêché, 1988). On the other hand, intercalation with alkali-metal donors often hybridizes the graphitic π electrons with intercalate electrons containing *s* and *p* character, thereby reducing the electrical anisotropy relative to pristine graphite, with anisotropy ratios as small as 10 for the case of stage-1 C_6Li (Dresselhaus and Dresselhaus, 1981). However, the ternary donor compounds (e.g., KHg-GICs and CsBi-GICs), show anisotropy ratios σ_a/σ_c comparable to the magnitudes previously reported for typical acceptor GICs (McRae and Marêché, 1988).

3.3 Electronic Structure

An extensive amount of work has been done in calculating the electronic structure of the various host materials supporting intercalation, such as graphite and the transition-metal dichalcogenides, and in some cases the electronic structure of the intercalation compounds has also been calculated (Zabel and Solin, 1992). From an experimental standpoint, photoemission has been extensively used for determinations of the electronic structure.

Although surface science techniques such as photoemission can, in principle, yield a great deal of valuable information about intercalation compounds, the near-surface sensitivity of these techniques causes them to emphasize the surface electronic structure rather than that typical of the bulk. This is a significant problem for intercalation compounds because of the large sizes of their *c*-axis unit cells. In addition, surface-science studies have thus far shown that the first few atomic layers of donor GICs have an excess intercalate concentration, while in acceptor GICs, the first few atomic layers exhibit a very low intercalate concentration (Dresselhaus, 1987). The cleavage of GICs at low temperature (e.g., ~77 K) has demonstrated the possibility of preparing surfaces retaining intercalate concentrations typical of the bulk for long enough times (minutes) to permit properties measurements to be carried out. Optical measurements, which probe many unit cells along the *c* axis, have also been widely applied to study interband transitions and phonon modes in various intercalation compounds. Because of the high degree of anisotropy in the structural properties, the electronic and optical properties are also highly anisotropic.

4. MAGNETIC INTERCALATION COMPOUNDS

A variety of magnetic materials has been prepared by the intercalation of magnetic species into various nonmagnetic host materials. In general, the intercalation of magnetic species into a host material results in a magnetically ordered intercalation compound below a magnetic ordering temperature T_c. By varying the separation between sequential magnetic layers through the staging mechanism, the interplanar magnetic coupling can be reduced in a controlled manner to very small values, thereby providing a convenient system for studying quasi-2D magnetism. Graphite intercalation compounds are of particular interest in the case of magnetic intercalation compounds because they provide novel systems for the study of quasi-2D magnetic behavior. The transition-metal dichalcogenides and clays also allow for the intercalation of layers of magnetic species in a nonmagnetic host material. The transition-metal dichalcogenides offer further possibilities insofar as by proper selection of the transition metal, the host material can itself be magnetically ordered; in this case, the intercalate can be either nonmagnetic or a different kind of magnetic layer. Some of the most interesting magnetic studies of 2D systems have so far been done on the graphite intercalation compounds because of their good staging characteristics.

Both donor (Eu) and acceptor ($FeCl_3$, $FeCl_2$, $CoCl_2$, $NiCl_2$, $MnCl_2$, $MoCl_5$) magnetic GICs have been synthesized and studied for their magnetic properties (Zabel and Solin, 1992). The magnetic ordering temperatures of the magnetic intercalation compounds are generally lower than those for their parent magnetic materials because of the smaller number of near neighbors imposed by the layer arrangement of the intercalation compounds. For the rare-earth donor GICs, the intercalate in-plane structure is commensurate with that of the adjacent graphite layers, forming a $(\sqrt{3}\times\sqrt{3})R30°$ superlattice structure, and thereby simplifying the treatment of the magnetic problem to some degree. Since the in-plane structures of incommensurate metal chloride acceptor GICs tend to be almost identical to those in the corresponding parent materials, the intraplanar magnetic exchange constants remain essentially unchanged upon intercalation, thereby providing a major simplification in the treatment of the magnetic problem in metal chloride acceptor GICs.

Of the various types of magnetic acceptor GICs, the quasi-2D XY systems (for which the spins are constrained to be in the layer planes) have been most widely studied, because of the special role these systems play in theoretical studies of critical phenomena. The absence of long-range order in 2D systems results in short-range correlations in the form of vortices. Close approximations to such magnetic phases can be observed in magnetic GICs over a limited range of temperatures and magnetic fields (Zabel and Solin, 1992).

Of the various magnetic acceptor GICs, the $CoCl_2$-GICs exhibit the largest *c*-axis magnetic anisotropy ($J_A/J=0.56$), so that these compounds are expected to provide the best approximation to a 2D XY model for GIC systems. Furthermore, it is possible to synthesize $CoCl_2$-GICs for a variety of stages, and thus to investigate the stage dependence of the observed phenomena. Moreover, the structural coherence lengths in the intercalate islands are large enough to contain a statistically meaningful number of spins ($>10^3$ spins/island), and yet small enough to permit a meaningful comparison with theoretical calculations for specific spin arrangements.

For all the acceptor 2D XY GIC systems that have been studied, two critical temperatures are identified (T_{cl} and T_{cu}), thereby delineating three temperature regimes, each exhibiting distinct magnetic behaviors: $T<T_{cl}$, $T_{cl}<T<T_{cu}$, and $T>T_{cu}$. At high temperature ($T\gg T_{cu}$), Curie–Weiss paramagnetic behavior is found, while at low temperature magnetically correlated states are observed (Zabel and Solin, 1992).

In the temperature range $T_{cl}<T<T_{cu}$ for the high-stage compounds, the spins are approximately confined to the basal plane and are arranged in a bound vortex configuration with strong in-plane spin-spin correlation but negligible interplanar correlation. Inelastic neutron-scattering studies provide strong evidence for the bound vortex state in the stage-2 $CoCl_2$-GIC. The absence of a remanent magnetization and the observation of a linear dependence of the magnetization on magnetic field for $T>T_{cu}$ identifies the phase above T_{cu} with paramagnetism.

Weak perturbations, such as the six-fold in-plane symmetry-breaking crystal field H_6 and the interplanar magnetic interaction J', become important at low temperatures and give rise to a 2D–3D crossover transition at T_{cl}. The spontaneous magnetization due to the coupling of the spins to H_6 gives rise to ferromagnetically ordered in-plane domains below a temperature of T_{cl}. The antiferromagnetic interplanar exchange interaction couples these ferromagnetic planar domains and results in an antiferromagnetic stacking arrangement of these domains, as implied by neutron scattering experiments (Zabel and Solin, 1992).

Magnetic phase transitions can be identified through the different field and temperature dependences that are found for the various properties such as the magnetic susceptibility, magnetization, and the magnetic contribution to the heat capacity. The most thoroughly studied magnetic donor GIC at the present time is the stage-1 europium compound, C_6Eu, for which the crystal structure is commensurate with the adjacent graphite layers. Each Eu atom has six nearest-neighbor Eu atoms at a distance of 4.31 Å within the layer plane, and six next-nearest-neighbor Eu atoms lie at a distance of 5.47 Å in *adjacent planes.* The configuration of the Eu^{2+} ion is $^8S_{7/2}$, which arises from a $(4f)^7$ electronic configuration, giving a total spin of 7/2 with no orbital angular momentum. Because the nearest-neighbor exchange interaction is antiferromagnetic, the spins form an antiferromagnetic frustrated triangular spin lattice. This spin system can easily be modified by introducing weak interactions, so that a variety of magnetic phases can be realized by small variations of the temperature and magnetic field. Field-dependent resistivity measurements (see Fig. 15) can be used to identify magnetic phase transitions, and the nature of

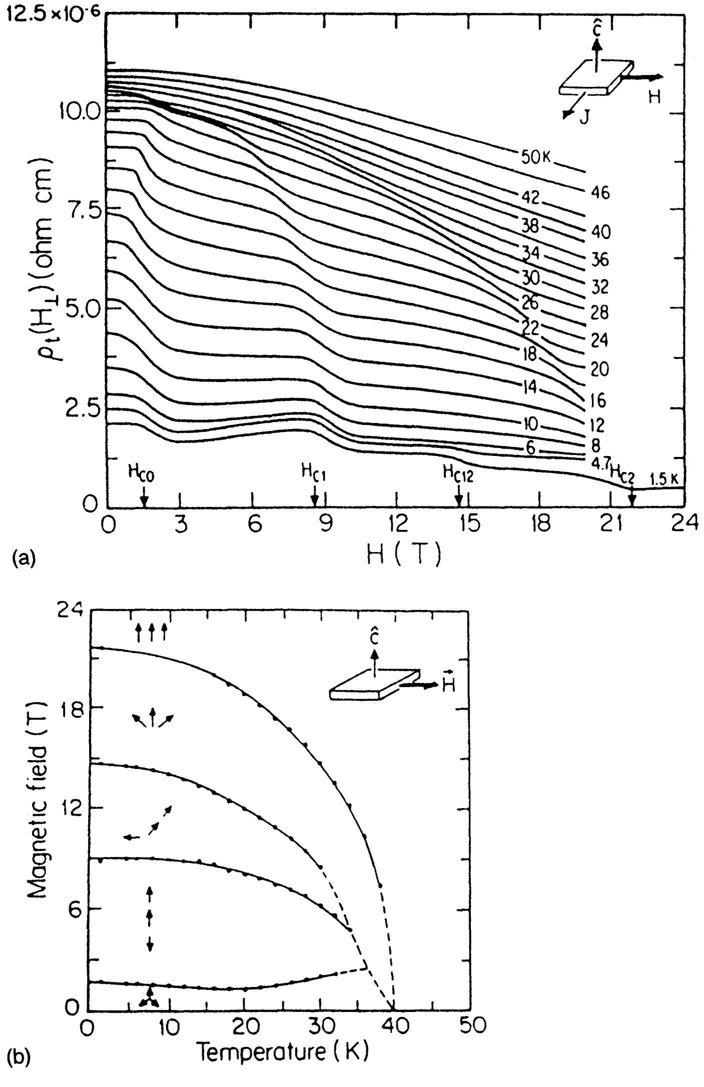

FIG. 15. (a) Anomalies in the field-dependent resistivity can be used to map out the magnetic phase diagram of a magnetic intercalation compound shown in (b). Specific results are shown here for the stage-1 donor compound C_6Eu. The orientations of three spins within the magnetic unit cell identify each of the magnetic phases. Ferromagnetic spin alignment along the magnetic field direction is achieved in the high-magnetic-field phase.

these magnetic phases is determined by magnetic measurements. On the basis of field-dependent resistivity measurements, a magnetic phase diagram has been developed for the low-temperature magnetic phases of C_6Eu (see Fig. 15).

The magnetic properties of donor GICs are distinctly different from those of the acceptor compounds because of differences relating to the basic magnetic coupling mechanism that occurs both in the pristine magnetic donor intercalates (which are metals) and in the intercalation compound (where the metallic behavior is associated predominantly with the graphite π bands). In the magnetic donor compounds, the mechanism for the magnetic exchange is through the conduction-band electrons, whereas the behavior of the magnetic acceptor GICs is dominated by the coupling between magnetic dipoles through induced dipoles on the nonmagnetic layers (i.e., by the superexchange mechanism).

5. SUPERCONDUCTING INTERCALATION COMPOUNDS

Superconductivity in intercalation compounds was first observed by Hannay *et al.* (1965), who identified superconducting transitions in the stage-1 heavy alkali-metal compounds with the intercalates K, Rb, and Cs in the graphite host material. The discovery of superconductivity in these materials attracted a great deal of interest insofar as neither the intercalate (an alkali metal) nor the host material (graphite) is by itself superconducting. Superconductivity in C_8K is also interesting with regard to its large anisotropy (the upper critical field H_{c2} is an order of magnitude larger for $H \perp c$ axis than for $H \parallel c$ axis), and for the unusual effect that for $H \parallel c$ axis, the intercalation compound exhibits type-I superconducting behavior (with no vortex formation), while for $H \perp c$ axis, the same sample can exhibit type-II behavior and vortex formation. Because of the low value for the superconducting transition temperature for C_8K (T_c=0.14 K), only a limited study of this system has been carried out (see Table 4). Other GICs with intercalates that are themselves superconducting (such as the stage-1 C_4KHg or the stage-2 C_8KHg) have T_c values in the range 1–2 K. Under pressure the alkali-metal intercalants enter the intercalate galleries at higher concentrations and give rise to T_c values up to 5 K (Zabel and Solin, 1992). The intercalation of fullerenes with alkali metals also leads to superconductivity (see FULLERENES), but with much higher transition temperatures (up to 33 K), because of the very much higher density of states near the Fermi level that can be achieved in this highly molecular solid.

Superconductivity is also observed in transition-metal dichalcogenides, but in this case the studies in the intercalation compounds have been focused in a different direction, since selected transition-metal dichalcogenides (such as TaS_2) are already superconducting prior to intercalation. In this case intercalation has been used to enhance the anisotropy of the superconducting phenomena.

Anisotropic superconductivity has been observed in a variety of layered materials (Dresselhaus and Chaiken, 1987), including deliberately structured materials, transition-metal dichalcogenides intercalated with large organic molecules, and graphite intercalation compounds. Because of the long range of the superconducting coherence distance ξ, the observation of 2D superconductivity focuses on samples with superlattice repeat distances I_c large compared with the superconducting coherence distance (in the *c*-axis direction) to

Table 4. Fundamental parameters[a] characterizing the superconductivity of C_8K (Zabel and Solin, 1992).

Parameter	Experimental value
T_c (mK)	128–198
Θ_D (K)	234.8
$N(0)V$	0.14
H_c (Oe)	10–13
$\kappa_\perp$ (T_c)	0.78
$\kappa_\parallel$ (T_c)	0.22
$\kappa_\perp / \kappa_\parallel$	3.55
$\lambda_\perp$ (0) (Å)	2300
$\lambda_\parallel$ (0) (Å)	8100
$\lambda_\perp / \lambda_\parallel$	0.28
$\xi_\perp$ (0) (Å)	10000
$\xi_\parallel$ (0) (Å)	2900
$\xi_\perp / \xi_\parallel$	3.45

---

[a] Θ_D is the Debye temperature, κ is the Landau–Ginzburg parameter, λ is the London penetration depth, ξ is the Ginzburg–Landau coherence length, and the subscripts $\parallel$ and $\perp$ refer to the directions parallel and perpendicular to the *c* axis, respectively.

achieve the condition of 2D superconductivity, $I_c > \xi_c$, where ξ_c denotes the coherence distance in the c direction for an anisotropic superconductor. Molecular-beam epitaxy and magnetron sputtering offer great promise for quantitative studies of 2D superconductivity and the 2D–3D crossover because of the flexibility of these synthesis techniques for the generation and control of large superlattice repeat distances in deliberately structured superconductors (Dresselhaus, 1987).

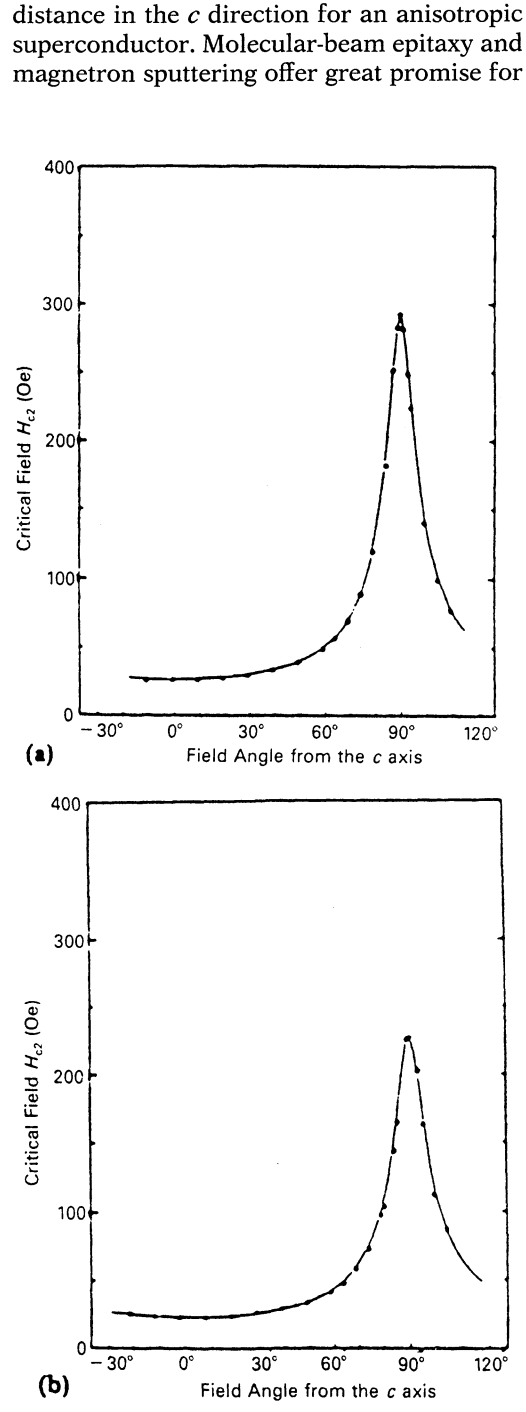

FIG. 16. Angular dependence of the upper critical field H_{c2} of the stage-1 ternary compounds (a) C_4KHg and (b) C_4RbHg. The curve in each case represents the best fit of the effective-mass model to the experimental points (Iye and Tanuma, 1984).

The earliest reports of superconductivity in layered transition-metal dichalcogenides intercalation compounds focused on the increase in T_c that occurred through intercalation with large organic molecules (Gamble and Geballe, 1976). The effect of lower dimensionality was observed in this work, especially in systems such as TaS_2 intercalated with *n*-octadecylamine, where a separation of nearly 60 Å was achieved between sequential Ta layers. This work was historically important in stimulating theoretical calculations of 2D superconductivity.

Most useful for studies of the 3D–2D superconducting transition have been the synthetic superlattice structures prepared by molecular beam epitaxy, because of the dimensional control that can be exercised in preparing the multilayers. Because of the abrupt interfaces and the possibility of preparing ordered sequences of superconducting monolayers, GICs provide a complementary tool for studying highly anisotropic superconducting materials. There is no known acceptor GIC that has shown evidence for superconductivity.

Critical-field studies for anisotropic superconductors have attracted considerable interest because of their similarity to the high-T_c superconducting cuprates, which are also layered compounds with anisotropic superconducting properties. For the intercalation compounds the angular dependence of the critical field is well approximated by the anisotropic Ginzburg–Landau formula (Zabel and Solin, 1992),

$$H_{c2}(\theta) = (\Phi_0/2\pi\xi_\perp^2) \times (\cos^2\theta + \epsilon^2 \sin^2\theta)^{-1/2}, \qquad (1)$$

in which $\Phi_0 = hc/2e = 2.07 \times 10^{-7}$ G cm^2 is the elementary flux quantum and θ is the angle between the magnetic field and the c axis. Here the parameter ϵ characterizes the anisotropic behavior and is given by

$$\epsilon^2 = m_\perp / m_\parallel = (H_{c2\perp} / H_{c2\parallel})^2 = (\xi_\parallel / \xi_\perp)^2, \qquad (2)$$

where ξ denotes the coherence length and m denotes the effective mass in the $\parallel$ and $\perp$

directions. We denote by $H_{c2\perp}$ the upper critical field for $\theta=0°$ whereby the diamagnetic screening currents lie in the layer planes. Similarly we denote by $H_{c2\parallel}$ the upper critical field for $\theta=90°$ whereby the diamagnetic screening currents must traverse different layer planes. These relations have been used to obtain qualitative fits to the experimental $H_{c2}(\theta)$ curves shown in Fig. 16. From these fits, values for the parameters $H_{c2\parallel}$, $H_{c2\perp}$, $\xi_{\parallel}$, and $\xi_{\perp}$ have been deduced. Specific values of these parameters are given in Table 5 for stage-1 KHg-GICs in comparison with values for pristine intercalate KHg, which is also superconducting, but shows no anisotropy. It is also of interest to note that intercalation increases the T_c value of a superconducting intercalate species (Zabel and Solin, 1992). For comparison a number of fundamental parameters characterizing the superconducting compound C_8K are listed in Table 4.

Also of interest is the temperature dependence of the critical fields $H_{c2}(T)$. Measurements of $H_{c2}(T)$ on GICs have been interpreted in terms of the anisotropic Ginzburg–Landau theory, which provides a qualitative fit to the data near T_c. Assuming an elliptical fluxoid to describe the anisotropy in the coherence length, the anisotropic Ginzburg–Landau theory yields the following expressions for the temperature dependence for the critical fields parallel and perpendicular to the c axis:

$$H_{c2\parallel}(T)=\frac{\Phi_0}{2\pi\xi_{\parallel}\,\xi_{\perp}}\left(1-\frac{T}{T_c}\right),$$
$$H_{c2\perp}(T)=\frac{\Phi_0}{2\pi\xi_{\perp}^2}\left(1-\frac{T}{T_c}\right). \qquad (3)$$

Characteristic of the Ginzburg–Landau theory is a linear T dependence of H_{c2} near T_c for both $H_{c2\perp}$ and $H_{c2\parallel}$. The anisotropy in H_{c2} comes in through the prefactor coefficients in Eq. (3). Critical-field measurements on stage-2 KHg-GICs for both $H\parallel$ c axis and $H\perp$ c axis are well approximated by a linear T dependence near T_c in accordance with Eq. (3). Fits to these data yield values for the parameters $\xi_{\parallel}$ and $\xi_{\perp}$, consistent with values obtained from fits to the angular dependence of $H_{c2}(\theta)$ discussed above.

The standard BCS model for superconductivity with only occupied graphite π bands cannot explain the observed transition temperatures because the π-band density of states is too small. On the other hand, a model with only heavy-mass intercalate-related bands cannot explain the large observed anisotropy in the superconducting properties of GICs. Therefore the model for superconductivity in GICs must include consideration of both the graphite π-band electrons and the occupied heavy-mass intercalate bands, showing that it is necessary to have at least two types of occupied bands or strong hybridization between them to produce superconductivity in GICs.

Table 5. Comparison of the superconducting parameters of stage-1 KHg-GICs and pristine KHg (Dresselhaus and Chaiken, 1987).

Parameter	Stage-1 KHg-GIC	Pristine KHg
I_c (Å)	10.22	—
T_c (K)	1.53	0.98
$H_{c2\perp}$ (Oe)	83	244
$H_{c2\parallel}$ (Oe)	850	244
$\xi_{\perp}$ (0) (Å)	1960	1135
$\xi_{\parallel}(0)$ (Å)	192	1135
$\xi_{\perp}/\xi_{\parallel}$	10.2	1

The theoretical models predict both the temperature dependence and anisotropy of H_{c2} for GICs. The models are generally consistent with the observed data. The models explain many of the detailed properties of superconducting GICs, including the absence of superconductivity in acceptors that lack occupied heavy-mass intercalate levels. The models show that the value of the superconducting transition temperature is more sensitive to changes in the π-band electronic density of states than to the corresponding changes in the heavy-mass band.

One key to gaining a detailed understanding of superconductivity has been through in-depth investigations of the tunneling characteristics in the normal and superconducting states, which in turn yield direct information on the density of states. The layered nature of many intercalation compounds makes them amenable for tunneling measurements. Such experiments have also been performed on intercalated fullerenes, thereby yielding a direct measurement of the temperature dependence of the superconducting band gap in these relatively high-T_c superconductors (see FULLERENES).

Since the critical fields for superconducting GICs are easily achieved in the laboratory, GICs provide model systems of interest for the study of anisotropic superconductors. Such studies have been of interest with regard to high-T_c superconductors for which the magnetic fields required to study the corresponding effects are difficult to achieve experimentally.

GLOSSARY

Basal Plane: The plane normal to the main symmetry axis, usually called the *c* axis.

BCS Theory: Microscopic theory of superconductivity based on the pairing of electrons that are coupled by the electron–phonon interaction.

Bi-intercalation: The intercalation of a layered binary intercalation compound with a second intercalate species to form an intercalation compound that is ordered with respect to each of the two intercalate species.

Binary Compound: An intercalation compound for which the intercalate is a single atomic or molecular species.

Chalcogen: Element from column VI of the periodic table: O, S, Se, Te.

Clays: Compounds in a class of layered aluminosilicates such as vermiculite, which intercalate water between layers and take up other metal ions by ion exchange interactions.

Commensurate: Intercalation compound in which atoms in the intercalate layer and in the host material are in registry.

Covalent Bonding: A localized bond between two atoms to which the valence electrons from each atom contribute.

Discommensuration: A modulation in the structure of two materials with different lattice constants at an interface to achieve regions where the two structures are locally in registry, but separated by boundaries called misfit dislocations where the material with the smaller lattice constant has an extra row of atoms.

Disproportionation: Formation of chemical species in the intercalate galleries with proportions of atomic constituents different from that prior to intercalation.

Electron Affinity: Energy required to take an electron from the top of the valence band (in a semiconductor) to the lowest ionization state.

Ginzburg–Landau theory: Macroscopic phenomenological theory of superconductivity.

Graphene layer: An isolated single layer of hexagonally arranged carbon atoms in a honeycomb structure such as found in graphite.

Intercalate Gallery: van der Waals gap between basic structural units of a layered host material in an intercalation compound.

Ionic Bonding: The electrostatic bonding between two atoms caused by the transfer of charge from the donor atom to the acceptor atom.

Octahedral Sites: Sites with six nearest neighbors in the cubically symmetric locations $(\pm a,0,0)$, $(0,\pm a,0)$, $(0,0,\pm a)$.

Polytypes: The ensemble of ordered arrangements possible for a given basic structural unit.

Stage: The ordered periodic superlattice arrangement of the intercalate in an intercalation compound, whereby the intercalate layers are separated by a fixed number of host layers.

Stage Index: Integer specifying number of host layers between consecutive intercalate layers.

Ternary Compound: An intercalation compound into which two distinct intercalates are introduced.

Tetrahedral Sites: Sites in the lattice with nearest neighbors at the corners of a regular tetrahedron.

Transition-Metal Ion: Metal ions containing unfilled *d* shells (where *d* electrons denote electrons with angular momentum of $2\hbar$).

van der Waals Bonding: Weak bonding between two atoms, such as might arise from π bonding between electrons, falling off rapidly with distance.

Vortex: A flow of charge or an arrangement of spins with circulation about a singular point or line.

INTRODUCTION

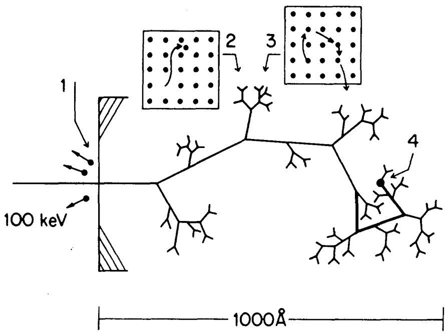
The possibility of using ion beams for materials modification was first explored nearly 50 years ago. However, not until the early 1970s, when the electronics industry began their frenetic drive toward minaturization of integrated circuits, did ion implantation become a wide-scale commercial process. It was also about 50 years ago when studies of radiation damage in metals and ceramics were initiated. These early investigations were part of the research and development program on nuclear weapons, but they were soon expanded to include materials problems in fission and fusion reactors. These two fields of ion implantation and radiation damage have now become integrated in the far more comprehensive field of ion-beam modifications of materials. No longer is ion-beam processing of materials restricted to the implantation of electrically active impurities into Si for semiconductor applications, but rather ion beams are being employed as a basic processing step in the fabrication of many advanced materials. For example, ion implantation is being used to provide corrosion and oxidation resistance in metals; to create nonequilibrium surface phases with special properties; to improve the quality, epitaxy, and adhesion of vapor-deposited thin films; and to clean or pattern surfaces. One of the most celebrated recent applications of ion-beam modifications of materials has derived from the field of tribology, where it was shown that the implantation of nitrogen into titanium hip joint replacements can extend the wear resistance of these prostheses beyond their required service lifetime. Indeed, the field of ion–solid interactions has moved from the workbench of nuclear physicists to the design tables of materials scientists.

Several features of ion-beam processing underlie its rapid growth in recent years:

digital Encyclopedia of Applied Physics
Copyright © WILEY-VCH Verlag GmbH & Co KGaA. All rights reserved.

1. The concentration depth profile of an implanted species can be tailored to the materials requirements, whereas those obtained by the more conventional means of in-diffusing surface films are dictated by the diffusion equation.
2. Any ion species can be implanted into the solid. Because ion implantation is a high-energy process, thermodynamic and kinetic constraints are minimized. Consequently, nonequilibrium phases can be produced.
3. Ion implantation is intrinsically a low-temperature processing step, and so high-temperature anneals, which can cause interdiffusion in complex devices or phase transformations of metastable systems, can be avoided.
4. Ion irradiation can be employed to create structural defects in the surface region. Although defects are generally undesirable for implantation of dopants in semiconductors, they often have beneficial effects for other applications. Defects serve as nucleation sites for epitaxial growth, they modify the index of refraction for waveguide applications, and in some metals they lead to amorphization and concomitant improvement in tribology properties.
5. Ion implantation is conducive to lateral patterning using masks or focused ion beams. With its natural control of ion depth penetration, three-dimensional patterning becomes possible with submicron resolution.

Although ion implantation is often associated with the simple addition of foreign atoms into a substrate, doping is only one of many changes that occur in the material. As ions slow down in a target, they initiate cascades of energetic collisions between lattice atoms, as illustrated in Fig. 1. These collisions lead to the ejection of atoms from the surface (sputtering), the creation of Frenkel pairs (vacancies and interstitial atoms) in the interior of the crystal, and the relocation of many target atoms from one lattice site to another. These various processes, and their relative frequencies of occurrence, are indicated in Fig. 1. In this article, an elementary discussion of the physical principles underlying ion-beam modifications of materials is presented, and several examples are cited to illustrate the versatility of this new technology.



Summary of Events

Process	Relative Occurrence
1. Sputtered Atoms	~3
2. Frenkel Pairs	~500
3. Relocated Atoms	~5000
4. Implanted Atoms	1

FIG. 1. Schematic view of the different processes that occur and their frequency as an ion penetrates a solid and comes to rest. The values are typical for an ion implantation energy of approximately 100 keV.

1. DEPTH DISTRIBUTIONS OF IMPLANTED IONS

One of the primary advantages of ion-beam processing of materials is that the depth distribution of the implanted ions can be controlled with high precision, and with the use of a mask or a focused ion beam, lateral patterning of the substrate is also possible. It is now feasible to predict these implantation distributions accurately, greatly facilitating the design of new structures. In this section, the theory of the stopping of ions in materials and the methods for calculating implantation profiles are presented. In the next section, defect production during ion implantation is discussed, and several illustrative examples of the use of ion implantation in materials are provided.

1.1 Electronic Stopping Power

As energetic ions penetrate a solid, they lose energy by colliding with atomic nuclei and electrons. Theories of electronic stopping in the energy regime most relevant to ion-beam modifications of materials were developed by Firsov (1959) and Lindhard *et al.* (1963). The Firsov model, which is the easier to visualize, assumes that the ion velocity is slow relative to the electron orbital velocities, so that electrons behave "adiabatically," i.e., they are able fully to readjust their electronic states relative to the projectile position. Consequently, electrons are free to exchange between the projectile and target atom during collisions. Since the ion must perform work in accelerating target electrons up to its own velocity during an electron exchange, but without recapturing that energy when electrons leave, the ion loses energy. The energy loss is thus determined by calculating the electron currents flowing between the moving ion and the substrate atoms. Within the Thomas–Fermi model of an atom, the stopping power is given by the expression

$$\begin{aligned}\frac{dE}{dx}&=-NS_e(E)\\&=-N\{(0.336\ \mathrm{eV}^{1/2}\ \text{Å}^2)[Z_1+Z_2]\\&\quad\times[E/A_1]^{1/2}\},\end{aligned}\tag{1}$$

where $S_e(E)$ is the so-called electronic stopping cross section and has units of energy-area, Z_1 and Z_2 are the atomic numbers of the implanted ion and target atoms, respectively, A_1 is the atomic mass of the ion, N is the atomic density, E is the projectile energy, and x is the distance along the ion trajectory. Equation (1) shows that the electronic stopping power increases with increasing ion velocity and atomic number; the theory of Lindhard and Scharff yields similar results. It is interesting to note that because the stopping power depends linearly on the velocity of the ion, enormous electronic stopping powers can be obtained with heavy, GeV ions—energy losses exceeding 5 keV/Å. This incredibly high power density has recently been exploited for materials modification applications. In high-temperature superconductors, for example, it was shown that heavy GeV particles produce long, highly damaged tracks, over 20 μm in length and approximately 40 Å in diameter, and that these tracks are very effective in pinning magnetic flux lines. Thus, GeV particle irradiation can be employed to enhance the critical current densities of high-temperature superconductors (Roas *et al.* 1990). GeV irradiations are also being used to produce high-precision filters. For this application, long, porous tubes of uniform diameter are created by selective etching of the damage tracks (Spohr, 1990).

1.2 Nuclear Stopping Power

The loss of projectile energy due to the nuclear collisions is described by the expression

$$\frac{dE}{dx}=-NS_n(E)=-N\int_0^{T_{\max}}T\frac{d\sigma(E,T)}{dT}\,dT.\tag{2}$$

The nuclear stopping cross section $S_n(E)$ is defined by the right side of Eq. (2) (it also has units of energy-area), and $d\sigma(E,T)$ is the differential cross section for an ion of energy E to transfer an energy between T and $T+dT$ to a target atom. The cross section is governed by the appropriate interatomic potential, which for ion implantation is a screened Coulomb potential. Historically, Thomas–Fermi potentials have been employed for this purpose, although recently the more accurate Universal potential (Ziegler *et al.* 1985) has been preferred. The maximum energy transfer in Eq. (2), $T_{\max}$, occurs in a head-on collision; it is given by

$$T_{\max}=4\frac{A_1A_2}{(A_1+A_2)^2}E.\tag{3}$$

Equation (3) shows that the maximum energy transfer is largest when the ion and substrate atoms have similar masses. For this reason, energetic electrons, even those with energies in excess of 1 MeV, cause little structural damage in materials. Lindhard and co-workers (1963) showed that by employing reduced units, the nuclear stopping of all ion–solid combinations could be described by a single universal stopping function,

$$s_n(\epsilon)=-d\epsilon/d\rho,\tag{4}$$

where the reduced energy ϵ is

$$\epsilon=\left\{\frac{A_2E}{A_1+A_2}\right\}\left\{\frac{Z_1Z_2e^2}{a}\right\}^{-1}\tag{4a}$$

and the reduced length ρ is

$$\rho=N4\pi a^2A_1A_2x/(A_1+A_2)^2\ .\tag{4b}$$

The screening length a is

$$a=0.8853a_0/(Z_1^{2/3}+Z_2^{2/3})^{1/3}\ .\tag{4c}$$

where a_0 is the Bohr radius. The stopping function is shown in Fig. 2. Stopping powers for all ion–solid combinations can be determined from this one curve using the expression

$$\frac{dE}{dx} = -NS_n(E) = -N\left\{\frac{\pi a^2 T_m}{\epsilon}\right\} s_n(\epsilon). \tag{5}$$

Also shown in reduced units in Fig. 2 is the electronic stopping power. [$s_e(\epsilon)$ is not strictly a universal function, but it does not vary strongly with atomic number.] It is noteworthy that the total stopping power $s_{\text{tot}}(\epsilon) = s_n(\epsilon) + s_e(\epsilon)$ is rather constant over the range $0.2 < \epsilon < 2$, which is the range of energies of most implantations. The maximum nuclear stopping occurs at $\epsilon = 0.44$, and the electronic stopping becomes greater than the nuclear stopping at $\epsilon = 4$. This scaling with reduced energy units thus provides a natural way to compare implantations for all ion–target combinations. Table 1 lists the implantation energy at which $\epsilon = 1$ for various ion–solid combinations.

1.3 Implantation Range Distribution

1.3.1 Transport Theory. The distance that an ion travels before coming to rest within a solid, i.e., the path length, is given by the expression

$$L(E) = \int_E^0 \frac{dE}{dE/dx} = \frac{1}{N}\int_E^0 \frac{dE}{S_n(E) + S_e(E)}. \tag{6}$$

The path length, however, is usually of less interest for ion implantation than is the ion range, i.e., the distance between an ion's point of entry at the surface and its final location in the solid. Since the ranges of ions vary because of their different points of entry in the solid, lattice vibrations, and the discrete nature of collisions, a distribution of ranges is generated by an implantation, even for a single ion type, energy, and angle of incidence. The range distribution is comprised of longitudinal (normal to the surface) and transverse (parallel to the surface) components. Although the longitudinal component, or projected range R_P, and its variance are generally of primary concern for ion implantation, the transverse straggling ($\langle R_T^2 \rangle / \langle R_P^2 \rangle$) is of interest when implantations are performed through a mask, since it determines the minimum line width in circuit patterns (see, e.g., Tamura, 1991).

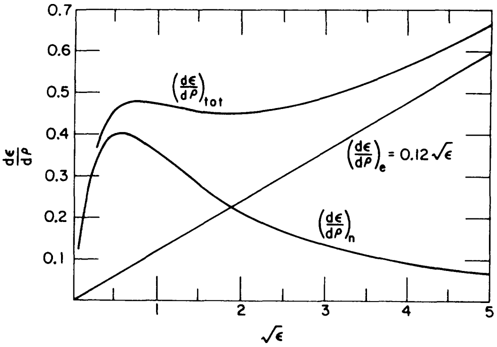


FIG. 2. Energy dependence of the nuclear and electronic stopping powers in reduced units. The nuclear curve is a universal function, but the electronic stopping depends somewhat on the ion–target combination. At low energies, most energy is dissipated through collisions with substrate atoms, but at high energies, most is lost by electronic excitation. (After Schiøtt, 1970.)

The range distributions of particles can be determined by solving the appropriate Boltzmann transport equation. Although the formalism is straightforward, solving the integro-differential equations is unwieldy. A more tractable procedure has been to calculate the moments of the distribution and then to construct the range distribution from an expansion of the various moments. The Edgeworth expansion has been found useful for this purpose (see Sigmund, 1969; Winterbon, 1975). The first two moments of the Edgeworth expansion, the mean range and its variance, determine a Gaussian distribution, and they often provide sufficient accuracy. The third moment becomes important for low-energy implantations since these distribu-

Table 1. Projectile energies (in keV) for which $\epsilon = 1$.

tions are skewed toward the surface. A convenient expression for the mean range is (Schiøtt, 1970)

$$R_P=C_1(\mu)A_2\,\frac{(Z_1^{2/3}+Z_2^{2/3})^{1/2}}{Z_1Z_2}\,E\mu\text{g/cm}^2\ \text{keV}, \tag{7}$$

where $\mu=A_2/A_1$ and $C_1(\mu)\approx 0.62+0.171\log\mu$. The rule of thumb (Davies, 1992)

$$\langle R_P^2\rangle^{1/2}/\langle R_P\rangle=0.35[2(A_1A_2)^{1/2}/(A_1+A_2)] \tag{8}$$

can be used for the variance. Figure 3 compares the range distributions generated from a Gaussian distribution, using Eqs. (7) and (8), with those determined more accurately by computer simulation, a method now described.

1.3.2 Computer Simulation. With the vast improvements in personal computers in recent years and the development of efficient codes, simulation has become the primary means of calculating range distributions. These codes also yield the depth distributions of defects and electronic excitations that are produced by the ions. The procedure employed by simulation programs is to follow the path of an implanted ion by calculating the scattering integrals and electronic losses of the ion as it collides with target atoms, one by one. Distributions are generated by compiling the histories of many trajectories, with each having a different point of entry in the target. The trajectories of the recoil atoms can also be obtained in a similar manner, although at much greater computer overhead due to their greater number. Only marginal improvement in the accuracy of the implantation profile is obtained by this procedure, but for calculations of sputtering, defect production, and ion-beam mixing (see below), the inclusion of recoil atoms is necessary. The most widely used simulation code, TRIM, was developed by Biersack and Haggmark (1980). It is distinguished by an ingenious scheme to reduce the computational effort in calculating the scattering integral. Additional computer economy is achieved in TRIM by the assumption that the target material is amorphous. This reduces the lengthy process of locating the ion's next scattering partner in a lattice to a simple application of a random number generator. Because of this inherent randomness, TRIM is a Monte Carlo simulation and is most useful for providing statistical averages. Accurate concentration distributions can presently be obtained running TRIM on a personal computer in under 1 h (see Zeigler *et al.*, 1985, for details). For some applications, the crystalline structure of the target has a large influence on the ion trajectories. In these cases, a lattice must be included in the simulation model, as in the code MARLOWE (Robinson and Torrens, 1974). Since these codes must search the lattice for the successive collision partners of the ion and recoil atoms, they are accordingly slower than TRIM.

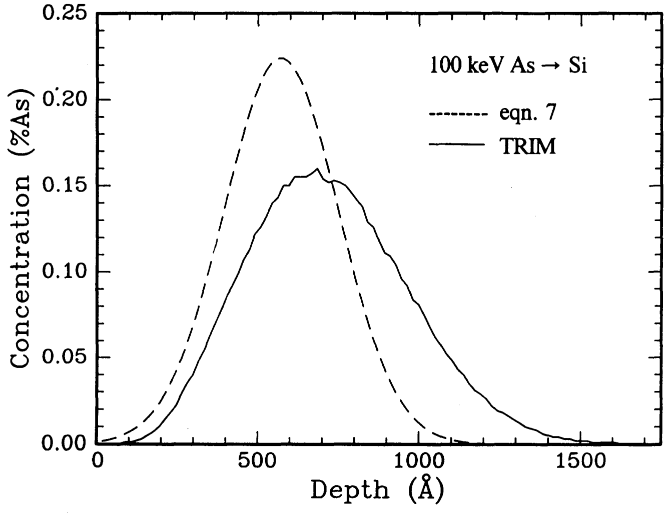

FIG. 3. Range distribution for the implantation of Si with 100-keV As calculated by TRIM and by Eqs. (7) and (8).

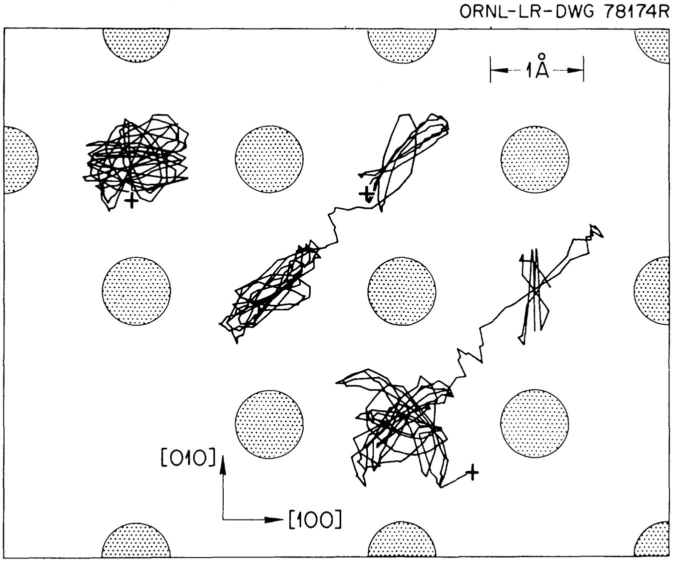

FIG. 4. Computer simulations showing the oscillatory motion of channeled ions in the (100) plane perpendicular to the ⟨001⟩ channeling direction. Radius of shaded circles is the distance of closest approach. (After Robinson and Oen, 1963.)

1.4 Channeling

Years ago, Stark (1912) predicted that the crystal lattice should influence the trajectory of ions in a crystalline solid, and by the early 1960s several experimenters began noticing long tails in their ion range distributions. But it was not until 1963 that the phenomenon of "channeling" was clearly elucidated by Robinson and Oen (1963), using computer simulation. In their simulations, which employed a lattice model, Robinson and Oen observed that some Cu projectiles had extremely long trajectories in a Cu lattice, particularly when the initial ion velocity was aligned with a major crystal axis. By following these special trajectories, they revealed that ions could travel through the relatively open spaces of a lattice as a result of a steering effect of the atomic rows. Figure 4 shows the transverse motion of a 1-keV Cu ion as it channels in a ⟨100⟩ direction of Cu. As the ion nears an atomic row, the repulsive interatomic potential nudges the ion back toward the center of the channel. The ion thus oscillates in two dimensions as it penetrates into the solid. Experimental evidence for channeling is shown in Fig. 5 (Piercy *et al.*, 1963), where the ranges of 40-keV Kr^+ in single-crystalline Al are shown for different incident ion directions. (Actual range distributions are the slopes of the curves in Fig. 5 as a function of depth.) The range in amorphous Al_2O_3 is shown for comparison. In the absence of channeling, the ranges of 40-keV Kr in Al and Al_2O_3 should be nearly the same. In many cases, the beam and substrate need only be aligned to within 3°–10° for channeling to occur, so that some fraction of the implanted ions can scatter into a channeling direction, independent of the initial orientation. This propensity for channeling poses serious problems for ion implantation applications where long tails in the range distribution are undesirable, such as shallow junction devices. Accordingly, much effort has been expended in finding crystallographic directions in Si, and other semiconductors, where channeling effects are minimized.

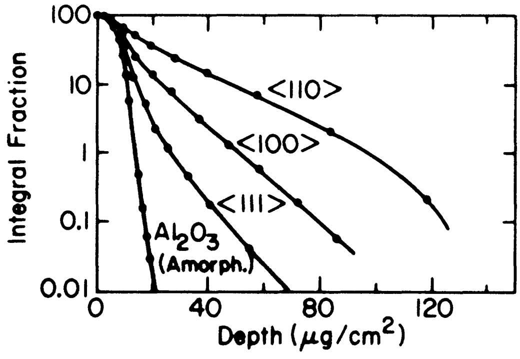

FIG. 5. Measurements of the range of 40-keV Kr in Al when the implantation beam is aligned with different crystallographic directions. Here the number of ions implanted deeper than a given depth is shown. For comparison, the range in amorphous Al_2O_3 is shown (after Piercy *et al.*, 1963).

2. IMPLANTATION DAMAGE

2.1 Displacement Processes

If a target atom recoils with an energy greater than the displacement energy E_d, it leaves its lattice site and creates a vacancy. The recoil atom may then fall into an interstitial site, or, if its energy is sufficiently high, it may displace additional atoms before coming to rest. Displacement energies in metals and semiconductors range from 5 to 40 eV (see Table 2). These values of E_d are surprisingly low in metals and derive from an efficient means of transporting energy and mass in a crystalline lattice by linear replacement collision sequences. Vineyard and co-workers (Gibson *et al.*, 1960) revealed, using molecular-dynamics computer simulations, that defects are created by series of collisions whereby one atom collides with its neighbor and replaces it in a linear sequence, as shown in Fig. 6.

2.2 Cascade Damage

High-energy particles can produce recoils with energies that are much greater than the minimum energy required for displacements. In this case, both the primary and the recoil atom leave the lattice site and produce additional displacements at other sites. If the energies of the secondary recoil atoms are sufficiently high, they too continue the multiplication process of displacing atoms, thus creating a displacement cascade. Since the cross section for atomic collisions increases rapidly with decreasing energy, because of the screened Coulomb interaction between atoms, a projectile will produce recoils closer and closer together as it slows down. The energies of the recoil atoms are usually low; therefore they too do not travel far before undergoing additional collisions in the localized vicinity of their creation (see Fig. 1). Consequently, defects produced in a displacement cascade are spatially correlated and often form defect clusters. This has been demonstrated experimentally using field ion microscopy, as shown in Fig. 7. In some semiconductor systems and intermetallic compounds, the high concentration of defects can lead to small amorphous zones.

Table 2. Threshold displacement energies for several elements or compounds.

Material	Energy (eV)
Al	16
Si	13
Cu	21
Ge	14
GaAs	10
Ni	23
Mo	33
Au	35

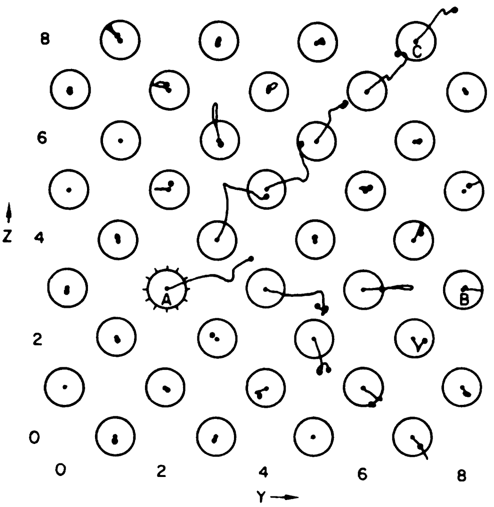

FIG. 6. Computer simulations illustrating replacement collision sequences in Cu (after Gibson *et al.*, 1960).

The number of Frenkel pairs that are produced in a cascade, $\nu_{FP}(T)$, can be estimated from the "modified Kinchin-Pease" expression (1955),

$$\nu_{FP}(T) = 0.8E_D(T)/2E_d, \tag{9}$$

where $E_D(T)$, the damage energy, is the total cascade energy T less the energy lost to electronic excitations. [The original Kinchin-Pease expression was $\nu_{FP}(T) = T/2E_d$.] Computer simulations, such as TRIM, are convenient for obtaining both the depth distribution and total number of defects produced by ion implantation.

2.3 Thermal Spikes

Although some of the kinetic energy of the implanted ion is lost to electronic excitations and some is stored as potential energy in the Frenkel pairs, most of the ion energy is dissipated in the lattice as heat. For 100-keV As

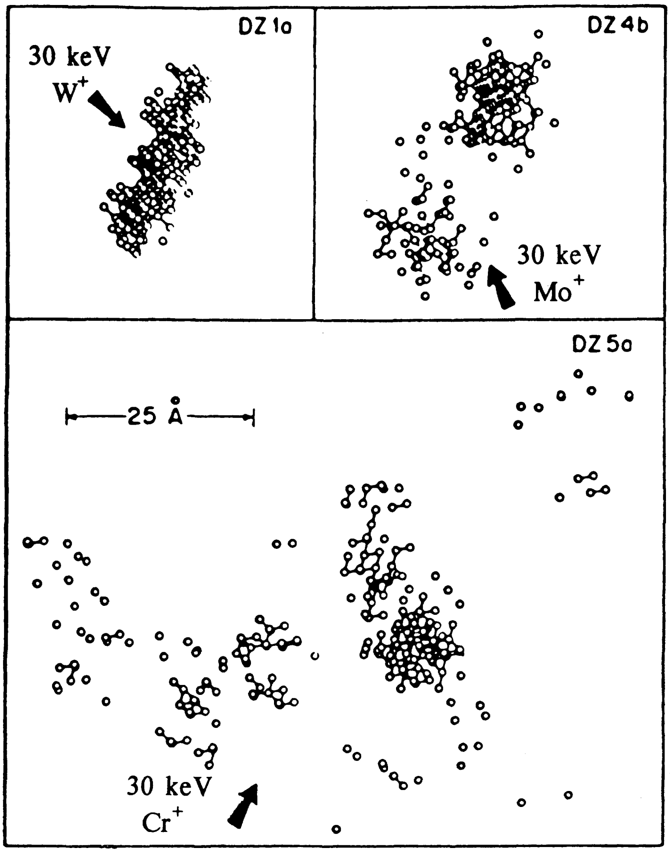

FIG. 7. Distribution of vacancies produced in displacement cascades of W. As the projectile mass increases, the density of defects also increases because of the increasing value of $S_n(E)$. Arrows indicate the initial directions of the incoming ions. (After Wei *et al.*, 1981.)

implantation of Ge, for example, 40 keV of energy is lost to electronic excitation, ≈2 keV is stored in defect energy, and the remainder, 58 keV, is converted to heat. The localization of such a large amount of energy in the small volume of a cascade can result in energy densities of several eV/atom. A long-standing question in the field of atomic collisions in solids has been whether this large localization of energy persists sufficiently long for thermal processes to evolve. The most vivid evidence for thermal spikes has derived from molecular-dynamics computer simulations. Figure 8, for example, shows the collision dynamics of a 10-keV Au ion impacting a Au surface (Ghaly and Averback, 1993). Clearly illustrated in Fig. 8(a), which shows a snapshot of the atoms in the vicinity of a cascade early in the event, are a shock wave emanating from the cascade center, replacement collision sequences, and a highly disordered cascade core. Shown in Fig. 8(b), which is a snapshot of the atoms some time later, is a well-defined local melt zone in the near surface; the melt is found to persist for several picoseconds. In materials with higher melting temperatures and smaller atomic numbers, the effects of thermal spikes are smaller.

2.4 Applications of Ion Implantation

The number of applications of ion implantation has grown enormously in the past decade, and they cannot be categorized here. A few examples, however, serve to illustrate the diversity of materials problems for which ion implantation has been successful.

2.4.1 Doping of Semiconductor Devices. The use of implantation for the doping of semiconductors has now been an industrial process for over 20 years, and a number of different devices include implantation as a processing step (see e.g., Ryssel and Ruge, 1986). As outlined above, implantation of semiconductors causes damage as well as increasing the dopant concentration, and damage generally degrades the electrical proper-

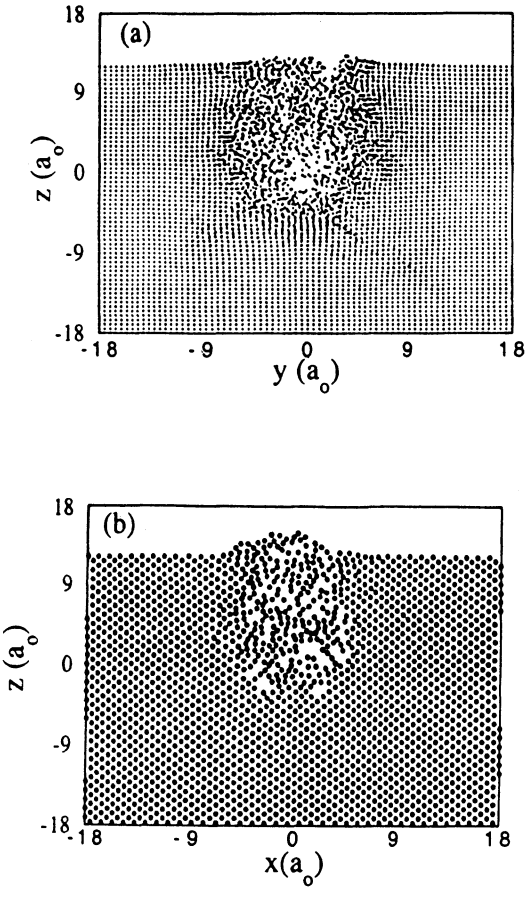

FIG. 8. Snapshots of atomic positions at two instants of time, 1.0 and 9.8 ps after a 10-keV Au atom impinges on a Au substrate. For clarity, only atoms in a cross-sectional slab containing four (100) lattice planes are shown. (a) A shock wave propagating from the cascade core, trails of replacement sequences, and atomic disorder are observed early in the event, while (b) local melting is observed sometime later. (After Ghaly and Averback, 1993.)

ties of the device. Moreover, the dopants do not always lie on substitutional sites in the lattice when initially implanted, and therefore they may not be electrically active. Consequently, annealing treatments are necessary to remove the damage and to activate the impurities. In Si, the damage can consist of defect clusters and dense dislocation networks. This type of damage is very resistant to annealing and typically requires annealing temperatures of 950 °C. Such high-temperature anneals are unpractical for most devices because of problems of interdiffusion. In many cases, however, the irradiation renders the implanted region amorphous. This can be advantageous because crystallization occurs at a relatively low annealing temperature, less than 650 °C in Si. The crystallization begins at the amorphous–crystal interface located at the end of the implanted ion range, and it advances toward the surface by a process called solid-phase epitaxy (SPE). SPE leaves very few defects in the reformed crystal, while dopants find lattice sites and become activated. Rates of regrowth on various cystallographic planes in Si are illustrated in Fig. 9.

2.4.2 Buried Layers. One of the advantages of ion implantation over diffusion doping is that the peak impurity concentration can be located beneath the surface. An interesting application of this capability is the production of planar waveguides in $KNbO_3$ and $LiNbO_3$ using He implantation (Townsend, 1987). Because He ions are very light, their stopping in a material occurs primarily via electronic excitation until they reach the end of their range, where the nuclear stopping becomes larger (see Fig. 2). Consequently, the damage produced by He implantation is mostly

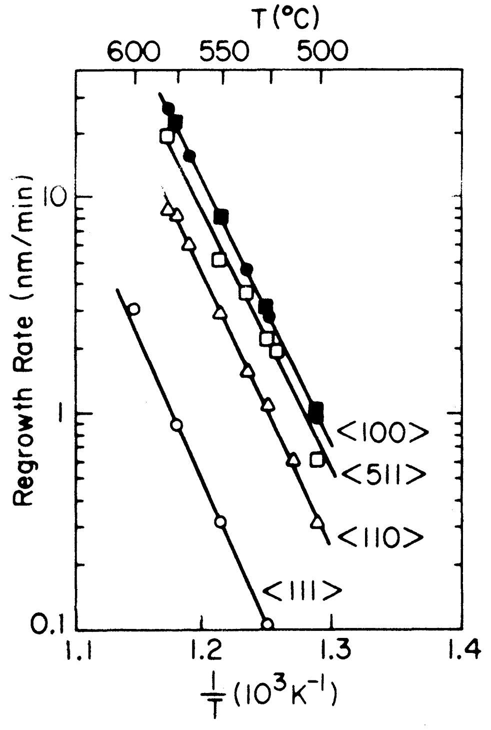

FIG. 9. The SPE regrowth rate at various amorphous-crystalline Si interfaces as a function of temperature (after Csepregi *et al.*, 1978).

confined to a narrow layer at a depth about equal to the projected range. This subsurface damage layer in $KNbO_3$ and $LiNbO_3$, in fact, becomes amorphous after sufficiently prolonged irradiation. Since the densities of these amorphous glasses are less than those of their corresponding crystalline phases, their indices of refraction are smaller. The buried amorphous layers thus create optical barriers or waveguides, with the thickness of the guiding region dictated by the energy of the He ion.

Buried layers are of interest for a variety of other applications as well. Co, for example, is implanted into Si to form a buried silicide layer, $CoSi_2$, a process called mesoepitaxy. These buried conductive layers serve as permeable base regions in transistor devices and interconnects for high-speed integrated circuits (Mantl, 1992). Oxygen is also used for implantation in Si to form buried insulator layers of SiO_2. These layers isolate the device from the silicon substrate. Consequently, they are useful for radiation hardening since the insulating layer prevents electron-hole pairs that are created by ionizing radiation anywhere in the thick Si substrate from entering the thin, active, device region at the substrate surface.

2.4.3 Tribological Applications. Materials selected for particular applications on account of such properties as strength, density, etc., often do not possess similarly attractive surface properties, such as oxidation resistance, wear resistance, or toughness. Ion implantation can be used to modify these surface properties without affecting the bulk material. Moreover, implantation has the advantages over surface plating and in-diffusion in that any material can be treated, any ion can be implanted, and discrete interfaces between the surface alloy and bulk material, which are susceptible to spalling, are avoided. One success of this method is illustrated in Fig. 10; it shows the improvement in sliding friction and wear resistance in 304 stainless steel resulting from implantation with Ti ions. The improved properties were attributed to the formation of a thin amorphous layer at the surface of the steel. Nitrogen implantation has been found effective for these purposes in a number of other metals, and because of its lower cost to implant, it is more commonly used than Ti (Rehn *et al.*, 1987).

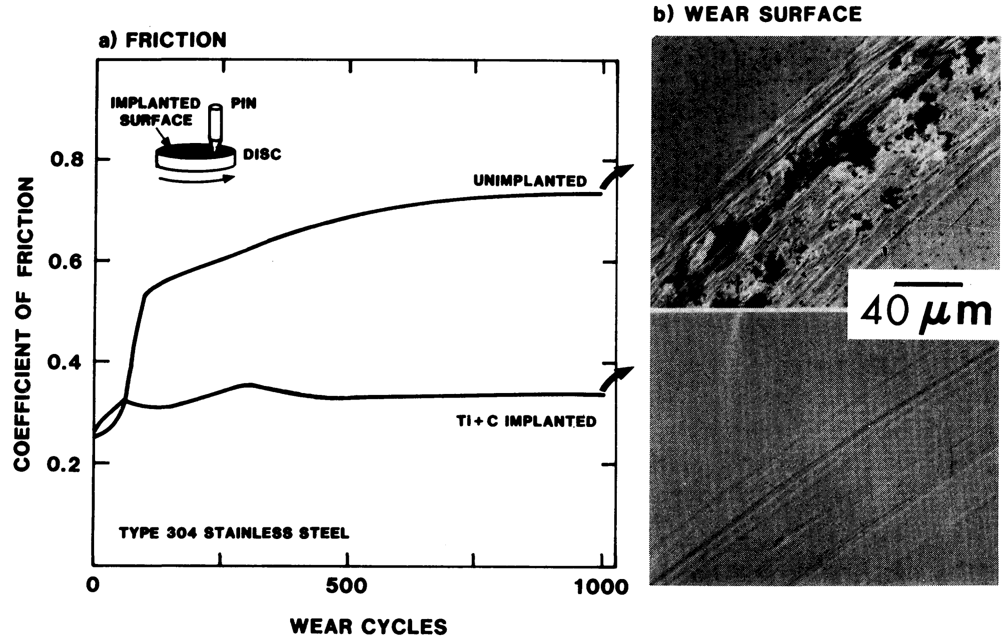

FIG. 10. Improvement of wear resistance in 304 stainless steel due to implantation with Ti and C. Doses of 2×10^{17} cm^{-2} 90–180-keV Ti and 2×10^{17} cm^{-2} 50-keV C were employed. (a) Coefficient of friction versus time (wear cycles); (b) scanning electron micrograph of the wear tracks. (After Follstaedt *et al.*, 1989.)

3. ION-BEAM MIXING

The large number of ions set into motion in a displacement cascade gives rise to a "mixing" of atoms in the solid. Three distinct mechanisms of mixing can be distinguished: recoil implantation, cascade mixing, and thermal spike mixing; these are schematically illustrated in Fig. 11.

3.1 Mechanisms of Ion-Beam Mixing

3.1.1 Recoil Implantation. The first target atom impacted by an implanted ion necessarily recoils in the forward direction, deeper into the solid. This process of recoil implantation can be important during ion implantation. For example, oxygen can be driven from a thin surface layer deeper into a target and degrade electrical properties of thin devices. Or, the stoichiometry of compound targets can be altered by preferential recoil implantation of one of the components. This is most significant in targets like InP or $LiNbO_3$ where the atomic numbers (and collision cross sections) of the components are substantially different. For a thin surface layer, the distribution of recoil implantation atoms can be approximated by the expression

$$S(x)=N^{2/3}\int dT\,\frac{d\sigma(E,T)}{dT}\,F(x-x',\theta), \qquad (10)$$

where $F(x-x',\theta)$, the range distribution of a recoil atom, can be obtained from Eq. (7) with a correction for scattering angle θ relative to the surface normal.

3.1.2 Cascade Mixing. After several collisions, the momenta of the implanted ion and recoil atoms become randomized so that the relocation of most displaced atoms is a stochastic process. Calculations of the mixing due to the random relocation of atoms is far more difficult than those for recoil mixing as they require solving the Boltzmann transport equation (Sigmund and Gras-Marti, 1981). Accurate results, however, can be obtained more simply using computer simulations based on TRIM. The parameter Q is often employed for quantifying ion-beam mixing; it is defined as

$$Q=\langle\Delta x^2\rangle/2\phi F_D, \qquad (11)$$

where $\langle\Delta x^2\rangle$ is the variance of the mixing profile, ϕ is the ion fluence, and F_D is the deposited damage energy per unit length normal to the surface. The parameter Q is a measure of mixing per unit damage energy per unit volume and thus is normalized for all ion–solid combinations. Calculated values for the mixing parameter are in the range $Q=1$–7 Å^5/eV. Table 3 shows measured values of Q. It is observed that the mixing parameter is much larger than the values calculated by cascade

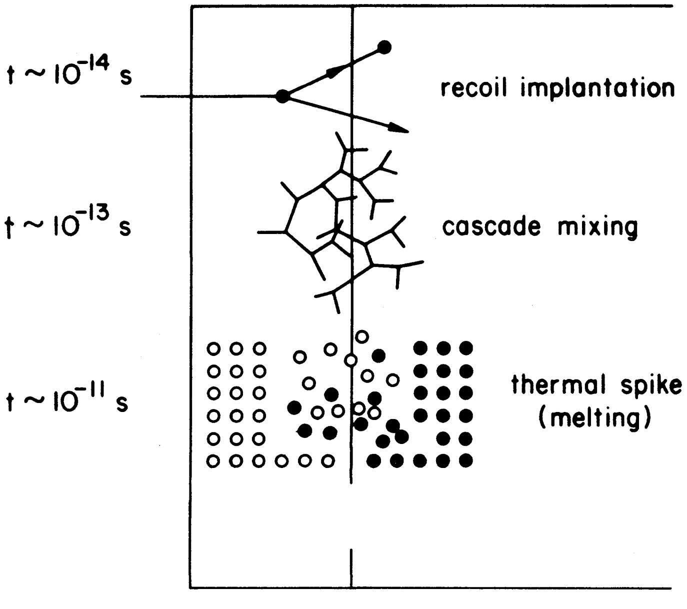

FIG. 11. Schematic illustration of the three contributions to ion-beam mixing: recoil implantation, cascade mixing, and thermal spike mixing.

Table 3. Mixing parameter Q in several metals.

Metal	Q (Å^5/eV)
Al	20
Ti	4
Ni	7
Cu	25
Ag	75
Pd	12
Au	120
Pt	19

mixing or recoil implantation for many metals and semiconductors.

3.1.3 Thermal-Spike Mixing. The possibility of local melting in a cascade provides another contribution to atomic mixing. Calculations of thermal-spike mixing have been performed using the equation

$$\langle \Delta x^2 \rangle = 2 \int \frac{d\sigma(E,T)}{dT}\, dT \int NV(T,t)D(T,t)\, dt, \tag{12}$$

where $V(T,t)$ and $D(T,t)$ are the instantaneous volume and diffusion coefficient of the hot cascade. (The outer integral sums over all the possible recoils that an ion makes with target atoms.) Since the diffusion coefficient of liquids is much larger than that of solids, most of the thermal-spike mixing takes place in the melt. Uncertainties in the cooling rates and appropriate diffusion coefficients make Eq. (12) difficult to evaluate accurately, but it nevertheless shows that mixing in the thermal spike is large in metals that have low melting temperatures and high energy densities (high atomic number). Values of the mixing parameter listed in Table 3 are consistent with these predictions. Johnson *et al.* (1985) have shown that because the characteristic energy of thermal-spike mixing is some tenths of electron volts, in contrast to the much higher energies of the implanted ion and recoil and cascade mixing, thermodynamics can sometimes play a role. This is a fundamentally new concept in the theory of ion–solid interactions, and it has helped significantly in understanding many details of ion-beam modifications of materials.

Calculations of the contributions to ion-beam mixing from thermal spikes cannot be obtained from simulation programs like TRIM, since these codes assume independent, two-body collisions and low densities of moving atoms. For thermal phenomena, however, the collective motion of atoms is vital. Recent studies of ion-beam mixing using molecular-dynamics computer simulations are beginning to clarify this process in metals (see Averback *et al.*, 1991), but the role of thermal spikes in ion-beam mixing in semiconductors and insulators is still poorly understood.

3.1.4 Phase Formation During Ion-Beam Mixing. The large number of atoms relocated during ion irradiation makes it possible to fabricate surface alloys and compounds far more efficiently than by direct ion implantation. The production of a 100-Å contact layer of Ni_2Si by direct implantation of Ni into Si requires an ion dose of over 2×10^{16} cm^{-2}. In comparison, a dose of only $\approx 1\times10^{15}$ cm^{-2} Xe ions is needed to mix a Ni film with a Si layer to produce a film of similar thickness. This technique has been applied to produce Ohmic contacts on semiconductor devices as well as surface alloys on metals for tribology applications.

An example of the use of ion-beam mixing to create metastable phases with specialized properties is illustrated by the mixing of a Cu/Bi diffusion couple. Cu and Bi are virtually immiscible in the solid state, so that CuBi alloys cannot be produced by conventional methods. Irradiation at low temperature, however, causes their intermixing and the formation of an amorphous phase as shown by the diffraction patterns in Fig. 12. The amorphous Cu-Bi phase has the interesting property of being superconducting at low temperatures, even though neither Cu nor Bi is itself a superconductor. On warming, however, the constituent metals precipitate and the superconductivity is lost.

3.2 Ion-Beam–Assisted Deposition

A variation of the ion-beam mixing process of growing technological significance is ion-beam–assisted deposition (IBAD), for which a low-energy ion beam is focused onto the specimen surface during the growth of a thin film. IBAD is employed for two distinct purposes:

1. creating a mixed interfacial layer between the substrate and the thin film to improve film adhesion;
2. improving the quality, stoichiometry, or

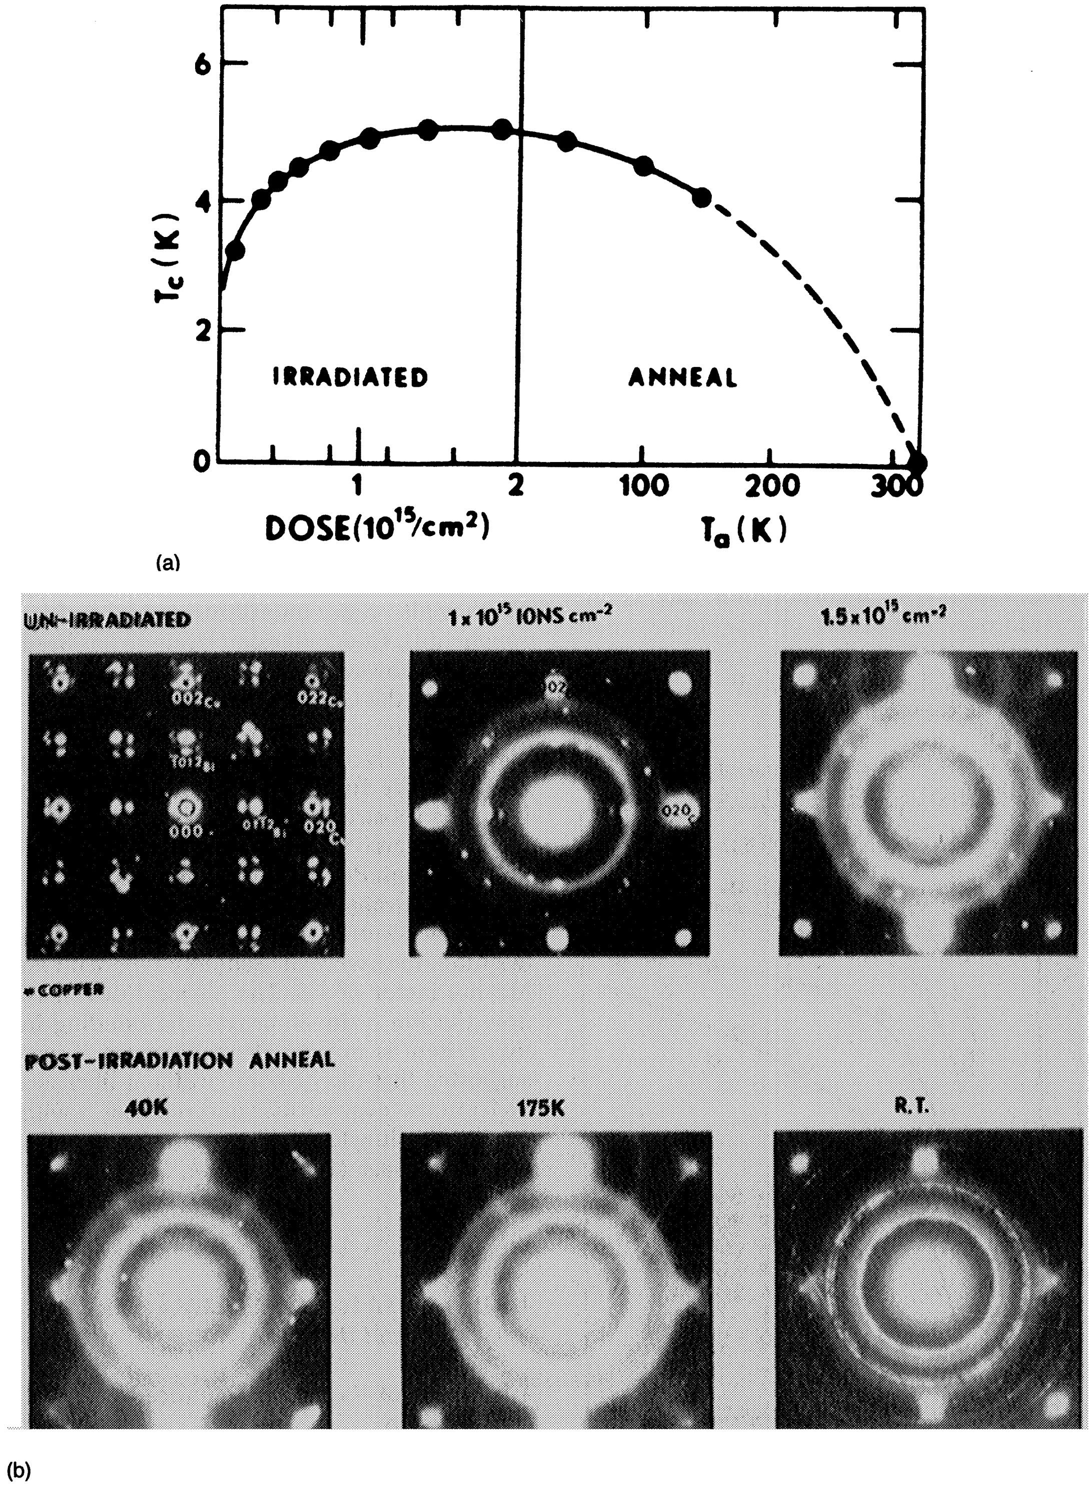

FIG. 12. Ion-beam mixing of Cu/Bi produces an amorphous alloy that is superconducting. (a) The variation of the critical temperature with 380-keV Kr fluence and annealing temperature; (b) electron diffraction patterns illustrating the amorphization during irradiation and subsequent crystallization during annealing. (After Averback *et al.*, 1985.)

epitaxy of the growing thin film.

A variation of the second process is direct ion-beam deposition (IBD), for which a high-intensity, low-energy ion-beam source is employed but without simultaneous vapor deposition. Two examples illustrate these purposes.

3.2.1 Dopant Incorporation. The synthesis of devices by thin-film deposition, e.g., molecular-beam epitaxy (MBE), is often limited by the difficulty of incorporating electrically active impurities in the growing film. As, Sb, In, and Ga are difficult to incorporate into Si, while Zn, Cd, Mn, S, and Te are difficult to incorporate into GaAs. The use of accelerated dopant beams during growth is proving to be a practical solution to this problem (Greene *et al.*, 1989). Shown in Fig. 13 is the incorporation probability of In in a growing Si film, plotted as a function of inverse temperature, for various energies of the In beam (Hasan *et al.*, 1989). The incorporation rate is increased over five orders of magnitude when the energy of the In beam is increased from thermal energies to over 50 eV. In addition, the incorporation was near unity for beam energies over 200 eV for growth temperatures up to 850 °C. These investigations also showed that the In atoms were located on substitutional sites and that they were electrically active for concentrations as high as 2×10^{18} cm^{-3}, which is well above the solubility limit. No evidence of radiation damage was observed in these experiments, and carrier (hole) mobilities were higher than those obtained using implantation and high-temperature annealing (Hasan *et al.*, 1989).

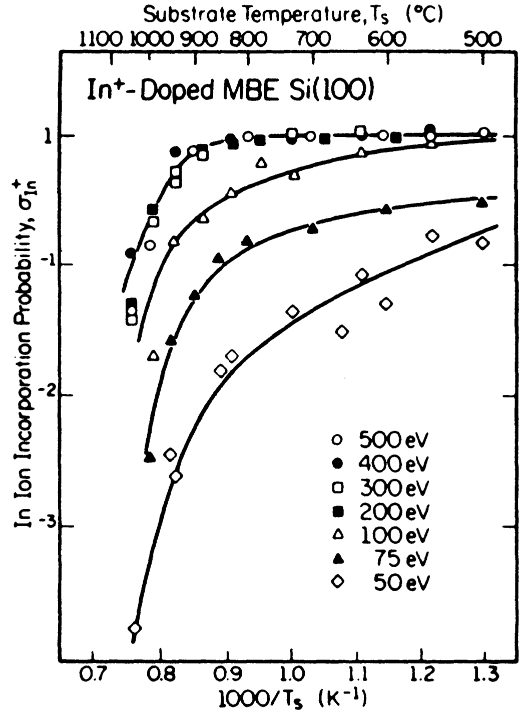

FIG. 13. The incorporation probability of In ions in MBE-grown Si as a function of the In energy and substrate temperature (after Hasan *et al.*, 1989).

3.3.2 Improved Adhesion. The fabrication of Schottky contacts that have good thermal stability, interface integrity, and adhesive strength on semiconductor devices poses several problems. In principle, Au should make an excellent Schottky barrier on GaAs; however, conventional deposition of Au on GaAs does not provide adequate bonding. High-temperature anneals improve the bonding, but they also cause interdiffusion and surface roughening. Good adhesion strength has been obtained, however, by directing a 300-eV Ar beam onto the GaAs surface during the deposition of Au, as shown in Fig. 14 (Kellock *et al.*, 1991). Here, the peel strength of the Au film, i.e., the force needed to peel the film from the substrate, is shown as a function of the Ar:Au arrival rate for several substrate temperatures. Far better adhesion is observed in the film prepared by beam-assisted growth. These films were stable at least up to 250 °C; in addition, they were all Schottky type with an ideality factor of 1.3. The physical details of how the ion beam improves the bonding in this system is not yet clear; however, it was suggested that the Ar bombardment liberates As from the near surface and replaces it with Au, thus leading to the formation of a complex Au-Ga-As phase (Kellock *et al.*, 1990).

4. IMPLANTATION AT ELEVATED TEMPERATURE

4.1 Theory of Radiation-Enhanced Diffusion

It is well established that diffusion in solids involves the motion of point defects—vacancies and interstitials. This is expressed through the equation

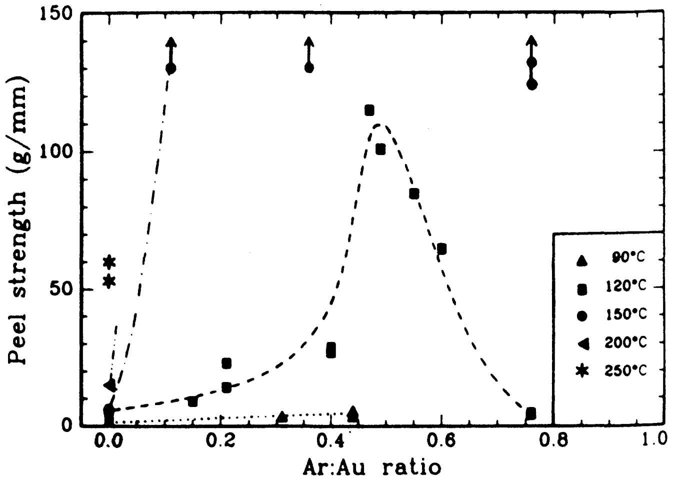

FIG. 14. The peel strength of a Au film vapor deposited on GaAs plotted as functions of the ratio of arrival of 300-eV Ar ions and Au atoms and temperature (after Kellock *et al.*, 1991).

$$D = D_i C_i + D_v C_v \tag{13}$$

where D_j and C_j are diffusivities and concentrations of vacancies and interstitials. The diffusivities have the form $D_j = D_{0j} \exp\{\Delta H_j / kT\}$, and ΔH_j is the activation enthalpy for defect migration; D_{0j} is a preexponential, or entropic, factor. In absence of irradiation, the concentrations of defects refer to their values in thermal equilibrium. However, during implantation, the displacement processes described above introduce large supersaturations of point defects, both interstitials and vacancies, and according to Eq. (13), they enhance diffusion. The instantaneous concentration of defects can be calculated using chemical rate theory (see, e.g., Sizmann, 1978). The diffusion coefficient that derives from this theory is plotted in Fig. 15 as a function of inverse temperature. At low temperatures, the defects are nearly immobile so that the radiation-enhanced diffusion (RED) becomes smaller than ion-beam mixing. At very high temperatures, normal thermal diffusion prevails. At intermediate temperatures, however, diffusion is controlled by RED. The temperature dependence of RED varies depending on a number of factors: temperature, ion flux, and the perfection of the crystal. The important point, however, is that RED occurs at substantially lower temperatures than normal thermal diffusion. Moreover, it is distinguished from ion-beam mixing in that

1. it can be orders of magnitude larger than ion beam mixing;
2. it is a "near" equilibrium process. This means that defects tend to anneal out during the irradiation and that equilibrium, rather than metastable, phases are usually produced.

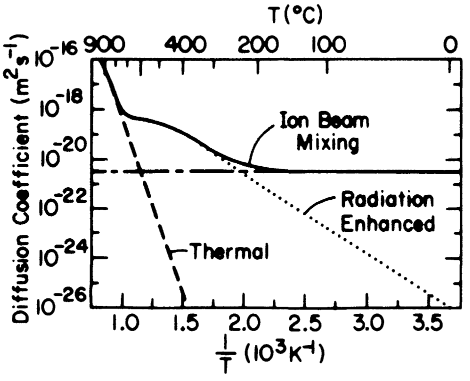

FIG. 15. Radiation-enhanced diffusion coefficient as a function of inverse temperature.

4.2 Examples of Radiation-Enhanced Diffusion

It may be expected from the current discussion that implantation at elevated temperatures may result in defect-free material and activated impurities in semiconductor devices. In some cases, doping of semiconductors is performed at elevated temperatures, but because of the enhanced diffusion of the impurity, precipitation, and the buildup of complex damage structures, this method is not widely used. Rather, rapid thermal annealing is employed to remove defects in implanted semiconductors. A more promising application of high-temperature implantation is the synthesis of buried $CoSi_2$ in Si discussed in Sec. 2.4.2. To produce good mesoepitaxial layers, it is imperative that the Si substrate remain crystalline during the Co implantation, otherwise the coherence between the silicide and Si substrate would be lost. Consequently, the Co is implanted at a temperature above which amorphous Si crystallizes, $\approx$300 °C. In addition, RED provides sufficient atomic mobility for the implanted Co to precipitate as an epitaxial layer of $CoSi_2$. The quality of these buried silicide layers is illustrated in Figs. 16 and 17. In Fig. 16(a), the cross-sectional transmission electron microscope image shows the flatness of the buried layer, while Fig. 16(b) reveals the atomic perfection at the interfaces. Figure 17 shows the effect of substrate temperature on crystal perfection. Here channeling of He ions is employed as a measure of the crystal quality (low yields implying little damage). For implantation below $\approx$300 °C the surface region becomes polycrystalline, even after high-temperature annealing. At too-high implantation temperatures, the crystal quality also diminishes since the $CoSi_2$ precipitates grow too rapidly and become three dimensional, rather than two-dimensional, flat films. Thus, careful control of RED is critical to this emerging technology.

A second example of RED is the formation of $NbSi_2$ using Ar irradiation at high temperatures. In Fig. 18 it is shown that $NbSi_2$ can be efficiently formed by ion-beam mixing at temperatures less than $\approx$300 °C. The formation of

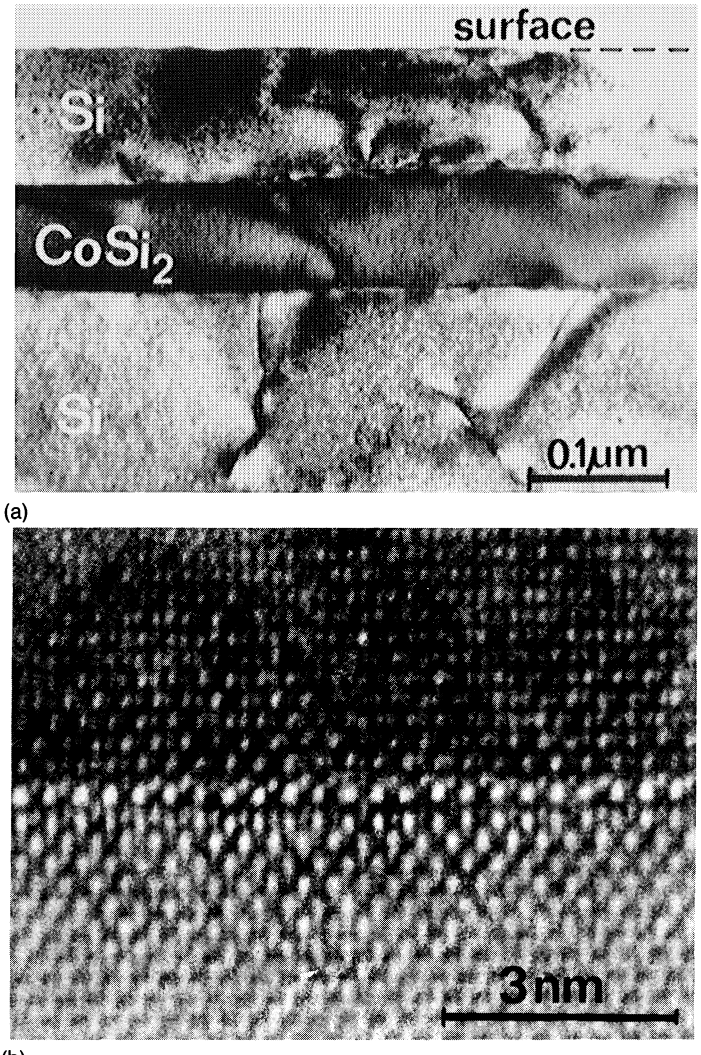

FIG. 16. Perfection of mesoepitaxial layer of $CoSi_2$ in Si. (a) Cross-sectional TEM image showing the flatness of the buried layer; (b) high-resolution TEM image showing the atomic perfection of the interfaces between the $CoSi_2$ and Si interfaces. (After Werner and Jaeger, 1993.)

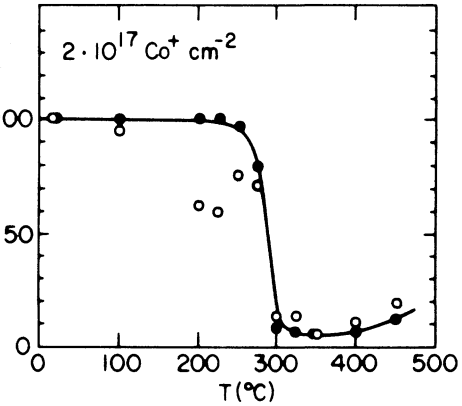

FIG. 17. The effect of implantation temperature on mesoepitaxial perfection. The quality of the film is characterized here by ion channeling measurements. A large yield of backscattered ions means that there is a large number of crystalline imperfections blocking the channels. (After Mantl, 1992.)

$NbSi_2$ by thermal annealing, however, does not take place until ≈450 °C. Ion-beam mixing of Nb and Si at low temperatures requires much higher fluences, and it does not yield the $NbSi_2$ phase.

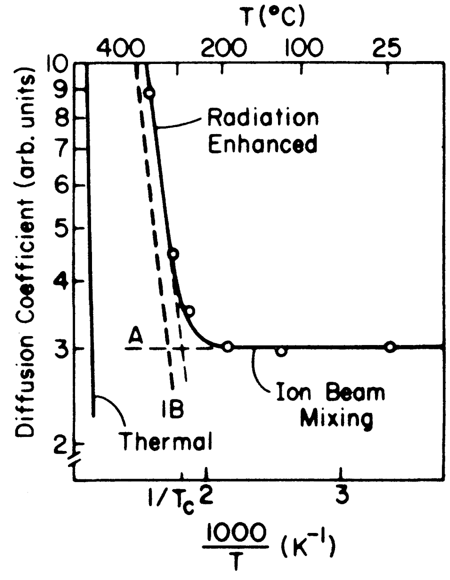

FIG. 18. Logarithmic plot of the intermixing of Nb and Si films to form $NbSi_2$ during Si irradiation as a function of inverse temperature. At low temperatures the intermixing is due to ion-beam mixing and is independent of temperature. At higher temperatures, the mixing is due to radiation-enhanced diffusion. Thermal diffusion occurs at much higher temperatures. (After Matteson *et al.*, 1979.)

5. SUMMARY

In recent years, ion-beam modification of materials has become an important processing step for a number of advanced materials. This development has become possible after many years of fundamental research on the interaction of energetic particles with solids and defects in crystals. Computer simulation programs are now readily available for accurately calculating the depth distributions of implanted ions, even in complex substrates. These programs can also reliably calculate sputtering yields and defect production. The damage created by the implantation is also becoming better understood, and along with this better understanding, methods to eliminate it, or to exploit it, are being developed. In this article, the fundamental processes involved in ion-beam modification were presented. Several applications were described that illustrate how various aspects of implantation can be utilized. These ranged from the doping of semiconductors, to ion-beam–assisted growth of thin films, to the formation of metastable phases at metal and ceramic surfaces for wear and oxidation resistance. In this age of advanced materials, where processing must operate on the submicron level, ion-beam modification of materials is certain to play an ever increasing role.

GLOSSARY

Channeling: The guidance of implanted atoms by lattice atoms to travel in the open spaces of axial or planar channels in a crystalline target.

Compositional Disordering: The intermixing of compositionally modulated structures.

Damage Energy: The fraction of an implanted ion's energy that is utilized in displacing atoms from their lattice sites. It is approximately the energy of the implantation particle less that dissipated in electronic excitations.

Displacement Energy: The energy required to displace an atom from its lattice site and create a Frenkel pair.

Frenkel Pair: An interstitial atom and its associated vacancy.

Ion-Beam–Assisted Deposition: The deposition of a thin film onto a surface while simultaneously bombarding the surface with ions.

Ion-Beam Mixing: The athermal rearrangement of atoms during ion irradiation. It is often associated with the intermixing of contiguous thin-film layers by ion irradiation.

Mesoepitaxy: The formation of a subsurface, coherent layer by ion implantation.

Radiation-Enhanced Diffusion: The enhancement of diffusion in a material at elevated temperatures by using irradiation to produce point defects.

Range Distribution: The concentration profile of an implanted species as a function of distance beneath the surface.

Recoil Implantation: The forward recoil of substrate atoms deeper into a substrate during ion implantation.

Replacement Collision Sequence: A linear chain of collisions along the close-packed directions of a lattice whereby one atom collides with and replaces its neighbor.

Sputtering: The erosion of a surface during ion irradiation. The sputtering yield is the number of target atoms ejected from the surface per incident ion.

Stopping Power: The loss of energy of an implanted ion per unit distance along its trajectory in a material.

Straggling: A measure of the variance of a range distribution. The straggling normal to the surface is the ratio of the square root of the variance to the mean range. The transverse straggling is the ratio of the variances in directions parallel and perpendicular to the surface.

Thermal Spike: Local, transient heating of a material around the trajectory of an implanted ion.

TRIM (Transport of Ions in Matter): A popular computer code for generating range damage and ionization profiles for ion implantation.

INTRODUCTION: GENERAL BACKGROUND TO DIFFUSION IN SOLIDS

The classical "textbook" picture of a solid is that the atoms in a solid stay located on their lattice sites, and the only motions that are present are the lattice vibrations. In fact, atoms in a real solid are continually changing their positions, and at temperatures close to the melting point an atom will change site about a million times per second. The study of these translational atomic movements, *diffusion*, in solids is a mature field of chemical physics with a long and rich history. In his pioneering studies of the electrical behavior of materials in the 1830s, Michael Faraday measured the conductivity of a number of ionic solids. It was almost a century ago that Sir William Roberts-Austen (a student of Thomas Graham, who formulated the laws of diffusion in gases) made the first diffusion measurement on a metallic system, gold in lead. Since those early days there has been a steady growth of interest in all aspects of diffusion in solids. From the viewpoint of basic science, the ability to model diffusion is a severe test of the theoretical concepts of

physics, particularly the understanding of the interatomic potentials, and there will be a continual striving to predict accurately the diffusion parameters of solids. A vast number of technological processes involve diffusion phenomena, including the manufacture of semiconductor devices by doping with impurities, sintering, plastic deformation, and corrosion. It is therefore important that physical scientists understand the basic phenomena and theories of solid-state diffusion and ionic conductivity. The objective of this article is to present an overview of the current state of knowledge that emphasizes the principal features. Readers wishing more detail are referred to the extensive bibliography at the end of the chapter, which will guide them to several authoritative texts and articles on specific topics. The focus is on diffusion in crystalline solids where the basic phenomena and ideas are now well established. Although there have been extensive studies of amorphous materials and glasses, the theory of diffusion in these systems is still in a state of flux (Greaves, 1990).

The first section treats the basic theories of diffusion in solids, both the macroscopic, phenomenological aspects and the atomistic mechanisms. The next section covers the variety of experimental techniques. A special emphasis is given to the measurement of conductivity of ionic solids, as this has proved particularly fruitful in the development of many basic concepts of solid-state diffusion. Also included in this section is a brief treatment of the methods of computer simulation, a technique that is proving invaluable in understanding the details of the diffusion processes. The third section reviews the current knowledge of the diffusion processes in the different solid types. A final section briefly introduces the difficult, but important, topic of diffusion in an applied field, i.e., a gradient of temperature (*thermomigration*) or of electric field (*electromigration*).

1. THEORY OF SOLID-STATE DIFFUSION

1.1 Phenomenological Theory of Diffusion

1.1.1 Classical Approach. Translational diffusion in classical physics is governed by *Fick's laws*. In a one-dimensional system the flux of a given type of particle, i.e., the number passing through unit cross-sectional area in unit time, can be expressed as

$$J=-D\left(\frac{\partial c}{\partial x}\right), \tag{1}$$

where c is the number concentration of particles, $\partial c/\partial x$ is the gradient of the concentration of particles along the x direction, and D is the diffusion coefficient. A dimensional analysis shows that D has units of L^2T^{-1} and is usually reported as $\mathrm{cm^2\,s^{-1}}$ or $\mathrm{m^2\,s^{-1}}$. Equation (1) is *Fick's first law*. In three dimensions this can be written as

$$\mathbf{J}=-\mathbf{D}\cdot\nabla c, \tag{2}$$

where D is now a second-rank tensor.

Fick's first law is analogous to Fourier's law of heat flow and Ohm's law and is a specific statement of the more general law of physics that a flow is directly proportional to a driving force, the driving force being a gradient of "potential." In the form of Eqs. (1) and (2), Fick's first law is not particularly useful to the experimentalist, as the evaluation of D would involve the measurement of a flux and a concentration gradient, both of which could be time dependent. If the particles are conserved, then the equation of material balance will apply, and therefore a further condition must be obeyed, i.e.,

$$\frac{\partial J}{\partial x}=-\frac{\partial c}{\partial t}. \tag{3}$$

This continuity equation is simply derived by considering the net flow into and out of a small volume along the diffusion axis. Combining Eqs. (1) and (3) yields

$$\frac{\partial c}{\partial t}=\frac{\partial}{\partial x}\left(D\frac{\partial c}{\partial x}\right). \tag{4}$$

If D is independent of concentration, then Eq. (4) reduces to

$$\frac{\partial c}{\partial t}=D\frac{\partial^2 c}{\partial x^2}, \tag{5}$$

which is often referred to as *Fick's second law*.

Equation (5) is a second-order differential equation to which a variety of solutions can be derived to correspond with the different experimental situations, i.e., different boundary conditions. These can be found in the standard texts (e.g., Crank, 1975), and the only solution quoted here is that for the initial condition of an *infinitely* thin source on the surface of an *infinite* sample. This geometry is commonly used in tracer diffusion experiments, and the appropriate solution to Eq. (5) is

$$c(x,t)=\frac{A}{\sqrt{\pi Dt}}\exp\left(-\frac{x^2}{4Dt}\right). \tag{6}$$

Here $c(x,t)$ is the concentration of particles at a penetration depth x into the surface after time t, and A is the initial concentration of particles on unit area of the surface. Thus the penetration profile, the plot of $c(x,t)$ vs x, will have a Gaussian shape, and the diffusion coefficient can be determined from the plot of $\ln c(x,t)$ vs x^2; i.e., the slope is $-1/4Dt$.

External forces acting on the system will perturb the diffusion, and intuitively Eq. (1) may be modified by including an additional flux. This term is referred to as a *drift* and can be simply equated to the concentration of particles multiplied by an average drift velocity, $\bar{v}$, imparted by the force. Thus the resulting total flux can be expressed as

$$J=-D\left(\frac{\partial c}{\partial x}\right)+\bar{v}c. \tag{7}$$

Examples of external driving forces are gradients of electrical potential, temperature, and stress. For particles of charge q in a gradient of electric potential E $(=-d\Phi/dx)$, the drift velocity is given by

$$\bar{v}=\mu E, \tag{8}$$

where μ is the mobility of the charged particle, i.e., the drift velocity in unit potential gradient. If the system is in a steady state with no net flux, then from Eq. (7)

$$D\left(\frac{\partial c}{\partial x}\right)=\bar{v}c=\mu Ec. \tag{9}$$

Assuming thermodynamic equilibrium in the system, the concentration of particles will obey Boltzmann statistics, and hence

$$c(x)=a\exp\left(\frac{-q\Phi(x)}{kT}\right), \tag{10}$$

where a is a constant, k is the Boltzmann constant, and T is the temperature. Differentiating Eq. (10) with respect to x yields

$$\frac{\delta c}{\delta x}=\frac{-cq}{kT}\frac{d\Phi}{dx}=\frac{cqE}{kT}. \tag{11}$$

Combining Eqs. (9) and (11) gives the result

$$\mu/D=q/kT; \tag{12}$$

and since the conductivity σ is defined by

$$\sigma=cq\mu, \tag{13}$$

the final result relating D and σ is

$$\sigma=cq^2D/kT. \tag{14}$$

Equation (14) is the *Nernst–Einstein equation* and is important in the study of atomic transport in ionic solids, as it provides a quantitative link between diffusion and conductivity experiments. This is discussed later in greater detail.

The treatment of diffusion in a temperature gradient, where the driving force is dT/dx, is not so straightforward. In the format of Eq. (7) the flux is given in this case by

$$J=-D\left(\frac{\partial c}{\partial x}\right)-\frac{cQ^{*\prime}}{kT^2}\frac{dT}{dx}. \tag{15}$$

Here $Q^{*\prime}$ is the reduced heat of transport and has the units of energy. By convention $Q^{*\prime}$ is positive if the particle moves down the temperature gradient. The meaning of $Q^{*\prime}$ is further explained in the treatment given below.

1.1.2 Irreversible Thermodynamics. The treatment of diffusion theory presented above is based on empirical and intuitive approaches to the phenomenon. A rigorous approach to the problem is possible using *irreversible* (or *nonequilibrium*) *thermodynamics*. Only the basic ideas can be treated here, and for more detail the reader is referred to standard texts (de Groot and Mazur, 1962; Prigogine, 1967), while the special applications to solid-state diffusion are treated by Howard and Lidiard (1964).

In a system in which diffusion is occurring there will be local fluxes of atoms or species of type i, $\mathbf{J}_i$, and there will be a heat flux $\mathbf{J}_q$. The thermodynamics of irreversible processes relates these fluxes linearly to certain conjugate thermodynamic forces, $\mathbf{X}_i$ and $\mathbf{X}_q$, to give the relations

$$\mathbf{J}_i = \sum_{j=1}^{n} L_{ij}\mathbf{X}_j + L_{iq}\mathbf{X}_q \tag{16}$$

and

$$\mathbf{J}_q = \sum_{j=1}^{n} \mathbf{L}_{qj}\mathbf{X}_j + L_{qq}\mathbf{X}_q. \tag{17}$$

The L_{ij}'s are called the *phenomenological coefficients* and are independent of the forces (but will depend on concentration and temperature).

The conjugate forces are given by

$$\mathbf{X}_i = -T\nabla(\mu_i/T) \tag{18}$$

and

$$\mathbf{X}_q = T\nabla(1/T), \tag{19}$$

where μ_i is the chemical potential of species i.

The diagonal coefficients (L_{ii}) are simply related to atomic mobilities and thermal conductivities. The off-diagonal or cross coefficients express the coupling between the various fluxes and forces. For example, a heat flux will give rise to a diffusional flux and vice versa. An important point in the general theory is the *Onsager reciprocal relations* between the coefficients, i.e.,

$$L_{ij} = L_{ji} \tag{20}$$

and

$$L_{iq} = L_{qi}. \tag{21}$$

It is more convenient to use the *reduced heat flux* $\mathbf{J}'_q$ in which the flux of enthalpy due to the diffusion of species is subtracted from $\mathbf{J}_q$, i.e.,

$$\mathbf{J}'_q = \mathbf{J}_q - \sum_{i=1}^{n} \mathbf{J}_i h_i. \tag{22}$$

Here h_i is the partial specific enthalpy of species i. In choosing the reduced heat flux the conjugate thermodynamic force needs to be redefined as $\mathbf{X}'_i$, given by

$$\mathbf{X}'_j = -(\nabla\mu_i)_T. \tag{23}$$

Thus $\mathbf{X}'_i$ is the gradient of chemical potential produced by the variation of composition in the absence of a temperature gradient.

It is useful to define the *heat of transport* Q^*_i by the relation

$$L_{iq} = \sum_{j=1}^{n} Q^*_j L_{ij}. \tag{24}$$

Thus Eqs. (16) and (17) can be reexpressed as

$$\mathbf{J}_i = \sum_{j=1}^{n} L_{ij}(\mathbf{X}_j + Q^*_j\mathbf{X}_q) \tag{25}$$

and

$$\mathbf{J}_q = \sum_{i=1}^{n} Q^*_i\mathbf{J}_i + \left(L_{qq} - \sum_{j=1}^{n} L_{jq}Q^*_j\right)\mathbf{X}_q, \tag{26}$$

which in the absence of a temperature gradient reduces to

$$\mathbf{J}_q = \sum_{j=1}^{n} Q^*_j\mathbf{J}_j. \tag{27}$$

In the framework of reduced heat flux a *reduced heat of transport* $Q^{*\prime}_j$ is defined by

$$Q^{*\prime}_j = Q^*_j - h_i, \tag{28}$$

and then Eqs. (25) and (27) are

$$\mathbf{J}_i = \sum_{j=1}^{n} L_{ij}(\mathbf{X}'_j + Q^{*\prime}_j\mathbf{X}'_q) \tag{29}$$

and

$$\mathbf{J}'_q = \sum_{j=1}^{n} Q^{*\prime}_j\mathbf{J}_j. \tag{30}$$

Equation (30) provides a physical meaning of the reduced heat of transport as the flux of heat in an isothermal system due to the flux of matter.

It is important to note that the fluxes of all species in a system cannot be independent. Thus measuring the fluxes relative to the lattice frame at rest yields

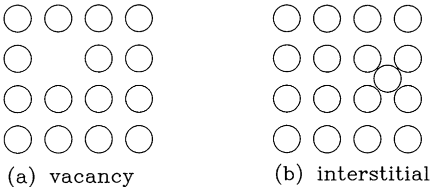
$$\sum_{i=1}^{n} \mathbf{J}_i = 0, \tag{31}$$

so that if there are n species in a system there are only $n-1$ *independent* heats of transport. This is important when considering diffusion due to point defects.

1.2 Atomistic Theory of Solid-State Diffusion

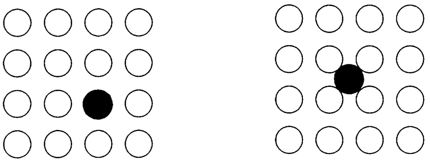
1.2.1 Introduction to Point Defects. All real crystals are imperfect, and they contain a variety of types of defects. These include *bulk defects,* such as grain boundaries and dislocations, which extend over many lattice spacings, *surfaces*, and *point defects*, the latter being at the atomic level. The mechanisms of diffusion in crystalline solids that move an atom from one lattice site to another, *lattice* or *bulk diffusion*, involve the point defects. Diffusion will occur along the other types of defect—in fact it should occur more readily because of the open nature of their structures; however, it will not be covered here. It is more difficult to treat dislocation and surface diffusion in a detailed analysis, as the atomic pathway is less well defined, although there has been some progress in recent years (Kaur and Gust, 1988; King, 1987). In addition, these defects are not thermodynamically inherent in crystals, and their concentrations, and hence the contribution to the total diffusion, will depend on the history of the sample. At high temperatures, lattice diffusion will usually dominate.

In a monatomic solid, there are four basic types of point defect, as illustrated in Fig. 1. In an absolutely pure crystal there may be *vacancies* [Fig. 1(a)], unoccupied lattice sites, and *interstitials* [Fig. 1(b)], atoms on interstitial positions in the lattice. These are sometimes referred to as *intrinsic* or *thermally activated* point defects as they will be present in any crystal above 0 K, arising from the fact that the energy of some atoms in the Boltzmann distribution will be sufficient to cause them to migrate from their normal lattice sites. A real crystal will also contain impurity atoms dissolved in the lattice. There are two types of these *extrinsic* or *impurity point defects: substitutional impurities* [Fig. 1(c)], where the impurity occupies a site normally filled by the host atom, and *interstitial impurities* [Fig. 1(d)], where the impurities occupy interstitial sites in the lattice.



(a) vacancy

(b) interstitial atom



(c) substitutional impurity

(d) interstitial impurity

FIG. 1. Schematic representation of the basic point defects in monatomic solids.

In a real crystal, there will be interactions between the point defects, and this can lead to association of the simple defects to form more complex *aggregates* or *clusters*. Obvious examples are the *divacancy* (or vacancy pair), with two vacancies in adjacent lattice sites, and the *impurity–vacancy pair*, a substitutional impurity and vacancy on adjacent lattice sites. The concentration of a particular type of aggregate will depend on temperature, the concentration of the basic component defects, and their interaction energy. The last term will depend on the nature of the intermolecular forces, and the importance of aggregation, as will be seen later, depends very much on the type of solid under consideration.

1.2.2 Thermodynamics of Point Defects in a Monatomic Solid. The simplest case to deal with is a crystal containing vacancies in a single electronic state, and the treatment given below follows that developed in other texts (Howard and Lidiard, 1964; Chadwick and Glyde, 1977). The results for other types of defect will be described as appropriate.

The Gibbs free energy of a perfect crystal containing N atoms at a temperature T and uniform pressure P can be defined as $G_0(T,P)$. If n_v noninteracting, mobile vacancies are introduced into the crystal, the Gibbs free energy of this real crystal, $G(T,P)$, is given by

$$G(T,P)=G_0(T,P)+n_v g_v-kT\ \ln\Omega. \qquad (32)$$

Here g_v ($\equiv h_v-Ts_v$) is the Gibbs free energy of formation of a single vacancy, k is the Boltzmann constant, and Ω is the number of states of the system, i.e., the number of ways of arranging N atoms and n_v vacancies on $N+n_v$ lattice sites. Thus the final term in Eq. (32) is a *configurational entropy term*, given by

$$\ln\Omega=\ln\left(\frac{(N+n_v)!}{N!n_v!}\right). \qquad (33)$$

At thermal equilibrium $G(T,P)$ will be a minimum with respect to n_v, i.e.,

$$\left(\frac{\partial G}{\partial n_v}\right)_{T,P,N}=\mu_v=0, \qquad (34)$$

where μ_v is the *chemical potential of the vacancies*. The contributions to $G(T,P)$ from the vacancy free energy and the configurational entropy term are shown schematically in Fig. 2. Substituting from Eq. (33) into (32) and performing the differentiation (which requires the use of Stirling's theorem, i.e., $\ln N! = N \ln N - N$ for large values of N), yields

$$\mu_v = g_v + kT \ln\left(\frac{n_v}{N+n_v}\right) = 0 \tag{35}$$

or the site fraction of vacancies* c_v as

$$c_v = \frac{n_v}{N+n_v} = \exp\left(\frac{-g_v}{kT}\right). \tag{36}$$

Equation (36) shows that the vacancy concentration increases exponentially with temperature, reaching a maximum at the melting point. The physical process of vacancy formation may involve an atom *in* the surface layer jumping from its site to a new site *on* the surface and the subsequent migration of the vacancy so created into the bulk of the crystal. The exact reversal of the process leads to vacancy annihilation. In a crystal there is a dynamic equilibrium, the rates of vacancy formation and annihilation being equal. These rates are governed by the distances between the surfaces (*sources* and *sinks* for vacancies) and the diffusion coefficient of the vacancies. Fortunately for the experimentalist, internal surfaces, such as grain boundaries and dislocations, act as sources and sinks so that vacancy concentrations are usually in thermal equilibrium. In fact, special conditions have to be employed to perturb the equilibrium; e.g., rapid cooling (~ 1000 K s^{-1}) from near the melting point to low temperatures (where diffusion is very slow) will quench in high vacancy concentrations.

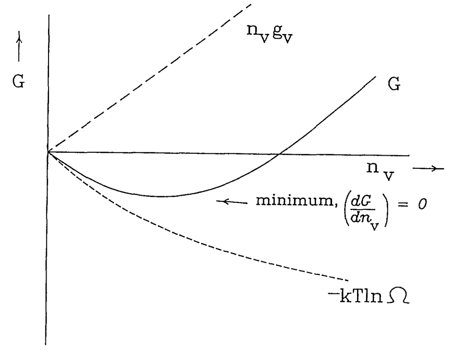


FIG. 2. Schematic representation of the vacancy contribution to the Gibbs free energy of a solid.

The derivation leading to Eq. (36) can easily be extended to a crystal containing n_i interstitial atoms to yield a site fraction (the fraction of interstitial sites in the crystal that are occupied by atoms) as

$$c_i = \frac{n_i}{\beta(N-n_i)} = \exp\left(\frac{-g_i}{kT}\right). \tag{37}$$

Here g_i ($\equiv h_i - Ts_i$) is the Gibbs free energy to form an interstitial atom, and β is the number of interstitial sites associated with a normal lattice site, i.e., a purely geometric factor depending on the crystal structure of the material. It is clear from Eqs. (36) and (37) that both vacancies and interstitial atoms will be present in any real crystal above absolute zero, although their relative concentrations will depend on g_v and g_i. Simple arguments based on atom sizes and compressibility lead to the prediction that in close-packed structures $g_i > g_v$ and the interstitial concentration is negligible with respect to vacancy concentrations.

It is worth considering the extension of the derivation of Eq. (36) to the case of vacancy pairs. This yields an expression for the *site fraction of pairs* c_p as

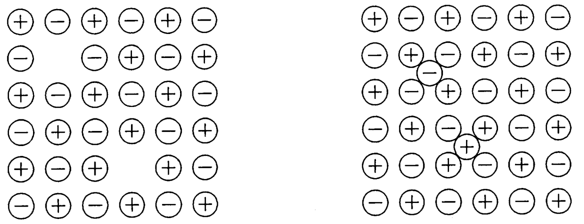
$$c_p = \frac{z}{2} \exp\left(\frac{-(2g_v + \Delta g_{v2})}{kT}\right), \tag{38}$$

where z is the coordination number of the lattice and Δg_{v2} is the binding energy of the pair. Written in this form Δg_{v2} is the free-energy change on bringing two vacancies from infinity to form a pair; i.e., if Δg_{v2} is negative, then divacancy formation is favorable. The term $z/2$ arises as there are $z/2$ ways of orienting a pair in the lattice. Combining Eqs. (36) and (38) yields

$$\frac{c_p}{c_v^2} = \frac{z}{2} \exp\left(\frac{-\Delta g_{v2}}{kT}\right), \tag{39}$$

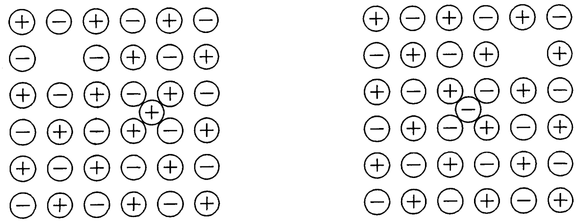
---

*In the treatment of point defects it is more convenient to use *site fractions*, as defined in Eq. (36), as the expression of concentration rather than the more conventional number concentration. Since $N \gg n_v$ the site fraction is *virtually* equal to the mole fraction of vacancies.



(a) Schottky pair

(b) anti Schottky pair



(c) cation Frenkel pair

(d) anion Frenkel pair

FIG. 3. Schematic representation of the point defects in a *MX* ionic crystal.

which can also be derived by considering the vacancy association reaction (vacancy + vacancy ⇆ divacancy) in terms of the mass action law. It should be noted that Eq. (38) will apply even when the vacancies are not in thermal equilibrium. Under normal circumstances, c_p will be expected to depend exponentially on temperature and to be significantly smaller than c_v.

Finally the perturbation on the system by the addition of impurities needs to be discussed. Assuming that the impurity concentration is low and that the impurity dissolves substitutionally, then the formation of impurity–vacancy pairs, i.e., an impurity and a vacancy on adjacent lattice sites, needs to be included in the treatment of the point-defect thermodynamics. In an analogous manner to the treatment of vacancy pairs, it can be shown that the site fraction of impurity–vacancy pairs, c_{Iv}, is given by

$$c_{Iv}=zc_I \exp\left(\frac{-(g_v+\Delta g_{Iv})}{kT}\right) \qquad (40)$$

or

$$\frac{c_{Iv}}{c_I c_v}=z \exp\left(\frac{-\Delta g_{Iv}}{kT}\right), \qquad (41)$$

where c_I is the site fraction of isolated impurity atoms and Δg_{Iv} is the binding energy of the pair. The total vacancy concentration $\overset{T}{c}_v$ $(=c_v+c_{Iv})$ is given by

$$\overset{T}{c}_v=\exp\left(\frac{g_v}{kT}\right)\left[1+zc_I \exp\left(\frac{-\Delta g_{Iv}}{kT}\right)\right]. \qquad (42)$$

Thus if Δg_{Iv} is negative and there is a tendency to form these pairs, the site fraction of vacancies is increased in comparison to the pure metal.

1.2.3 Point-Defect Thermodynamics in an Ionic Solid. In an ionic solid the point-defect picture is more complicated than that in a monatomic solid. This arises from the fact that an isolated point defect, such as a vacancy or an interstitial ion, will have an *effective* charge with respect to the lattice, and any perturbation must maintain electrical neutrality and preserve the lattice structure. In a 1:1 crystal *MX* that is strongly ionic the point defects in a pure crystal will occur in pairs.* The common types of intrinsic defects are shown in Fig. 3. The *Schottky pair* [Fig. 3(a)] consists of a cation vacancy and an anion vacancy, the *cation Frenkel pair* [Fig. 3(c)] consists of a cation vacancy and a cation interstitial, and the *anion Frenkel pair* [Fig. 3(d)] consists of an anion vacancy and an anion interstitial. The *anti-Schottky pair* [Fig. 3(b)], consisting of a cation and an anion interstitial, is a theoretically possible type of defect pair although it is not found in real systems.

---

*Only the case of a strongly ionic crystal, such as an alkali halide, is considered here. In semi-ionic solids, such as a transition-metal oxide, charge compensation on formation of a lattice defect may occur by creation of an electron or hole.

The concentration of point defects in an ionic crystal can be treated in a similar manner to that outlined in Sec. 1.2.2 for vacancies in a monatomic solid. Treatments for ionic crystals can be found in several standard texts (see, for example, Lidiard, 1957; Corish and Jacobs, 1973; Jacobs, 1983). The example taken here will be that of an MX crystal consisting of N_M cations and N_X anions and containing Schottky defects, n_{cv} cation vacancies, and n_{av} anion vacancies. The Gibbs free energy of the crystal can be expressed as

$$G(T,P)=G_0(T,P)n_{cv}g_{cv}+n_{av}g_{av}-kT\ \ln\Omega, \tag{43}$$

where g_{cv} ($\equiv h_{cv}-Ts_{cv}$) and g_{av} ($\equiv h_{av}-Ts_{av}$) are the Gibbs free energies of formation of cation vacancies and anion vacancies, respectively. In this case, with two sublattices, the configurational entropy is given by

$$kT\ \ln\Omega=kT\ \ln\left[\left(\frac{(N_M+n_{cv})!}{N_M!n_{cv}!}\right)\times\left(\frac{(N_X+n_{av})!}{N_X!n_{av}!}\right)\right]. \tag{44}$$

The minimization of $G(TP)$ with respect to the defect concentrations to find the equilibrium condition, i.e.,

$$\delta G=\sum_j\left(\frac{\partial G}{\partial n_j}\right)_{T,P,N}\delta n_j=0, \tag{45}$$

where n_j is the number of defects of type j, must be performed with the constraints that electrical neutrality is maintained and the number of sites on the two sublattices remains equal. If virtual chemical potentials of the defects are defined by

$$\mu_{cv}=g_{cv}+kT\ \ln\left(\frac{n_{cv}}{N_M+n_{cv}}\right) \tag{46}$$

and

$$\mu_{av}=g_{av}+kT\ \ln\left(\frac{n_{av}}{N_X+n_{av}}\right), \tag{46}$$

then the equilibrium condition can be rewritten as

$$\mu_{cv}+\mu_{av}=0, \tag{47}$$

which leads to

$$\frac{n_{cv}}{N_M+n_{cv}}\frac{n_{av}}{N_X+n_{av}}=c_{cv}c_{av}=\exp\left(\frac{-g_s}{kT}\right). \tag{48}$$

Here $g_s=g_{cv}+g_{av}$, the Gibbs free energy of formation of a Schottky pair, and c_{cv} and c_{av} are the site fractions of cation and anion vacancies, respectively.

Equation (48) has the form of a solubility product, and it is useful in ionic solids to consider defect equilibria in terms of quasi-chemical equilibria controlled by mass-action equations. Thus Schottky defect formation can be expressed as

$$\text{perfect lattice}\leftrightharpoons\text{cation vacancy}+\text{anion vacancy} \tag{49}$$

controlled by the mass-action equation

$$c_{cv}c_{av}=K_S=\exp(-g_S/kT), \tag{50}$$

where K_S is the equilibrium constant for the Schottky-pair formation equilibrium. Clearly it follows that in a pure crystal N_M will be equal to N_X and c_{cv} will be equal to c_{av} ($=K_S^{1/2}$).

Expressions similar to Eq. (50) can be obtained for other types of defect; for example, for cation Frenkel pairs the expression is

$$c_{cv}c_{ci}=\exp(-g_{cF}/kT), \tag{51}$$

where c_{ci} is the concentration of cation interstitials and g_{cF} ($\equiv h_{cF}-s_{cF}T$) is the Gibbs free energy of formation of cation Frenkel pairs. Clearly the type of point defect dominant in a particular crystal will depend on the relative magnitudes of their free energies of formation, which in turn depend on the ionic sizes and crystal structures. Among the simple materials the alkali halides contain Schottky pairs, the alkaline earth fluorides contain anion Frenkel pairs, and silver chloride and bromide contain cation Frenkel pairs.

A great deal of information on the point defects in an ionic crystal can be obtained by adding (or "doping") the crystal with aliovalent impurity. The additional charge introduced into the lattice has to be compensated, and this is usually achieved by perturbing the defect concentrations. Taking again the example of an MX crystal containing Schottky defects, the effect of adding substitutionally a small amount of a divalent cation, IX_2, is to introduce cation vacancies. The conditions of electrical neutrality, i.e.,

$$N_M+2n_I=N_X, \tag{52}$$

and site conservation, i.e.,

$$N_M+n_I+n_{cv}=N_X+n_{av}, \tag{53}$$

give the result

$$n_{cv}=n_I+n_{av} \tag{54}$$

and hence

$$c_{cv}=c_I+c_{av}. \tag{55}$$

Here n_I is the number of I^{2+} ions, and c_I is the corresponding site fraction. Combining Eq. (55) with (50) yields the result

$$c_{cv}=\tfrac{1}{2}[c_I+(c_I^2+4K_s)^{1/2}]. \tag{56}$$

This expression has two limits:

1. at low temperatures,

   $$c_I \gg 4K_S;\ \text{then}\ c_{cv}=c_I \tag{57}$$

   and c_{cv} is independent of temperature—the *extrinsic region*—and
2. at high temperatures,

   $$c_I \ll 4K_S;\ \text{then}\ c_{cv}=c_{av}=K_S^{1/2} = \exp(-g_S/2kT) \tag{58}$$

   and defects are thermally created—the *intrinsic region.*

Since the cation vacancy and the I^{2+} ion have opposite effective charges, they will tend to associate as a neutral pair on adjacent lattice sites (termed *impurity-vacancy pairs* or *I-V pairs*). The reaction can be written as

$$\text{cation vacancy}+I^{2+} \leftrightarrows I\text{-}V\ \text{pair} \tag{59}$$

and the mass-action relation as

$$\frac{c_{IV}}{c_I c_{cv}}=K_{IV}=\exp\left(\frac{-g_{IV}}{kT}\right). \tag{60}$$

Here c_{IV} is the site fraction of pairs, K_{IV} the equilibrium constant for association, and g_{IV} $(\equiv h_{IV}-Ts_{IV})$ the binding energy of the *I-V* pair.

The concentration of cation vacancies, c_{cv}, as a function of temperature in a *MX* crystal in which Schottky disorder dominates is shown schematically in Fig. 4. Three regions are shown: the intrinsic high-temperature region where the defects are thermally controlled, the extrinsic region at moderate temperatures where c_{cv} is equal to the divalent impurity concentration, and the association region where the cation vacancies form *I-V* pairs. As the temperature decreases a fourth region superimposes on the association region, the *precipitation region,* where the *I-V* pairs aggregate to large clusters and eventually form a separate phase, i.e., crystallites of IX_2. The plot is representative of the behavior of alkali halides, as they usually contain traces of divalent cations (e.g., calcium, magnesium, etc.) as natural impurities.

It is relatively straightforward to extend the above treatment of other types of defect, and examples can be found in several texts (Lidiard, 1957; Corish and Jacobs, 1973; Jacobs, 1983). The treatment can also be made more exact by replacing concentrations with

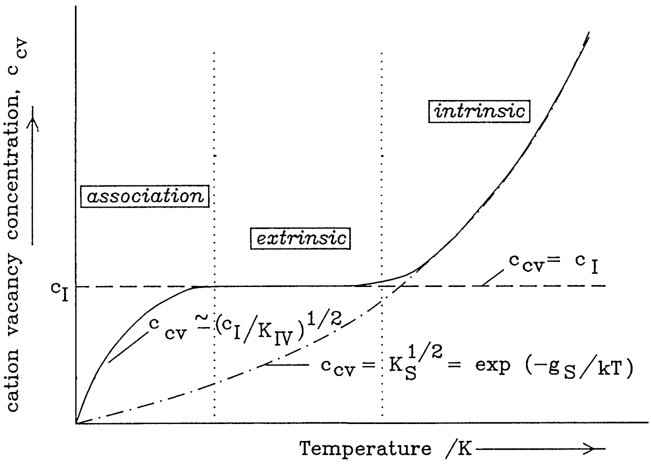


FIG. 4. Cation vacancy concentration in a *MX* crystal with Schottky disorder and doped with a divalent cation as a function of temperature.

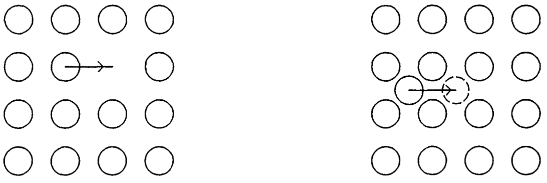
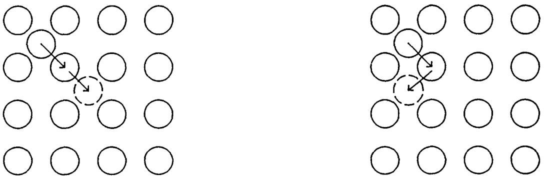


(a) vacancy (b) direct interstitial



(c) collinear interstitialcy (d) non−collinear interstitialcy

FIG. 5. Schematic representation of the diffusion mechanisms in a solid.

thermodynamic activities. The nonideal behavior arises from the long-range Coulombic interactions between the defects, which are usually treated in a similar manner to electrolyte solutions by the Debye–Hückel–Lidiard theory.

1.2.4 Point-Defect Concentrations in Solids. The process of taking an atom from the lattice to form a vacancy is similar to that of sublimation. If there is no relaxation of the lattice around the vacancy then it is possible to a first approximation (Jost, 1960) to equate the enthalpy of vacancy formation, h_v, with the latent heat of sublimation, L_s, i.e.,

$$h_v \simeq L_s. \tag{61}$$

Estimation of the entropy of vacancy formation is more difficult, as it arises from the change in vibrational frequency spectrum of the crystal on forming the vacancy. Calculations for solid argon yield the result

$$s_v \simeq 2k. \tag{62}$$

Combining these values into g_v and substituting into Eq. (36) gives an estimate of c_v as about 1×10^{-4} for solid argon at the melting point T_m. This is quite a good estimate, and for many types of solid $c_v(T_m)$ lies in the range 10^{-4} to 10^{-3}. In close-packed solids c_i will be orders of magnitude smaller than c_v since $g_i > g_v$.

A variety of techniques can be used to determine the point-defect concentrations in solids, and the reader is referred to specific texts (see, for example, Flynn, 1972; Crawford and Slifkin, 1972). In general, this can be experimentally difficult because of the low magnitude of the concentrations and is usually only possible at temperatures close to T_m. An exception is the case of ionic solids where the measurement of ionic conductivity, which will be described in Sec. 2.2, can provide accurate information in a basically simple experiment.

1.2.5 Mechanisms of Diffusion. In nearly all crystalline solids where the mechanism of diffusion has been firmly established the mechanism involves point defects. The earliest theories of solid-state diffusion proposed that at the atomic level two atoms on neighboring sites simply exchanged positions. It was soon realized that this mechanism, known as the *direct exchange mechanism*, would be energetically unfavorable in close-packed solids, as it would require considerable dilation of the lattice to allow the atoms to move past each other. An extension of this mechanism is the *ring mechanism* where a group of atoms move around in a circular fashion, each atom in the group taking the place of its neighbor in the direction of motion. Although this reduces the energy of the process, the ring mechanism does not operate in most systems.

The diffusion mechanisms involving point defects are shown schematically in Fig. 5. The simplest of these is the *vacancy mechanism*, shown in Fig. 5(a), in which an atom "jumps" into a vacancy on a neighboring site. This process is energetically favorable and is the dominant diffusion process in most close-packed crystal structures. For example, this is the mechanism that operates for self-diffusion in fcc metals. In systems where the dominant defects are interstitial atoms, the diffusion can occur via these defects by a number of possible processes. In the *direct interstitial mechanism*, shown in Fig. 5(b), the interstitial atom jumps directly from interstitial site to interstitial site. This is the mechanism by which small impurity atoms that occupy the interstitial sites in metals diffuse—for example, carbon in iron. In pure solids interstitials can diffuse by the *interstitialcy mechanism*, shown in Figs. 5(c) and 5(d), where an interstitial moves onto a neighboring normal lattice site with the displacement of the original occupant atom onto a new interstitial site. There are two variants of this mechanism, the *collinear interstitialcy mechanism* [Fig. 5(c)], where the motion of the two atoms is along the same direction, and the *noncollinear interstitialcy mechanism*, where the two atoms move along different directions. Proven examples of the interstitialcy mechanism can be found in the motion of silver ions in silver halides and fluoride ions in the alkaline earth fluorides.

Variations on the basic point-defect mechanisms described above are also possible, such as the diffusion of atoms via divacancies and the *dumbbell interstitial* (two atoms located around the same lattice site).

It is important to note the use of the term *jump* to describe the process of the atom's motion. This implies that the movement is rapid, occurring over the time scale of the period of a lattice vibration, and that the time the atom is in "flight" between its initial and final sites is very short compared to its average "residence" time on a lattice site.

1.2.6 Random-Walk Theory. The diffusion of atoms in a solid with no applied driving force is analogous to Brownian motion, as each atom can be pictured as making jumps from lattice site to lattice site, the direction of each jump being in a random direction relative to preceding jumps. Thus the process can be treated by the random-walk theory developed originally by Einstein and Smoluchowski.

If an atom makes n consecutive jumps, each described by the translational vector $\mathbf{r}_i$, then the total displacement vector between the initial and final sites of the atom is given by

$$\mathbf{R}_n=\mathbf{r}_1+\mathbf{r}_2+\mathbf{r}_3\cdots=\sum_{i=1}^{n}\mathbf{r}_i. \tag{63}$$

It follows that the displacement squared is simply

$$\mathbf{R}_n^2=\sum_{i=1}^{n}\mathbf{r}_i^2+2\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\mathbf{r}_i\cdot\mathbf{r}_j. \tag{64}$$

The average displacement squared of many atoms after n jumps is given by

$$\langle\mathbf{R}_n^2\rangle=\sum_{i=1}^{n}\langle\mathbf{r}_i^2\rangle+2\sum_{i=1}^{n-1}\sum_{j=i+1}^{n}\langle\mathbf{r}_i\cdot\mathbf{r}_j\rangle. \tag{65}$$

If there is only one mechanism of diffusion operative then in a cubic crystalline solid the length of each jump step will be the same, r. In addition, if the jumps are *truly random* then the last term in Eq. (65) will be averaged out to zero. For a cubic solid $\langle\mathbf{r}_i\cdot\mathbf{r}_j\rangle$ will be replaced by $\langle r^2\cos\theta_{ij}\rangle$, where θ_{ij} is the angle between the ith and jth jumps. Since all angles between jumps i and j will be found, the equation can be written simply as

$$\langle\mathbf{R}_n^2\rangle=nr^2. \tag{66}$$

Thus the average displacement, the root mean square displacement, is given by

$$\sqrt{\langle\mathbf{R}_n^2\rangle}=\sqrt{n}r. \tag{67}$$

If the n jumps take place in a time t, then the jump frequency Γ is given by

$$\Gamma=n/t \tag{68}$$

and

$$\langle\mathbf{R}_n^2\rangle=t\Gamma r^2. \tag{69}$$

The Einstein equation relates the diffusion equation to the mean square displacement, and for a cubic solid this is

$$D=\langle\mathbf{R}_n^2\rangle/6t. \tag{70}$$

Thus combining this equation with Eq. (67) yields

$$D=\Gamma r^2/6, \tag{71}$$

which is the *Einstein–Smoluchowski equation*.

1.2.7 Relations between Macroscopic and Microscopic Parameters. It is the Einstein–Smoluchowski equation that allows the connection to be made between the measured diffusion coefficient in an experiment and the parameters involved in the atomistic mechanism of diffusion. Here the case of self-diffusion of atoms in a monatomic solid by a vacancy mechanism is taken as the example.

The jump frequency of an atom, Γ, will depend on the probability that a vacant site is adjacent to the atom (the product of the site fraction of vacancies, c_v, and the coordination number z) and the jump frequency w_0 of the vacancy:

$$\Gamma = zc_v w_0. \tag{72}$$

Absolute reaction-rate theory, developed for chemical kinetics (Glasstone *et al.*, 1941), can be used to obtain an expression for w_0 in the form

$$w_0 = \nu \exp(-\Delta g_v^m/kT). \tag{73}$$

Here ν is the vibrational frequency of the atom in the direction of the vacancy (usually taken as the Debye frequency) and Δg_v^m ($\equiv \Delta h_v^m - T\Delta s_v^m$) is the Gibbs free energy of vacancy migration, i.e., the height of the potential-energy barrier that the atom has to overcome in passing from its initial site into its final site. There has been debate about the validity of this approach, as it implies that the jump process would have to occur slowly enough for thermodynamic equilibrium to be maintained. Thus "dynamic theories" have been proposed; however, it has been shown (Glyde, 1967) that these lead to essentially the same form of result.

Combining Eqs. (72) and (73) and substituting into Eq. (71) with the expansion of c_v yield the final expression

$$D = \frac{\nu z r^2}{6} \exp\left(\frac{s_v + \Delta s_v^m}{k}\right) \exp\left(\frac{-(h_v + \Delta h_v^m)}{kT}\right). \tag{74}$$

In experiments the temperature dependence of the diffusion coefficient in a crystalline solid usually obeys the *Arrhenius equation*:

$$D = D_0 \exp(-Q/kT), \tag{75}$$

where D_0 is called the preexponential factor and Q is the activation energy. Hence by comparing Eqs. (74) and (75) the following identities between the experimental and microscopic parameters can be made:

$$D_0 = \frac{\nu z r^2}{6} \exp\left(\frac{s_v + \Delta s_v^m}{k}\right) \tag{76}$$

and

$$Q = h_v + \Delta h_v^m. \tag{77}$$

It is possible to make a rough estimate of Δh_v^m at the same level of approximation used to estimate h_v, i.e., Eq. (61). As an atom moves from its site the number of bonds it needs to "break" with its neighbors is similar to those broken in vacancy formation. Thus Δh_v^m will also be approximately equal to L_s, i.e.,

$$\Delta h_v^m = L_s \tag{78}$$

and therefore

$$Q \simeq 2L_s. \tag{79}$$

This prediction should be reasonable where there is no relaxation, either electronic or lattice—for example, in molecular solids. If it is assumed that $\Delta s_v^m \simeq s_v \simeq 2k$, then it is possible to estimate the value of D at T_m as 10^{-8} $\mathrm{cm}^2\,\mathrm{s}^{-1}$, which is the value typically found experimentally for most solids.

1.2.8 Correlation Effects in Diffusion. In order to measure the diffusion coefficient it is necessary to "tag" atoms so that their motions can be followed; for example, they may be isotopically labeled as in a tracer experiment. If the motion of an individual atom that is tagged is followed, then it will be found that there can be correlations between successive diffusive jumps, depending on the mechanism. The simplest example that demonstrates correlation is that of diffusion in a pure solid via a vacancy mechanism. If the tagged atom makes a jump into a vacancy, then its *most probable next jump* is back to its original site, as there is a vacancy there ready to accept it. Thus the tracer jumps will be correlated although the jumps of the vacancy are random. For the tracer it is necessary to modify the diffusion coefficient to

$$D_t = fD_{\text{random}}. \tag{80}$$

Here D_t is the measured diffusion coefficient of the tracer, D_{random} is the diffusion coefficient given by random-walk expressions, and f is the correlation factor. Sometimes f is referred to as the *Bardeen–Herring correlation factor*, after the first workers (Bardeen and Herring, 1952) to note this correlation in the motion of tagged atoms. Since accurate values of f can be theoretically calculated for all the possible diffusion mechanisms in the different lattice structures, the determination of f provides an experimental route to the identification of diffusion mechanisms (LeClaire, 1970). Values of f are given in Table 1.

2. EXPERIMENTAL METHODS OF STUDYING DIFFUSION

A wide variety of methods can be employed in the investigation of diffusion. The focus here is on those that can provide direct, reliable information on the diffusion parameters and insights into the diffusion mechanisms. Of particular interest are clearly those methods that can yield accurate values of the diffusion coefficient. Thus techniques that provide indirect or limited diffusion information are not treated here. For example, the rate of plastic deformation (*creep*) under certain conditions is governed by atomic diffusion, and a study of the temperature dependence will yield good values of the activation energy for diffusion, Q, of the atoms. However, this technique, although useful, is limited in the detail it can provide and is not included in the discussion.

2.1 Methods of Measuring Diffusion Coefficients

2.1.1 Study of the Diffusion Penetration Profile. The most reliable method of measuring the diffusion coefficient is to determine the profile of labeled atoms that have been diffused from the surface of a sample in a known time at a constant temperature. In order to ensure that the true bulk diffusion coefficient is measured, the sample should be a single crystal with the minimum number of dislocations.

Table 1. Values of the correlation factor f for self-diffusion in simple lattices.

Mechanism of diffusion	Lattice	f
Vacancy	fcc	0.7815
	bcc	0.727
	sc	0.653
	Honeycomb	0.3333
Divacancy	fcc	0.458
Direct interstitial	Independent of structure	1
Collinear interstitialcy	fcc	0.9643
	sc	0.8000

The majority of the accurate diffusion coefficients that are available have been measured by the *radiotracer serial sectioning technique*, or its variants, and it is applicable to a wide range of solid types. The full details can be found in a number of texts (see, for example, Bénière, 1983; Mundy and Rothman, 1983). The basic procedures of this technique are shown in Fig. 6. First, a very thin layer of radiotracer is applied to a flat surface of the sample by vacuum sublimation or by deposition from a solution. The tracer may be an isotope of the host crystal (e.g., ^{22}Na to measure self-diffusion in Na, ^{36}Cl to measure chloride ion self-diffusion in NaCl, ^{14}C to measure carbon diffusion in steel, etc.). The sample is then annealed at constant temperature T for a known time t. Following the anneal the sample is sectioned parallel to the face of the tracer deposit and the sections subjected to a radioactive assay. This allows the determination of the penetration profile and the evaluation of the tracer diffusion coefficient from Eq. (6), i.e., using a plot of ln(tracer concentration) versus (penetration)^2. Two advantages of this technique are its simplicity and the relative cheapness of the equipment. In addition, the determination of D_t *directly* from the penetration profile provides a good test that bulk diffusion is being observed; the diffusion plot should be linear, and D_t should be independent of annealing time. An obvious disadvantage is the destructive nature of the sectioning, while the technique is limited to systems where convenient radiotracers, in terms of half-life and radiological safety, are available.

The controlling parameters in this experiment are basically the anneal time and the thickness of the sections. Reasonable times for the anneal lie in the range 10^3 s (any shorter and heating–cooling corrections become large) to 10^6 s (longer times would generally be inconvenient). A variety of techniques can be used to section the sample. For bulk samples, of the order of 10 mm dimensions, the sections are generally taken off with a microtome (for reasonably hard materials,

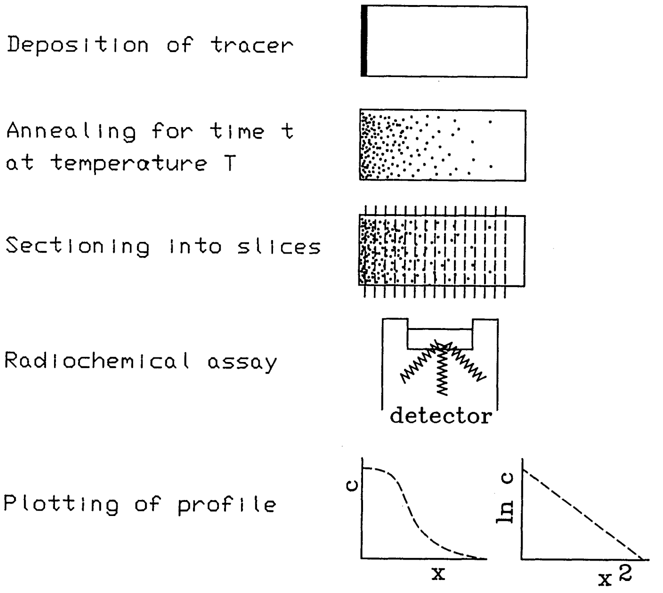


FIG. 6. Procedures of the radiotracer serial-sectioning diffusion experiment.

e.g., alkali halides), with a lathe (for metals), or by grinding (very hard materials), and the individual sections are usually in the 1- to 100-μm range. Using the criterion (Bénière, 1983) that the diffusion zone $[\sim 4(Dt)^{1/2}]$ should be divided into at least 13 sections over which the activity falls by a factor of 100 gives the useful range of D_t that can be studied with these types of sectioning as roughly 10^{-14} to 10^{-6} cm^2 s^{-1}. For smaller values of D_t, thinner sections need to be taken, and this is possible by sputtering (sections ~5 to 100 nm) and electrochemical etching (sections ~50 nm), putting the lower limit of D_t at around 10^{-17} cm^2 s^{-1}.

A very important variation of the technique is to use a stable isotope and secondary-ion mass spectroscopy (SIMS) to study the penetration profile (Macht and Naundorf, 1982; Lodding, 1987). This has proved particularly useful in the study of oxygen diffusion, as there is no radioactive isotope of this element and the diffusion is usually very slow. The sections taken in SIMS are in the range 1–100 nm allowing values of D_t as low as 10^{-19} cm^2 s^{-1} to be studied. In addition, very small samples, around 1 mm dimensions, can be used. However, the equipment required for a SIMS experiment is extremely expensive and requires a highly trained operator. Other means of determining the penetration profile of a tracer that are particularly useful in studying slow diffusion are the use of Rutherford backscattering and nuclear reaction analysis.

2.1.2 Measurement of the Atomic Jump Frequency. A wide variety of relaxation techniques can be used to deduce the jump frequency of atoms and hence allow the evaluation of D via the Einstein–Smoluchowski equation, i.e., Eq. (71). Generally these techniques rely on a theoretical model to relate the observed parameter to the microscopic atomic motion. This involves making some assumption about the nature of the *correlation function* (the function that expresses the probability that a particle originally at a position $\mathbf{r}=0$ at time $t=0$ is found at a position $\mathbf{r}=\mathbf{r}$ after a time t) and the *pair correlation function* (the probability that if an atom is at $\mathbf{r}=\mathbf{0}$ another atom will be found at $\mathbf{r}=\mathbf{r}$) (van Hove, 1954). Techniques that come into this category are dielectric relaxation spectroscopy, neutron scattering (Springer and Richter, 1987; Lechner, 1983), Mössbauer spectroscopy, and nuclear magnetic resonance (NMR) spectroscopy (Wolf, 1979; Strange, 1986; Kanert, 1982). The general advantages of these techniques are that they are nondestructive and rapid (the atoms only need to make a few jumps to give the effect and thus the observation time is short), and they are usually less demanding on sample requirements when compared to tracer methods (powders can be used in some cases). However, they often have limited applications to certain elements (e.g., Mössbauer spectroscopy can only be used for ^{57}Fe, ^{119}Sn, and a few other elements) and systems where diffusion is relatively fast, i.e., $D > 10^{-9}$ cm^2 s^{-1}. In addition, it is usually difficult to use these methods to give accurate values of D, because of deficiencies in the theoretical treatment of the correlation functions for an ensemble of atoms, although they will yield good values of Q. An exception to some of these current limitations is the NMR technique.

NMR diffusion experiments (see MAGNETIC RESONANCE, NUCLEAR) are best suited to systems where the NMR-active isotope is in high abundance and has nuclear spin s equal to $\frac{1}{2}$ (e.g., ^1H, ^{19}F) or a small quadrupolar moment (e.g., ^7Li, ^{23}Na). A reasonably large number of interesting systems fall into this category, particularly organic solids. There are a variety of NMR experimental procedures, but those in current common usage involve the measurement of a spin relaxation time in a pulsed spectrometer (Farrar and Becker, 1971; Fukushima and Roeder, 1981). The basis of the experiments involves disturbing the equilibrium spin population between a certain set of energy levels in the system by the application of a short burst (pulse) of radio-frequency power and then measuring the characteristic time required for the spins to return to equilibrium by monitoring the magnetization of the sample. For example, the spin–spin relaxation time T_1 is the time for the spins to equilibrate between the Zeeman levels whose separation is determined by the magnitude of the applied external magnetic field, $\mathbf{B}_0$. A spin in an excited state can only relax down to the lower level by losing a quantum of energy equal to the separation between the states, $\Delta E = \hbar\omega$, where ω is the Larmor precession frequency. This involves the spin interacting with oscillating magnetic fields in the system that fluctuate at a frequency equal to ω, i.e., it is a stimulated emission. In the system a spin will experience a *local field* due to dipole–dipole interactions with the neighboring spins. One source of oscillating magnetic field is the modulation of the local field caused by relative motion of the spins. Diffusive motion provides a fluctuating magnetic field whose frequency components are similar to those of a "noise spectrum." Analysis of this spectrum into its Fourier components yields the spectral density function, which depends on the atomic (spin) jump frequency Γ. The precise relationship between the measured relaxation time and Γ involves an assumption about the correlation function, and various models have been developed. However, it is clear that the relaxation will be most efficient (the relaxation time will be a minimum) when Γ is equal to ω. By measuring different relaxation times, i.e., probing different sets of energy levels for the spins, a wide range of Γ, and hence D, can be determined. Typically T_1 will monitor D in the range 10^{-11}–10^{-6} cm^2 s^{-1}; the spin–spin relaxation time T_2, the range 10^{-10}–10^{-6} cm^2 s^{-1}; the spin–lattice relaxation time in the rotating frame, $T_{1\rho}$, the range 10^{-14}–10^{-8} cm^2 s^{-1}; and the spin–lattice relaxation time in the local dipolar field, T_{1D}, the range 10^{-20}–10^{-12} cm^2 s^{-1}. Thus it is possible with one technique, using one spectrometer, to probe a very wide range of D.

Two further points concerning NMR methods are worthy of note. First, for cubic systems a precise theory relating relaxation times to Γ has been developed, tested, and shown to be reliable, and can be used to obtain accurate values of D. This is the *encounter model* as exploited by Wolf (1979) (see also Strange, 1986). Second, there is a further NMR technique, *pulsed-field gradient NMR*, that does not involve measurement of the relaxation time. In this experiment the spin is used to "label" atoms, like a tracer, and the time scale of the experiment is such that the atoms move macroscopic distances. Thus it is not subject to the criticisms outlined above and is particularly useful in the study of diffusion in liquids or solids where diffusion is rapid, i.e., $D > 10^{-9}$ cm^2 s^{-1} (Strange, 1986).

2.2 Ionic Conductivity Measurements

For materials that are ionic the measurement of the ionic conductivity provides a very powerful method of studying diffusion. As will be seen below, these experiments can yield not only information on the migration of the ions but also the concentration of point defects. This has been one of the major factors that has led to the current deep level of understanding of point defects and transport in ionic solids—a better understanding than in any other type of solid. Thus the measurement and interpretation of ionic conductivity has been described in a number of texts

(Lidiard, 1957; MacDonald, 1987; Chadwick, 1991; Corish and Jacobs, 1973; Jacobs, 1983) and is described here in some detail.

Samples for conductivity measurements are typically disks, about 100 mm^2 in cross-sectional area and 5 mm thick. Ideally the sample is a single crystal that has a known orientation, but this is not always available and it is common to use a compacted pellet. It is usually necessary to anneal the specimen close to the melting point prior to measurement to release any strains from the sample and to ensure a stable geometry. In the two-probe experiment most commonly in use, the large faces of the disk are placed in contact with the measuring electrodes in a cell with a controlled atmosphere and temperature. Many designs of conductivity cell have been published and the essential features of common systems are shown in Fig. 7. The key features of this design are that

1. the cell atmosphere can be controlled using either a purified inert gas stream or a dynamic vacuum (a very important feature when studying reactive materials like fluorides),
2. inert electrodes (usually graphite) are coated on the large faces of the sample to ensure good contact with the measuring electrodes and a true evaluation of σ from the measured conductance,
3. temperature is accurately measured by means of two thermocouples on each side of the sample, and
4. construction materials (high-purity silica, alumina, graphite, and platinum) that are involatile and unreactive to most materials are used in the hot zone.

This type of system can be used to make very precise conductivity measurements, and, provided the sample is thoroughly thermally equilibrated, the absolute accuracy is governed mainly by the accuracy of the thermocouples. The upper temperature limit of this cell, around 1000 °C, can be extended by replacing the silica components with alumina.

The conductivity is best measured by an ac technique to avoid polarization effects at the electrodes. Highly accurate ac conductivity–capacitance bridges, with errors around 1 part in 10^4, have been commercially available for many years. The earlier models were tedious to use as they were manually balanced and operated at a fixed, basic frequency, although separate signal generators and detectors could be attached to make frequency-dependence studies. Later generations of bridges were autobalancing, but still operated at fixed frequencies. The current generation of commercial systems are autobalancing, can rapidly scan a wide frequency range, and are readily interfaced to microcomputers to allow completely automated data collection. The evaluation from the raw data of the true "bulk" conductivity due to the motion of ions within the matrix of the lattice depends on the nature of the sample. The approach now in general use is that of complex-plane impedance analysis (Bauerle, 1969; Archer and Armstrong, 1981; MacDonald, 1987).

The application of a small, sinusoidally oscillating potential $\Delta E \sin \omega t$ with angular frequency ω ($=2\pi f$) across the electrodes will give rise to a current $\Delta i \sin(\omega t+\theta)$ that is

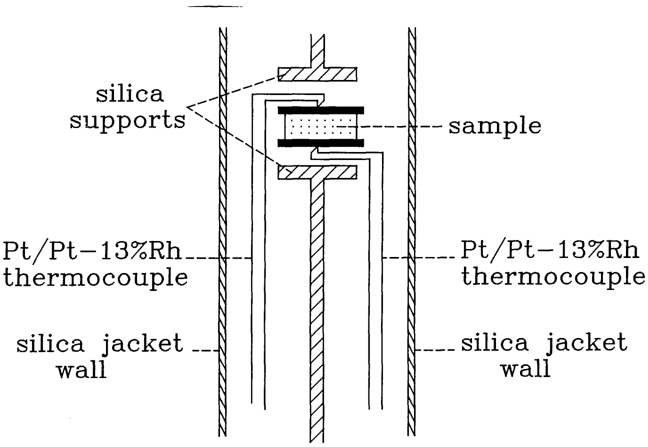

FIG. 7. Essential features of a cell for measuring the ionic conductivity of solids.

phase shifted by an angle θ. The impedance Z can be characterized by a combination of the ratio $\Delta E/\Delta i$ and the phase angle θ. It is convenient to represent Z at a given ω as a complex function and hence by a point on the complex impedance plane, where the y axis is the imaginary component, Z'', and the x axis is the real component, Z'. Thus $|Z|$ is the length of the line from the origin to the point and θ is the angle between this line and the x axis. The locus of Z as ω is varied will depend on the components in the circuit between the electrodes. The advantage of the complex-impedance representation is that a series combination of elements can be described by the vectorial addition of individual components. The situation is more complicated for a parallel combination of elements. For example, a simple combination of resistance R and capacitance C leads to a semicircle in the complex-impedance plot. For a parallel combination of elements it is often more useful to plot the admittance Y $(=1/Z)$ in the complex plane, i.e., the imaginary part B (the susceptance) versus the real part G (the conductance). All the parameters are interrelated, and it is possible to present the basic measurement of $|Z|$, ω, and θ in a variety of formats; the interconversion is a built-in feature of some of the commercial impedance analyzers. The problems in many studies are first to find the equivalent circuit that corresponds to the measurements and then to identify the circuit elements with physical features or chemical processes in the electrode-sample arrangement.

The simplest situation is that for a single crystal of a normal ionic conductor such as an alkali halide. In this case the circuit can be represented as a resistance and capacitance in parallel. Provided the frequency is high enough to avoid electrode polarization, usually $\geqslant 1$ kHz, then the measured conductance G will be the true bulk conductance of the sample, and extremely accurate measurements can be taken (the individual data points can be accurate to $\pm 0.1\%$). For materials with high ionic conductivities and for polycrystalline pellets the bulk conductance has to be extracted from the complex impedance or admittance plot. The ideal complex impedance spectrum for a ceramic pellet would consist of three semicircles, as shown in Fig. 8. Each of the contributions to the electrical behavior of the bulk material, i.e., the interior of the grains, the grain boundaries, and the sample–electrode interface, is represented by an RC component, and these are connected in series. Thus, in principle, it is possible to extract the true bulk conductance and to analyze it in terms of defect structures and transport mechanisms. However, the accuracy is necessarily lower than that achievable for alkali halides, and the number of data points that can be feasibly collected over a given temperature range is less. The complex-impedance spectra for many real pellets are more complicated than Fig. 8, and a number of strategies have to be adopted to identify the bulk resistance (e.g., varying the sample geometry, electrode preparation, impurity concentration, etc.). Good examples can be found in the original paper by Bauerle (1969).

Typical conductivity data for an ionic crystal, in this case sodium chloride, are shown in Fig. 9. It should be noted that this is very

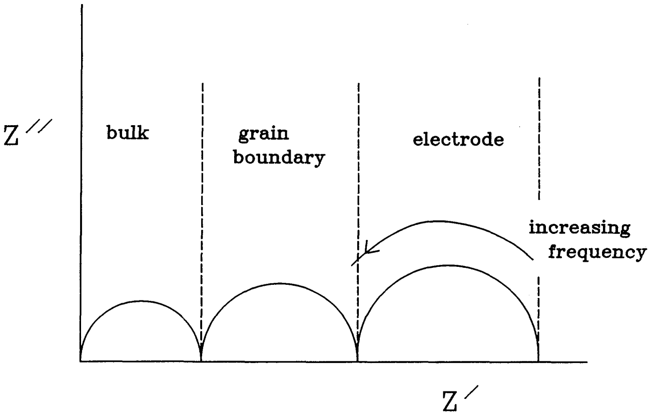

FIG. 8. Idealized complex-impedance spectrum for a ceramic ionic conductor.

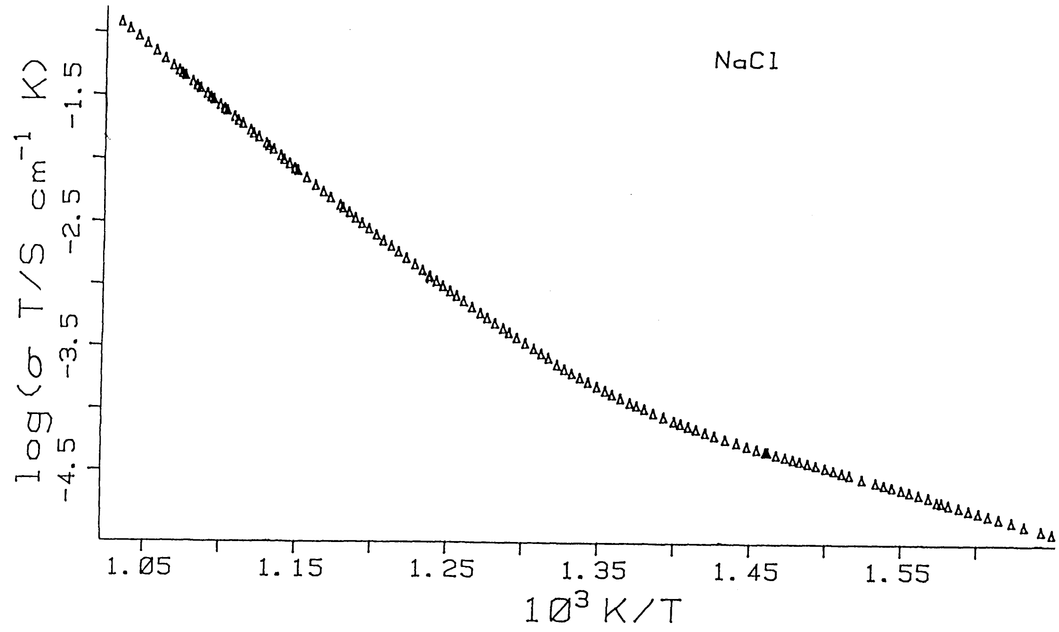

FIG. 9. Ionic conductivity data for a sodium chloride single crystal (after Hooton, 1988).

high-quality data with a high density of accurate points. The simplest first step in the analysis of data of this type is to determine the Arrhenius energies from the plot* of $\log(\sigma T)$ vs $1/T$. The next stage is to attempt to relate these to the microscopic conduction processes. The specific conductance of a substance is given by the relationship

$$\sigma = \sum_{\text{all } r} n_r |q_r| \mu_r, \tag{81}$$

where n_r is the number of conducting species of type r per unit volume, q_r and μ_r are its charge and mobility, respectively, and the sum is taken over all the types of mobile species. For a simple ionic crystal the species can be regarded either as the ions themselves or as the point defects by which they move. Thus values of n_r can be written down explicitly in terms of point-defect equilibria. Alkali halides will be considered as a simple example, and here the predominant point defects are Schottky pairs (a cation vacancy *cv* and an anion vacancy *av*) and the defect equilibrium is described by the equations in Sec. 1.2.2. It has already been mentioned that long-range defect interactions can be included by including activity coefficients γ_r, which can be calculated from the Debye–Hückel–Lidiard theory (Lidiard, 1957). This gives

$$\gamma_r = \exp\left(\frac{-q_r^2 \kappa}{2\epsilon kT(1+\kappa R)}\right), \tag{82}$$

where κ^{-1} is the Debye length, given by

$$\kappa^2 = 4\pi e^2 \sum_r \frac{c_r}{2a^3 \epsilon kT}. \tag{83}$$

Here, e is the protonic charge, ϵ is the permittivity, $2a^3$ is the volume per molecule of the salt, and R is the distance of closest approach between defects before the formation of a defect pair or complex. Thus it is possible to solve the mass-action equations using the constraints of charge and site balance and to write down an explicit expression for the concentration of any defect in terms of the thermodynamic parameters governing its formation and association with other defects and the corresponding activity coefficients.

The defect mobility μ_r is related to the defect jump frequency w_r by the expression

$$\mu_r = S_r |q_r| a_r^2 w_r / 6kT, \tag{84}$$

---

*In the older literature (and in some current papers) data are plotted as $\log\sigma$ vs $1/T$. However, this is not correct, as the mobility μ in Eq. (81) depends on $1/T$, and activation energies deduced from these plots will usually be slightly in error.

where S_r is the number of equivalent sites into which the defect can make a jump of distance a_r. The jump frequency w_r is given by Eq. (73). The mobilities can to be corrected for the drag experienced from the surrounding defect cloud by using the *Onsager–Pitts correction* (Lidiard, 1957).

Thus, given a model of the defect structure and transport mechanisms, it is possible to rewrite Eq. (81) with explicit expressions for the defect concentrations and mobilities. For an alkali halide crystal containing M^{2+} impurity this will contain nine parameters: the Schottky formation enthalpy and entropy, h_s and s_s; the migration enthalpies and entropies of the cation vacancy, $\Delta\mathscr{H}^{m}_{cv}$ and $\Delta\mathscr{S}^{m}_{cv}$, and anion vacancy, $\Delta\mathscr{H}^{m}_{av}$ and $\Delta\mathscr{S}^{m}_{av}$; the association enthalpy and entropy of the cation vacancy-M^{2+} complex, h_{IV} and s_{IV}; and the total M^{2+} concentration c_T. The modern procedure is to make a computer fit to the experimental data with these parameters as the variables in a nonlinear least-squares-fitting program. These programs will minimize the sum of the residual deviations squared, ϕ, i.e.,

$$\phi = \sum [\log(\sigma T)_{\text{calc}} - \log(\sigma T)_{\text{exptl}})]^2. \qquad (85)$$

The Debye–Hückel–Lidiard activity coefficients and the Onsager–Pitts correction are incorporated in the expressions, as are the temperature dependences of ϵ and a, if they are available. The advantages of the least-squares computer fitting approach are that it makes the best use of accurate data and that the *whole* conductivity plot is analyzed to yield a full set of defect parameters, for both defect formation and migration. Clearly, precautions in the fitting have to be taken (Jacobs, 1983; Chadwick, 1991); and to get really reliable defect parameters, crystals with a range of dopant concentrations have to be studied, and often other diffusion data are used as guidelines.

However, it is not always possible to obtain high-quality data over a wide temperature regime. In these situations a less detailed approach is required. It is usually reasonable to assume that only one type of the defect pair is present, and simple theoretical models will normally be able to identify which of the defects is the more mobile. It is then possible to obtain estimates of the enthalpy of defect migration and formation. For example, the more mobile defect in NaCl is the cation vacancy, and the dominant impurities in these crystals are divalent cations. Thus in the low-temperature region of Fig. 9 the cation vacancy concentration is determined by the impurities and, if *I-V* pairs are neglected, c_{cv} is given simply by Eq. (57). Substituting this into Eq. (81) shows that the slope of the *extrinsic conductivity region* is therefore equal to $-\Delta\mathscr{H}^{m}_{cv}/k$. Similarly, the value of c_{cv} in the high-temperature *intrinsic conductivity region* is given by Eq. (58), and the slope here is equal to $-(h_s/2+\Delta\mathscr{H}^{m}_{cv})/k$. Thus it is still possible to extract information on the defect-formation and -migration processes.

2.3 Methods of Identifying Diffusion Mechanisms

The ultimate aim of diffusion studies is to identify the nature of the atomic diffusion mechanism that is operative, i.e., vacancy, divacancy, interstitialcy, etc. Clearly, information on the nature of the dominant point defects in the solid will provide a starting point. For example, in close-packed metals the dominant defects are known to be vacancies, so that mechanisms based on interstitials can be ruled out. In less obvious situations one approach is to compare the experimentally determined diffusion parameters (predominantly activation energies but also activation volumes) with those obtained from theoretical calculations for the different mechanisms. In most cases this has been quite a sound approach, and with the advent of the modern computer-simulation procedures this is becoming even more reliable. For ionic solids the predictions from these calculations have been quite enlightening on some complex systems.

Direct experimental identification of the diffusion mechanism has usually relied on the determination of the correlation factor f. In principle, this can be determined from the study of the *isotope effect for diffusion* (LeClaire, 1970; Peterson, 1975), which involves the measurement of the differences in diffusion coefficient of two radiotracers, A and B, with different masses, e.g., ^{22}Na and ^{24}Na. However, there are only a few elements with convenient isotopes to use this approach, and the relations between f and D_A and D_B are not as simple as expected from the early work on this topic. The experiment will measure the product $f\Delta K$, where ΔK is the fraction of the kinetic energy of the jump that is carried by the tracer atom. In a jump many atoms around the tracer and defect will be involved; therefore, ΔK is not unity and is typically 0.8–0.9. In some well-understood systems where the diffusion mechanism and hence f are known, it is possible to work backward to determine ΔK; however, in an unknown system it can be hard to separate f and ΔK, and identification of the mechanism is not simple.

In ionic crystals the ionic conductivity arises from the movement of the effectively charged defects in the electric field. Since the diffusion of the defects is random, the diffusion coefficient calculated from the ionic conductivity D_σ via the Nernst–Einstein equation [Eq. (14)] will be the diffusion coefficient of the ions if they were moving randomly. Thus using Eq. (80) yields

$$f = D_t/D_\sigma, \tag{86}$$

and in principle the mechanism can be identified. However, the situation is often more complex. The ions may diffuse by more than one mechanism; e.g., the Ag^+ ions can diffuse by both vacancy- and interstitial-based mechanisms, and the ratio D_t/D_σ is not simply f. This ratio is still useful and is now referred to as the *Haven ratio.*

2.4 Computational Techniques

Computer simulation of defects and transport in solids is now well established, particularly for ionic materials, and the methodologies are described in a number of recent reviews (Catlow and Mackrodt, 1983; Catlow, 1987; Harding, 1990; Kehr and Binder, 1987). The simulation methods fall into three general types: *static lattice simulations, molecular dynamics* (MD) *methods,* and *Monte Carlo* (MC) *methods.*

Briefly, in the static lattice methods the atoms, with some appropriate mathematical representation of the interatomic potential, are placed on the sites of a representative portion of the lattice, and the energy of the lattice is calculated by pairwise summation of all the intermolecular forces. The calculation is then repeated with a defect in the center of the lattice to yield the energy of defect creation. The activation energy for diffusion can be calculated by placing the defect at the saddle point of the jump path—e.g., for the vacancy mechanism with the diffusing atom midway between the initial and final lattice sites. The success of the methods depends on the reliability of the interatomic potential and the ability to treat "edge" effects and relaxation in the system on defect creation. In ionic and semi-ionic solids the codes HADES and CASCADE have been thoroughly tested and shown to be remarkably successful for calculating defect formation and migration energies (Catlow and Mackrodt, 1983; Harding, 1990). These codes use the Mott–Littleton (1938) two-region procedure, where an inner region of ions (~ 100 ions) is treated explicitly and a large outer region is treated as an elastic and dielectric continuum. Fast minimization techniques are used to determine the minimum-energy configuration of the system. Quite sophisticated potentials, either empirical or *ab initio,* can be employed, and the effects of polarization of the ions have been incorporated using shell-model potentials. In essence the static lattice methods are calculations at 0 K and yield the internal energies of defect formation or migration. However, using the code SHEOL (Harding, 1990) the calculations for ionic solids can be extended to yield defect-free energies, enthalpies, and entropies. It should be noted that there are other methods of computing the defect entropies.

MD calculations (see MOLECULAR DYNAMICS) are often regarded as "experiments" (Bennett, 1984; Ciccotti and Hoover, 1986). An ensemble of atoms is arranged in the simulation box and the system allowed to evolve. Typically the box will contain 100 atoms with periodic boundary conditions to generate an infinite crystal. The atoms interact with a given potential, and they are started from coordinates close to lattice positions with trajectories and velocities corresponding to some given temperature. The system is allowed to "run," which means solving the classical equations of motion in a succession of small time steps (typically 10^{-15} s, which is less than the characteristic time of any motional process for the atoms, e.g., a lattice vibration) and continually updating the positions and velocities. Following an initial equilibration period the simulation should model all the properties, structural and dynamic, of the system. This method is useful for systems where there is rapid motion and a significant number of diffusive events can be observed in the time scale of the simulation. A limitation has been the demands on computing power due to the large memory requirement and therefore the necessity to use rather simplified potentials. With the developments in computers this limitation is not expected to be a major problem in the future.

MC methods (*q.v.*) (Kehr and Binder, 1987) are useful where high levels of disorder are present and a variety of types of jump of an atom may be possible in a system. The technique involves generating an ensemble of configurations by random moves and using an "acceptance criterion" to decide which of the configurations should be included in the ensemble. This leads to a picture of the most likely jump processes in the system.

3. DIFFUSION IN DIFFERENT SOLID TYPES

3.1 Metals and Alloys

Because of their technological importance there have been extensive studies of point defects and diffusion in metals (Brebec, 1983; Philibert, 1986). The most recent comprehensive and up-to-date collection of data can be found in the survey edited by Mehrer (1990). As expected for close-packed structures, the dominant disorder is single vacancies. Inevitably there will be vacancy aggregates (divacancies, trivacancies, etc.) present, but the concentrations are significantly smaller, and it is difficult to obtain reliable thermodynamic parameters of these defects. A variety of different techniques have been used to determine values of h_v in pure metals, and in the well-studied systems the values obtained from different experiments are consistent [see, for example, the comparison between the values from the positron-annihilation technique and quenching experiments (Eldrup, 1986)]. The values are considerably smaller than the simple prediction given in Sec. 1.2.3 that h_v would be $\sim L_s$; typically $h_v \sim (0.3–0.4)L_s$. The origin of this discrepancy is the atomic relaxation and electron charge redistribution that occurs on vacancy formation in a metal. Explicit calculations of defect parameters in metals are complicated by the complex electronic structure and the difficulty in describing the interatomic potential.

In the thoroughly studied fcc metals, like Al, Ag, Au, Cu, and Pt, the self-diffusion occurs predominantly via a vacancy mechanism. In cases where h_v and $\Delta \mathcal{H}_v^m$ can be determined separately, the sum of the two parameters agrees well with experimental values of Q, as illustrated in Table 2. The table also demonstrates the empirical observation that $\Delta \mathcal{H}_v^m \simeq 0.8 h_v$ for fcc metals. The Arrhenius plots of self-diffusion measurements for some of these metals exhibit slight curvature, the apparent activation energy increasing as T_m is approached. This can be seen in the data for Ag shown in Fig. 10. The most common interpretation of this effect is that there is a contribution to the diffusion from the migration via divacancies (Brebec, 1983; Philibert, 1986). Although the divacancy concentration is generally much lower than c_v, it is argued that they are more mobile than the single vacancies and hence have a significant effect on D as the temperature approaches T_m. It should be noted that an alternative interpretation is that single vacancies alone are responsible for self-diffusion but the defect enthalpies and entropies are slightly temperature dependent because of anharmonicity of the lattice vibrations (Mundy, 1992).

The self-diffusion in a number of bcc metals, notably β-Ti, β-Zr, β-Hf, and the rare-earth elements, reveals a strong curvature of the Arrhenius plots, and these have long been regarded as "anomalous" systems. A number of explanations have been proposed to explain the effect [see, for example, the recent reviews (Brebec, 1983; Philibert, 1986; Herzig and Kohler, 1987; Mundy, 1992)], including the presence of oxygen impurity, the presence of bulk defects, a contribution from divacancy diffusion, and temperature-dependent single-vacancy parameters. The contribution from divacancies has been a favored explanation, but recent work (Herzig and Kohler, 1987) related the self-diffusion to soft-phonon modes and provides a uniform explanation of the data in terms of single vacancies.

Table 2. Experimental values for the enthalpy of vacancy formation, h_v, enthalpy of vacancy migration, $\Delta \mathcal{H}_v^m$, and self-diffusion in fcc metals.

	Experimental enthalpies eV		
Metal	h_v	$\Delta \mathcal{H}_v^m$	Q
Cu	1.30	0.80	2.05
Ag	1.10	0.83	1.91
Au	0.98	0.82	1.81
Al	0.77	0.65	1.46

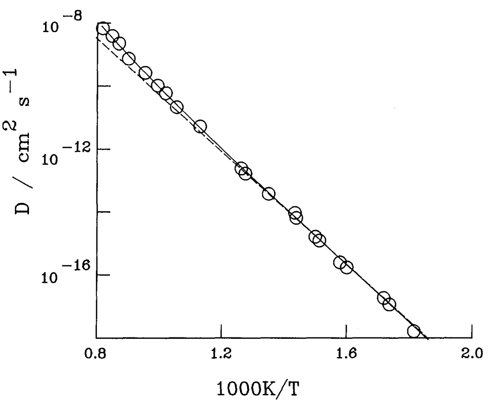

FIG. 10. Compiled self-diffusion coefficient of silver as a function of temperature (after Brebec, 1983).

The literature on metallic alloys is also very extensive, and a wide range of materials have been investigated (Brebec, 1983; Philibert, 1986). It is appropriate here to consider only the dilute alloys. The sites occupied in the host lattice depend mainly on the size of the impurity; atoms of a similar size will dissolve substitutionally, and small atoms can occupy interstitial sites (e.g., C, N, and O in bcc metals like α-Fe). Interstitial impurity diffusion in dilute alloys is consistent with the impurity migrating via the direct interstitial mechanism. In substitutional alloys the diffusion data are usually interpreted in terms of the *five-frequency model* (Brebec, 1983; Philibert, 1986). In this model the diffusion coefficients of the host impurity atoms are derived as functions of the defect concentrations and the five distinct types of jump of the vacancy:

1. vacancy adjacent to impurity exchanging with the impurity,
2. vacancy adjacent to impurity exchanging with host atom and remaining adjacent to the impurity,
3. vacancy adjacent to impurity exchanging with host atom and moving away from the impurity,
4. the reverse of **3**, and
5. vacancy exchanging with a host atom on sites not adjacent to the impurity.

There are some well-documented systems where the impurity exhibits anomalously fast diffusion in the alloy—for example, Cu, Pd, Au, Ni, and Ag in Pb, and Au in the alkali metals. In these cases the vacancy mechanism seems inappropriate and various forms of interstitial process have been suggested to explain the anomalies.

3.2 Molecular Solids

Molecular solids represent the largest group of materials, as they include all the organic and biological materials, which are virtually infinite in number given the facility of carbon to bond covalently with itself and a range of other elements (e.g., O, N, H, S, etc.). Information on the point defects in these materials is sparse, a result of both the experimental difficulties in studying these crystals (i.e., high vapor pressures, low purity) and the lack of technological interest in the systems as solids. The interest has been primarily of an academic nature, particularly in the case of the rare-earth gas solids where relative simplicity of the interatomic forces makes them ideal model systems.

It is convenient to divide molecular solids into three types:

1. *rare-gas crystals,*
2. *plastic crystals*—systems where the molecules are roughly spherical, undergo a rapid endospherical reorientation, and adopt highly symmetric crystal structures, usually fcc, bcc, and hcp (Sherwood, 1979), and
3. *nonplastic crystals*—the majority of organic crystals, where the molecular symmetry is low, the molecules are not reorienting, and the crystal structure is determined by packing factors.

In all three types the crystal structures are close packed and the expected dominant point defects are vacancies.

3.2.1 Rare-Gas Crystals. There have been a large number of theoretical estimates of the vacancy formation and migration parameters in rare-gas crystals (Chadwick and Glyde, 1977; Chadwick, 1983). The interatomic potentials employed range from Lennard–Jones potentials to sophisticated empirical potentials, and in most cases it is concluded that $h_v \simeq 1L_S$ and $\Delta \mathscr{H}_v^m \simeq 1L_S$, consistent with the simple predictions in Secs. 1.2.3 and 1.2.7. There have been several experimental studies of vacancy concentrations in rare-gas solids. The experiments are extremely difficult, and there is still some confusion over the experimental vacancy formation parameters. For example, the earlier experiments for solid krypton yielded $h_v \sim 0.7L_s$, whereas the value for neon was $1L_s$. The experiments for krypton were over a limited temperature range and the data analysis has been questioned, and there is a need for new studies on this system.

The diffusion data for rare-gas crystals from a number of sources, including radiotracers and NMR, suggest that these systems are well behaved (Chadwick and Glyde, 1977; Chadwick, 1983). The parameters are consistent with the simple theoretical predictions, i.e., Q is close to $2L_s$.

3.2.2 Plastic Crystals. In many respects the simpler plastic crystals can be considered as analogous to rare-gas crystals; the rapid molecular reorientation averages out the interactions between atoms on separate molecules, and these can be replaced by a single intermolecular potential acting between molecular centers of gravity. The simplest predictions (Chadwick, 1983) are therefore that $h_v \simeq 1L_s$ and $\Delta h_v^m \simeq 1L_s$. The same results have been obtained in the case of adamantane, where calculations have used atom–atom potentials (Meyer *et al.*, 1986). Reliable information on vacancy-formation parameters in plastic crystals is limited to a positron-annihilation study of two materials, adamantane and bicyclooctane, which yielded $h_v = 1L_s$ in both cases (Lightbody *et al.*, 1980).

There have been a large number of self-diffusion studies in plastic solids (Sherwood, 1979), as the motion is relatively rapid at moderate temperatures (D at T_m is typically 10^{-9}–10^{-8} cm^2 s^{-1} and T_m is less than 300 °C) and a wide number of diffusion techniques can be employed. NMR measurements for these materials are particularly appropriate, as D is in the required range and the organic plastic crystals usually contain a suitable nucleus (e.g., ^{1}H). In many cases the simple prediction of $Q \simeq 2L_s$ seems to be observed, but there are a number of systems where NMR methods yield lower values of Q (e.g., $Q \simeq 1L_s$ in cyclohexane and white phosphorus). This apparent anomaly is still unresolved.

3.2.3 Nonplastic Crystals. The diffusion in nonplastic solids is around 4 to 5 orders of magnitude *slower* than that in plastic crystals. The diffusion experiments are therefore difficult, and only a few systems, mainly simple aromatic ring systems like anthracene and naphthalene, have been studied. The general results are that $Q \simeq 2L_s$ and that the dominant point defects are single vacancies (Chadwick, 1983).

3.3 Covalent Solids

There has been considerable debate over the nature of the point defects in both elemental (e.g., C, Si, Ge) and compound covalent crystals. In essence the problems arise in assigning the electronic structure around the defect, e.g., what happens to the "dangling bonds" when an atom is removed to form a vacancy. Each broken bond contains one electron, which may occupy lower energy levels by forming new bonds across the vacancy with the dangling bonds of neighboring atoms. Self-diffusion and impurity diffusion have been very actively studied in these materials, particularly for systems where there are semiconductor applications, as the information is useful in device fabrication. In the elemental crystals the self-diffusion is extremely slow (D at T_m is typically 10^{-13}–10^{-12} cm^2 s^{-1}), and the mechanisms that are operative have not been fully resolved (Gosele and Tan, 1992; Leroy, 1990). It is now believed that both self-interstitials and vacancies are involved in the self-diffusion and most impurity diffusion processes in Si and GaAs, a suggestion made over 20 years ago (Seeger and Chik, 1968) that is now being substantiated by experiments.

3.4 Ionic Solids

Of all the solid types, the point defects and diffusion are best understood in ionic crystals. This is due to a combination of factors, some of which are evident from the foregoing sections. From the experimental viewpoint there are a number of good model systems, like the alkali and silver halides, that are readily available in the form of large single crystals. In addition, it is possible to control the defect concentrations precisely by means of doping with aliovalent impurities. However, the greatest advantage over other materials in defect and diffusion studies is that the technique of ionic conductivity provides a relatively simple and accurate means of determining defect-formation and -migration parameters. The combination of ionic conductivity and diffusion measurements also provides a means of identifying mechanisms via the Haven-ratio method. From the theoretical viewpoint the interionic potential can be well represented by fairly simple mathematical functions, and therefore computer simulation methods have proved highly successful.

In the last two decades it has been convenient to consider ionic solids as being of two types, *normal ionic conductors* and *fast-ion conductors*, and these will be discussed separately.

3.4.1 Normal Ionic Solids. Normal ionic conductors are materials like the alkali halides where the conductivity is well described by jump mechanisms of simple point defects and the ionic conductivity is around 10^{-3} S cm^{-1} at the melting point. Most of the detailed conductivity and diffusion work has focused on the simple systems like the metal halides, particularly those with the rock-salt and fluorite structures, because of the ease of experiment, although very similar behavior is expected for the higher-melting-point oxides. For a large number of systems there is now a wealth of experimental information, including the nature of the dominant point defects, the thermodynamic parameters for point-defect formation and migration, and the nature of the self-diffusion mechanisms (Lidiard, 1957; Corish and Jacobs, 1973; Chadwick, 1991; Jacobs, 1983). In many of these systems static lattice computer simulations have been extremely successful in calculating the defect parameters (Catlow, 1987).

The systems for which there is the best experimental information are the alkali halides, the silver halides, and the alkaline-earth fluorides. Some of these data are shown as an example in Table 3. Only the principal point-defect enthalpies are shown; however, in many cases the entropies and the parameters for defect association are available. The dominant defects in the alkali halides are Schottky pairs, and both ions diffuse by a vacancy mechanism. The diffusion coefficients of both ions are similar. For systems like NaCl and KCl there is a wealth of data, and the level of interpretation is now extremely sophisticated (see, for example, Hooton and Jacobs, 1988), including contributions to the ion transport from vacancy pairs and Frenkel defects (which are present in very low concentrations but are mobile enough to make a significant effect on the transport at high temperatures). In silver chloride and bromide the dominant point defects are cation Frenkel pairs, and not surprisingly the cation diffusion coefficient is about 1000 times higher than that for the anion. In the intrinsic region the silver ions move predominantly by interstitialcy mechanisms, both collinear and noncollinear, while in the extrinsic region of crystals doped with divalent cations (i.e., doped with excess cation

Table 3. Point-defect enthalpies (in eV) for simple ionic crystals.

Material	Point-defect enthalpy	Experimental value determined from ionic conductivity	Calculated value from computer simulation
NaCl	h_S	2.41	2.32
	Δh^m_{cv}	0.67	0.65
	Δh^m_{av}	0.77	0.71
KCl	h_S	2.50	2.50
	Δh^m_{cv}	0.67	0.71
	h^m_{av}	0.85	0.69
AgCl	h_{cF}	1.49	1.4
	Δh^m_{ci} (noncollinear)	0.10–0.12	
	Δh^m_{ci} (collinear)	0.002–0.004	
	Δh^m_{cv}	0.27–0.28	
CaF_2	h_{aF}	1.85	1.98
	Δh^m_{av}	0.52	0.40
	Δh^m_{ai} (noncollinear)	0.79	0.72
BaF_2	h_{aF}	1.91	1.98
	Δh^m_{av}	0.57	0.46
	Δh^m_{ai} (noncollinear)	0.76	0.72
MgO	h_S	5–7	7.5
	Δh^m_{cv}	2.2–2.6	2.18

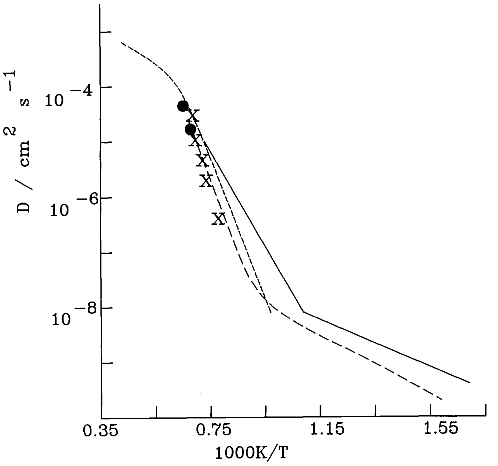

FIG. 11. Ionic transport data for Li_2O. A plot of the Li^+ diffusion coefficient from ionic conductivity (long-dashed curve), molecular-dynamics simulations (short-dashed curve), static lattice simulations of HADES and SHEOL (solid line), tracer (crosses), and neutron data (filled circles) (after Flack, 1990).

vacancies) the silver ions diffuse by a vacancy mechanism. The alkaline-earth fluorides at moderate temperature, up to about $0.8T_m$, behave as normal ionic crystals with anion Frenkel pairs as the dominant defects, and the fluoride ion diffuses predominantly by the vacancy mechanism, although there is a significant contribution from the noncollinear interstitialcy process (Jacobs, 1983).

The success of the computer modeling when applied to the point-defect parameters of ionic crystals is also seen in Table 3. In a recent study (Chadwick *et al.*, 1988; Flack, 1990) of lithium oxide, Li_2O (a material with the antifluorite structure), it was possible to compare experimental conductivity and diffusion data with a range of computer-simulation methods. The results are shown in Fig. 11 and the agreement is excellent. The successful testing of the computer calculations in simple systems means that they can now be used with confidence in predicting the behavior of more complex ionic materials.

3.4.2 Fast-Ion Conductors. There are a number of ionic solids with unusually high ionic conductivities, the magnitude of the conductivity approaching that found in molten salts and aqueous electrolyte solutions, and these are now variously referred to as *fast-ion conductors* or *superionic conductors* or *solid electrolytes*. Tremendous interest has been shown in these materials for technological applications where a purely ionic conductor is required, e.g., in solid-state batteries and fuel cells. There is an extensive literature on these materials, including books (Chandra, 1981; Laskar and Chandra, 1990; Stoneham, 1989), reviews (Schulz, 1982; Catlow, 1990; Chadwick, 1992), and a specialized journal (*Solid State Ionics*). Conductivity plots for a few fast-ion conductors are shown in Fig. 12. It can be seen that a wide range of solid types exhibit the phenomenon, i.e., fluorite-structured solids at high temperature (e.g., PbF_2), silver iodide and related compounds (e.g., $RbAg_4I_5$), and layered structures (e.g., β-aluminas). Clearly in terms of Eq. (81), in order for there to be a high ionic conductivity the point defect in the solid must have exceptionally high concentrations and/or exceptionally high mobilities.

The types of ion that show fast-ion conduction are usually small with low formal charges, e.g., Li^+, Na^+, F^-, H^+, and O^{2-}. It has now been realized that there is no unique origin to fast-ion conduction in the different systems, and therefore a variety of theoretical approaches have to be adopted. There are several ways of classifying fast-ion conductors, depending on their structure (open, tunnel, layered, glasses, polymers, etc.) or their applications. A very useful approach developed by Catlow (1990) and explored by others has been to use a hybrid classification based on structure and mechanism. Thus the types of class include solids that are fast-ion conductors as a result of a phase transition (like AgI), massively disordered and heavily doped materials (such as ZrO_2 stabilized in the cubic

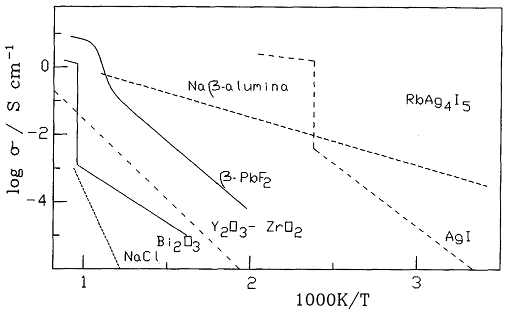

FIG. 12. Conductivity plots for several fast-ion conductors.

phase by impurity), and layered structures (like the β-aluminas).

There are still many problems to be resolved in fast-ion conductors, particularly the precise nature of the diffusion mechanisms. In many cases the diffusion is so rapid that many of the conventional experimental probes are inadequate. An additional problem is the lack of availability of good single crystals, and a measurement of the ionic conductivity is virtually the only transport technique that is applicable. Thus there is often a lack of precise information on which to base deductions concerning mechanisms. In much of the early work it was believed that the diffusion of the ions was liquidlike, with ions in continuous motion, and that defect-jump models would be inappropriate. However, a picture is now emerging, particularly from molecular-dynamics computer simulations (Gillan, 1989), that in most fast-ion conductors the mobile ion spends most of the time on a lattice site and a relatively short time "in transit" between sites. Molecular-dynamics simulations are particularly applicable to fast-ion conductors, as the diffusion is sufficiently rapid that a significant number of diffusive jumps can be observed in a computational time that is not prohibitive.

4. DIFFUSION IN AN APPLIED FIELD

The investigation of diffusion in an applied field, either an electric field (*electromigration*) or a temperature gradient (*thermomigration*), is difficult from both experimental and theoretical viewpoints (Allnatt and Chadwick, 1967; Wever, 1973; Hummel and Huntington, 1977; Gillan, 1983). However, the phenomena are extremely important technologically as they can lead to "unimixing" of a system. When there are large electric fields and current densities, as in a thin-film metal connection on a semiconductor device, electromigration can lead to a net movement of the metal in one direction and an eventual break in the connection. Similarly, a large temperature gradient, as is found in the walls of a furnace or in the fuel element of a nuclear reactor, can lead to segregation of one of the components of a material and ultimately mechanical or chemical breakdown. The academic interest in these phenomena lies in the fact that they provide a severe test of the atomistic models of diffusion in solids.

There have been few studies of electromigration. One method of study of impurity electromigration is to place a tracer between two slices of material and measure the drift of the tracer after the application of a large field across (and large current through) the sandwich. Self-electromigration is studied by placing markers along a specimen and noting their relative movement in the applied field. In metals the movement of the atoms can be considered as due to the *effective charge* of the atom interacting with the flow of electrons, termed the *electron wind effect*.

Thermomigration in pure solids can also be studied in marker-movement experiments, and these have been used to study metals. However, the experiments are extremely difficult to perform, as distortion of the samples complicates the interpretation. For impurity thermomigration it is possible to use the Soret effect, the steady concentration gradient of impurity developed in the temperature gradient. From Eq. (15) at steady state the flux will be zero and hence $Q^{*\prime}$ can be deduced from the concentration gradient, i.e.,

$$\frac{1}{c}\left(\frac{\delta c}{\delta x}\right)=\frac{Q^{*\prime}}{kT^2}\left(\frac{dT}{dx}\right) . \tag{87}$$

This experimental approach has been used to study thermomigration of impurities in a variety of types of solids. In ionic crystals the effect of thermomigration is to tend to separate the charged species. The incipient separation is opposed by an electric field, the *thermoelectric power*, and this provides a very convenient means of studying thermomigration (Allnatt and Chadwick, 1967; Gillan, 1983) and determining the heats of transport.

From the earlier description of the heat of transport, the heat carried from the initial site to the final site in an isothermal jump of an atom, it is clearly a complex parameter to evaluate, since at the atomic level the energy of the jump is spread over many atoms and $Q^{*\prime}$ depends on how this energy is redistributed after the jump. An early, simple theory, due to Wirtz (1943), predicted that $Q^{*\prime}$ would be equal to or less than the activation enthalpy of migration of the atom, Δh^m. Later this was simplified to $Q^{*\prime}=\Delta h^m$ in the LeClaire–Brinkman theory (LeClaire, 1954; Brinkman, 1954), i.e., the atom carries all the migration enthalpy from initial site to final site. In systems where there is simple vacancy diffusion, e.g., in alkali halide crystals, this seems to be reasonable as experiments show $Q^{*\prime} \sim \Delta h^m$. However, in cases where interstitial migration is known then this theory fails and does not even predict the correct sign for $Q^{*\prime}$; in these systems experimental values of $Q^{*\prime}$ are usually negative (Allnatt and Chadwick, 1967; Gillan, 1983). This probably reflects the highly cooperative nature of interstitial diffusion processes.

5. SUMMARY

The objective of this article has been to present the basics of the diffusion and ionic conductivity in solids to form a foundation on which to build by further reading. The nature of the different types of point-defect diffusion has been presented along with an introduction to defect thermodynamics. The situation in the different types of solid can be summarized as follows:

Metals: In pure metals the dominant defects are single vacancies. The defect physics of fcc metals is well understood as a result of reliable measurements of defect concentrations and diffusion. In bcc metals the dominant defects are also single vacancies, although there has been some debate concerning the role of divacancies in diffusion. The lattice positions occupied by impurities depends mainly on their size, small impurities (with respect to the host atoms) occupying interstitial sites and larger impurities dissolving substitutionally.

Covalent solids: The defects are less well understood in these systems because of the role of "dangling bonds" and the very low diffusion coefficients. The diffusion is complicated and appears to involve both vacancies and interstitial defects in some form.

Molecular solids: These have not been thoroughly studied, mainly because of the lack of technological applications. As the structures are close packed it is generally assumed that the dominant defects are single vacancies and diffusion is via a vacancy mechanism; these assumptions are upheld by the very limited amount of experimental data.

Ionic solids: These are extremely well understood in terms of their defect physics as the result of the ability to vary the defect concentrations deliberately, experimentally, by doping with aliovalent ions. In addition, ionic conductivity measurements provide an excellent probe of both the defect concentrations and mobilities.

The references given in the list of Further Reading will provide plenty of material for the interested reader to extend his or her knowledge and to consider the various processes where the defects and diffusion play a vital role, for example, in corrosion, catalysis, the photographic process, materials design, etc.

GLOSSARY

Correlation Factor: The degree of correlation between successive diffusive jumps of a labeled atom in a solid (more correctly termed the *Bardeen–Herring correlation factor*).

Divacancy: Two vacancies on neighboring lattice sites.

Doping: The deliberate addition of impurities to a solid.

Electromigration: Diffusion in an applied electric field.

Frenkel Defect: Defect in an ionic crystal consisting of a vacancy and an interstitial of one of the ions (hence two types are possible: *cation Frenkel defects* and *anion Frenkel defects*).

Fast-Ion Conductors: Solid with an unusually high ionic conductivity (sometimes referred to as *superionic conductors*).

Haven Ratio: For an ionic solid, the ratio of the tracer diffusion coefficient to the diffusion coefficient calculated from the ionic conductivity via the Nernst–Einstein equation.

Interstitial Atom: An atom on an interstitial lattice site in a crystal.

Interstitial Diffusion: The diffusion process in which an interstitial atom jumps from interstitial site to interstitial site.

Interstitialcy Diffusion: The diffusion process in which an interstitial atom jumps onto a normal lattice site as the atom on that site moves onto an interstitial site.

I-V Pairs: An impurity atom and a vacancy on neighboring lattice sites.

NMR: Nuclear magnetic resonance.

Plastic Crystal: A molecular solid with globular molecules that are undergoing rapid endospherical reorientation. The crystals have high symmetry (cubic or hexagonal lattices) and tend to be easily plastically deformed.

Point Defect: A defect in a crystal at the atomic level (see **Vacancy** and **Interstitial Atom**).

Schottky Defects: Point defect in an ionic solid consisting of cation and anion vacancies.

SIMS: Secondary-ion mass spectrometry.

Site Fraction: The concentration of a species in a crystal measured as the ratio of the number of molecules of the species to the total number of sites in the crystal the species could occupy.

Thermomigration: Diffusion in an applied temperature gradient.

Tracer Diffusion: The measurement of diffusion coefficients by monitoring the penetration of isotopic tracer atoms into a solid.

Vacancy: An unoccupied lattice site in a crystal.

Vacancy Diffusion: The diffusion process in which an atom moves by jumping into a neighboring vacancy.

INTRODUCTION

The formation, structure, and dynamics of the ionosphere—a layer of partially ionized gas extending from about 50 to beyond 1000 km—are the central topics of this article. Up to the start of the space age—around the 1960s—our main information about the ionosphere was obtained by the use of radio waves reflected from the different ionospheric layers. During the last three decades instrumented rockets and satellites have been widely used in the studies of the ionosphere, particularly the ionosphere poleward of approximately 60° latitude.

The polar ionosphere is much more complicated than the ionosphere at lower latitudes. While solar radiation with wavelengths below ~250 nm is the principal ionization source of the low-latitude ionosphere, energetic electrons and ions from the magnetosphere and solar wind significantly contribute to the production of the polar ionosphere. These charged particles are also the main source of the aurora, contributing to intense electric fields and currents within the ionosphere. The electric and magnetic fields control the motion of electrons and ions within the ionosphere and thereby influence the global distribution of ionization.

After a short historical preamble and a brief review of the Earth's neutral atmosphere and its magnetic field, we will concentrate on the production and the characteristics of the ionosphere. Physical and chemical processes as well as interactions between the different ionospheric regions and the magnetosphere will be discussed. A section on ionospheres of other planets together with a short summary of items that should have high priority during the coming decade conclude this article.

1. DEFINITION AND HISTORICAL PREAMBLE

The Earth's ionosphere extends from ~50 to over 1000 km and is a partially ionized gas that envelops the Earth, interfacing the upper atmosphere with the magnetosphere. Electrons in concentrations from 10^8 to greater than 10^{12} m^{-3} roam free from their parent ions and move with their thermal speed under the influence of the ambient electric (**E**) and magnetic (**B**) fields in an anisotropic manner relative to the geomagnetic field. As the atmo-

spheric density decreases with increasing altitude, the motion of charged particles changes from collision-dominated to collisionless motion following **E**×**B** drift paths. The electrons carry currents and influence radio-wave propagation, an effect that historically provided the first clues of the ionosphere's existence.

When Appleton and co-workers in 1925 had demonstrated the existence of the Earth's ionosphere by the use of radio waves and obtained reliable measurements of its height, studies were begun of both the nature of the upper atmosphere and the ionospheric formation (cf. Ratcliffe, 1972). Naturally, one first studied the simpler ionospheric aspects and only later concentrated on the more complicated polar ionosphere. Actually, between 1925 and 1955 ground-based radio measurements led to a fairly complete understanding of the average characteristics of the ionosphere and the atmosphere between the heights of about 90 and 300 km. The name ionosphere for this region was coined by R. A. Watson-Watt in 1926.

Quite a bit was known about the "ionosphere" even before it was discovered by the radio technique. The First International Polar Year (1882–83) could be regarded as marking the beginning of modern ionospheric and auroral research. Studies of the Earth's magnetic field by Stewart (1882) suggested that the upper atmosphere acted as the armature of an "atmospheric dynamo." Thus, the current hypothesized by Stewart explains the regular daily variations (S_q; S is short for Sun and q for quiet) of the geomagnetic field observed on the ground at mid and low latitudes. Two important suggestions regarding the ionosphere were made around the turn of our century, namely:

1. A. E. Kennelly and O. Heaviside suggested the existence of a layer of ionized gas in the upper atmosphere to explain G. Marconi's transmission of radio signals from England to Newfoundland.
2. On the basis of data from a network of geomagnetic observatories in the auroral regions, Birkeland (1908) introduced and estimated the heights of "ionospheric currents" 25 years before the basic character of the ionosphere was actually established (cf. Ratcliffe, 1972; Chapman and Bartels, 1940).

Probably the most spectacular of nature's phenomena, the aurora (also called the northern light and/or the polar light) has stirred man's imagination, curiosity, and fear since the dawn of man. The aurora is the visible means by which we can observe the coupling of energy from the Sun via the magnetosphere to the ionosphere and atmosphere. These processes involve field-aligned currents (now referred to as Birkeland currents) and horizontal currents (the auroral electrojet) in the polar ionosphere. It was from studies of the aurora around the turn of the century that sunspots and charged particles were first tied to ionospheric dynamics by Birkeland (1908).

Man's interest in the ionosphere mainly developed because of the need for long-distance radio communications and out of general curiosity. A fairly detailed ionospheric knowledge would be desirable in improving and extending communication quality. Today, modern, *in situ* ionospheric research is mainly conducted through the use of sophisticated instruments on board rockets and satellites, closely coordinated with data from advanced ground-based equipment. Even active controlled experiments—e.g., using radio transmitters to heat the ionosphere from the ground and/or chemical and charged-particle injections from rockets and satellites—are today regularly performed. The use of instrumented rockets and satellites, beginning about 1955, at first mainly confirmed previous findings and ideas about the ionosphere. However, after about 1960 new information about the topside ionosphere (i.e., above about 400 km) as well as the lower region (i.e., below 90 km) was obtained. In addition, new ground-based techniques, such as partial-reflection, cross-modulation, coherent-scatter, and incoherent-scatter radars, have yielded a lot of new information about the ionosphere during the last 30 years.

2. THE EARTH'S UPPER ATMOSPHERE AND MAGNETIC FIELD

The Earth's upper atmosphere and its magnetic field strongly influence the structure and dynamics of the ionosphere. The atmospheric composition affects the density of charged particles while the geomagnetic field influences charged-particle transport. Only those aspects important to the ionosphere will be discussed here.

We define the upper atmosphere as the atmosphere above the stratopause, i.e., above ~50 km. This is also where ionization levels become significant. The atmosphere has no sharp upper limit, but here we will concentrate on the atmosphere below ~1000 km.

Density, composition, and temperature are the atmospheric properties of primary importance to the ionosphere because of their effects on collision frequency and recombination processes, respectively. The average density profiles for the major atmospheric constituents of an International Standard Atmosphere are sketched in Fig. 1 (see also ATMOSPHERIC PHYSICS; ATMOSPHERIC STRUCTURE). Typical temperature curves are shown in Fig. 2. The density curves represent idealized, year-round, mid-latitude conditions under mean solar activity. Large temporal and spatial variations occur, especially above 200 km. The primary gases up to ~120 km are molecular oxygen (≈20%) and nitrogen (78%), while atomic oxygen is very important above 120 km. Minor constituents such as water vapor (H_2O), nitric oxide (NO), hydroxyl (OH), and sodium (Na) are all important for photochemical processes in the upper atmosphere up to 100 km. Notice that density and pressure decrease rapidly (approximately exponentially) with height up to approximately 100 km. Above this height the decrease is significantly slower (see Fig. 1). The atmosphere is considered to rotate with the Earth (cf. *U.S. Standard Atmosphere*, 1976).

The energy budget for the upper atmosphere, whose main energy source is ultraviolet radiation from the Sun, is sketched in Fig. 3. Electromagnetic radiation from the Sun (in units of $\mathrm{W\,m^{-2}\,nm^{-1}}$) outside the atmosphere and at the Earth's surface is shown in Fig. 4. The albedo is approximately 0.3, which means that ~30% of the radiation is reflected back into space. Roughly 45% of the energy is found within the visible spectrum, normally defined as from 400 to 700 nm, while approximately 10% of the energy is within the ultraviolet (uv) and x-ray bands. The total energy—integrated over all wavelengths—is called the solar constant because it is practically independent of solar activity; however, the uv segment of the spectrum varies significantly with solar activity. The solar constant outside the atmosphere is $\approx 1.370\ \mathrm{kW\,m^{-2}}$. If averaged over the whole sphere, a realistic value at the Earth's surface of $250\ \mathrm{W\,m^{-2}}$ is obtained. The upper atmosphere acts as a filter because, as it becomes ionized, it absorbs practically all x rays and uv radiation from the Sun (i.e.,

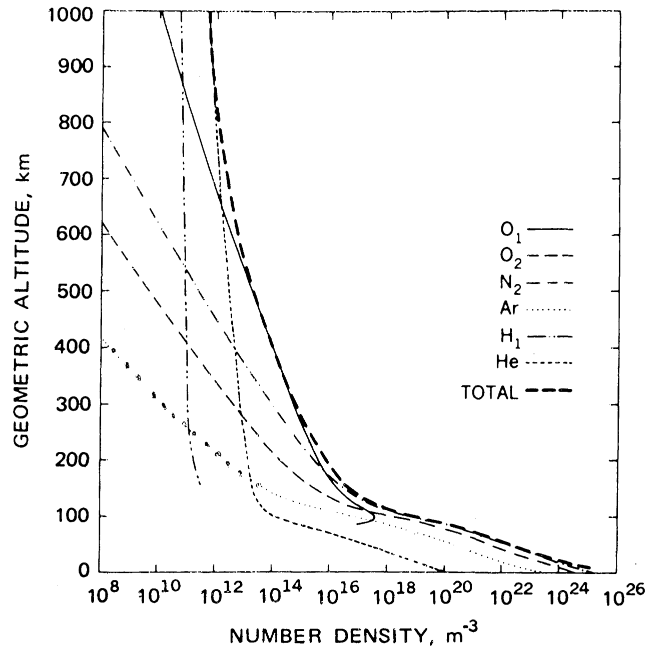

FIG. 1. Number densities of individual species and total number density as functions of altitude for the International Standard Atmosphere (from *U.S. Standard Atmosphere*, 1976).

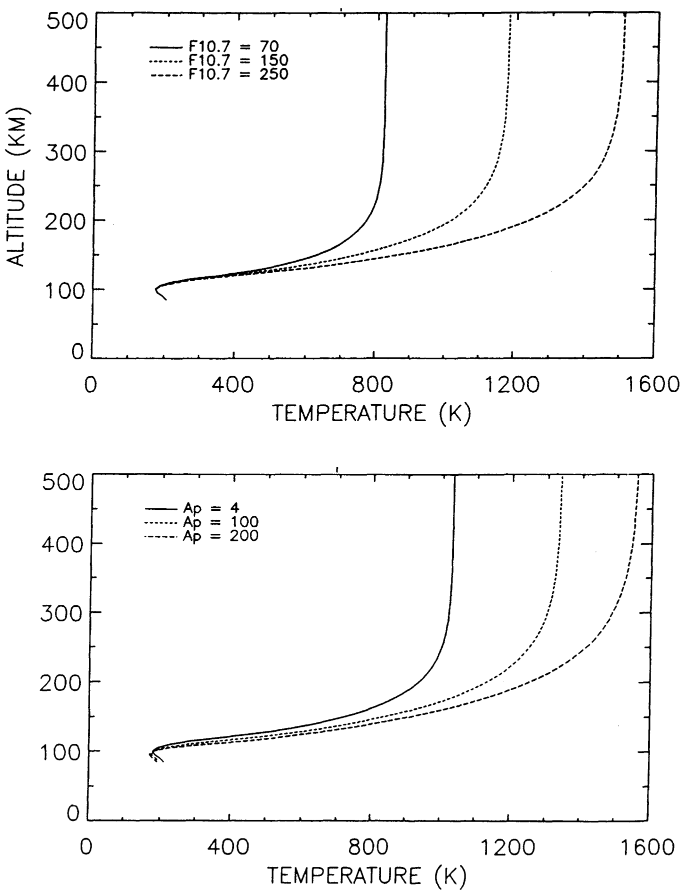

FIG. 2. Neutral temperature as a function of altitude. Top: The variation at 14 h LT and latitude 30° with solar activity, represented by the magnitude of the F10.7 flux (F10.7 is the electromagnetic radiation from the Sun at the wavelength 10.7 cm). Bottom: The variation at 2 h LT and latitude 65° with changes in magnetic storm activity represented by the global magnetic activity index A_p. The solar flux was held constant at the middle level of the top panel. The profiles are from the MSIS-90 model of Hedin (1991) [courtesy of F. Marcos, Geophysics Directorate, Philips Laboratory (USAF)].

solar radiation below ~250 nm, which we in the following will call the xuv band).

Notice that atmospheric waves generated close to the Earth contribute to the energy budget around 100 km. Also, as will be discussed later, energy from the magnetosphere, in the form of charged-particle precipitation and Joule heating, heats the upper atmosphere in the high-latitude regions. Neutral winds are also important for the energy balance. Winds and waves, as well as turbulence, affect the transport of energy to different regions of the ionosphere (see Fig. 3).

The temperature is variable and decreases in the mesosphere, reaching a minimum near 90 km. Above this height the temperature gradient is always positive (Fig. 2). A large fraction of the absorbed ultraviolet radiation from the Sun goes into heating of the upper atmosphere. Infrared radiation to outer space is a major energy loss (Fig. 3). The vertical temperature distribution, which results from the delicate balance of the various sources of energy and energy transport, varies considerably as it increases between 100 and 200 km. The temperature continues to increase up to approximately 500 km, where it approaches an asymptotic value (above about 500 km temperature no longer has a clear physical meaning). The top panel of Fig. 2 shows the variation of the dayside temperature with increasing solar radiation at 1400 LT (local time) and latitude 30°. The bottom panel shows the high-latitude, nightside temperature variability with magnetic activity at the middle level of solar flux, but at 0200 LT and latitude 65° in the auroral zone. Energy is deposited at high latitudes from the magnetosphere by energetic particle precipitation and field-aligned currents. Local heating affects both neutral temperature and composition, which in turn affect the ionization level (discussed in Secs. 4 and 5).

FIG. 3. A schematic representation of the energy budget of the upper atmosphere. The main energy source is electromagnetic and particle radiation from the Sun, but even atmospheric waves contribute to the energy budget around 100 km. The main energy sink is infrared radiation.

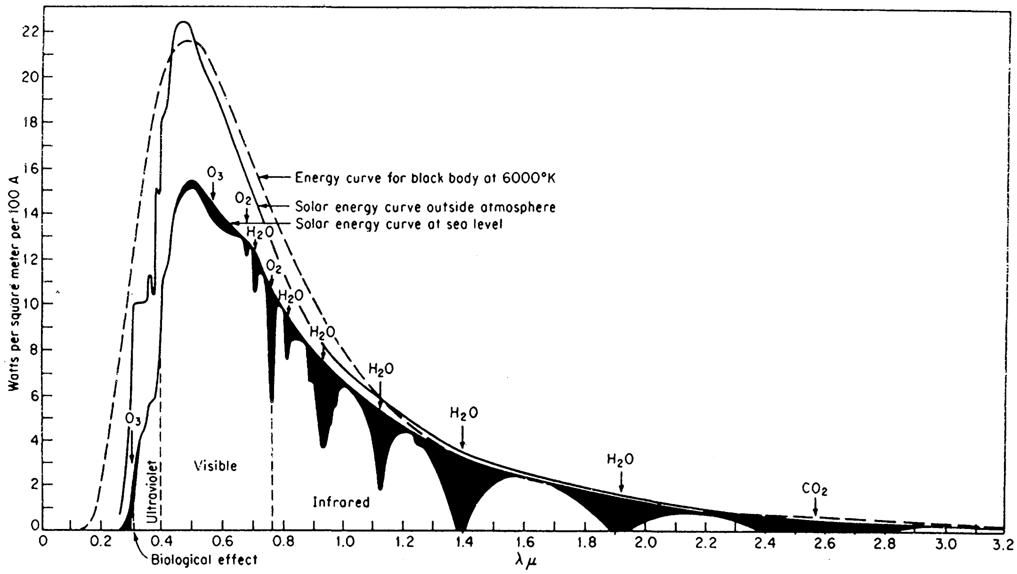

FIG. 4. Spectral energy curves of the solar energy outside the atmosphere and at sea level. Atmospheric absorption is indicated. For comparison the energy curve for a black body at 6000 K is also drawn. (From Egeland *et al.*, 1973.)

The solar xuv band significantly influences the upper atmosphere and changes its composition dramatically, particularly through photodissociation of atmospheric molecules (X_2) according to the formula

$$X_2 + h\nu \rightarrow X + X, \qquad (1)$$

where $h\nu$ is a photon—within the xuv band—with energy sufficient to dissociate atmospheric molecules. Equation (1) explains why molecules dominate the region below ~150 km, whereas atoms (nitrogen and oxygen) are the primary particles above this altitude (Fig. 1).

Diffusive separation becomes increasingly important with increasing altitudes, with the heavier constituents experiencing more gravitational attraction and the lighter ones less. As a result, the light gases dominate the upper atmosphere. Thus two elements that are rare near the Earth [i.e., helium (He) and hydrogen (H)] become relatively more and more abundant at higher altitudes. Above 600 km, layers of He and H dominate (cf. Fig. 1) because of their low masses. More important for the physics of the upper ionosphere is the existence of a several-hundred-kilometer-thick layer of atomic oxygen (O) above about 250 km. Even between 120 and 250 km, O is a very important constituent.

Because the Earth's magnetic field controls charged-particle motion in the ionosphere, a few of its main characteristics will be given here. The basic shape of this field is that of a dipole—similar to that of a bar magnet. However, significant differences exist that cause the magnetic field to deviate from the dipole shape and require a 15th-order spherical harmonic expansion to describe it accurately in the ionosphere. The intensity of the geomagnetic field gradually increases from the magnetic equator to the pole, where its strength of roughly 60 000 nT is nearly twice that at the equator. The Earth's magnetic axis is offset from its geographic axis in the northern hemisphere by ~11.5° and in the southern hemisphere by nearly 15°. Thus the dipole axis is offset from the center of the Earth. Magnetic ore deposits cause small spatial perturbations. Strong, variable electric currents in the ionosphere and magnetosphere further perturb the dipole shape. Because these time-varying currents (especially those associated with the aurora; cf. Sec. 8) cause large temporal perturbations in the Earth's magnetic field, a magnetic compass is not always an accurate aid in the auroral zones.

The dipole field decreases with distance from the Earth's surface as R^{-3}. At a distance of more than ~4 Earth radii the magnetic field is significantly compressed on the dayside of the Earth, while it is stretched out into a tail on the nightside by the continuous interaction of the magnetic field with the solar wind (cf. Fig. 4 of GEOELECTROMAGNETISM; also MAGNETOSPHERE). The resulting paraboloid-shaped surface with its nose at local noon encloses the region called the Earth's magnetosphere; i.e., the region where charged particles have greater energies than thermal particles and where their motion is controlled mainly by the Earth's magnetic field. The position of the nose depends on the balance of the solar-wind pressure against the magnetic pressure of the Earth's magnetic field, which dominates over the plasma pressure in the outer magnetosphere. The standoff distance is typically at 10 Earth radii. The magnetic field lines that connect the magnetosphere to the ionosphere guide the motion of charged particles and thus provide the paths for the interchange of currents and energy. At polar latitudes, where the magnetic field lines are nearly vertical, ions and electrons can escape from the ionosphere in a process termed the polar wind.

3. IONIZATION SOURCES

The atmosphere above 50 km and extending out to the order of 1000 km is called the ionosphere, because in this region charged particles—free electrons and ions—exist in large enough numbers to influence the propagation of radio waves. Ions are created by attachment of free electrons, by collisions with energetic particles, or by photoionization. The latter two processes create free electrons. The density of charged particles in any particular region depends on the balance between production and loss processes. All of these processes are dependent on the upper atmosphere composition and density.

The solar xuv band is particularly important for producing the ionosphere—via the process called photoionization, which can be written symbolically

$$X + h\nu \rightarrow X^{+} + e_n, \qquad (2)$$

where X is an atmospheric gas, atom, or molecule, $h\nu$ is solar radiation within the xuv band, while $X^+ + e_n$ is an ion–electron pair. Only photons within the xuv band have sufficient energy to ionize the atmospheric gases. Thus the xuv radiation changes the upper atmosphere from electrically neutral to electrically conducting. X^+ is a positive ion while e_n is a free, low-energy electron. The closer the solar radiation reaches the Earth, the denser the atmosphere. The production of ion pairs increases until a large fraction of the radiation is absorbed. It is therefore a combination of atmospheric density and composition affecting solar xuv radiation absorption that determines the height of the ionosphere.

The density of electrons and ions is determined by the balance between production and loss. Electrons and ions are lost by recombination processes

$$X^+ + e_n \rightarrow X, \tag{3a}$$

$$YX^+ + e_n \rightarrow X + Y, \tag{3b}$$

in which X is an atom and XY a molecule. Electrons and ions may also be transported away and thus lost to a particular area. Because solar xuv radiations vary with time, season, and location, large temporal variations are found in the concentrations of ion pairs in the ionosphere. Other variations result from different recombination rates for different atmospheric constituents and from variations in the magnetospheric particle input. For instance, NO^+ recombines with electrons much more quickly than O_2^+, and so spatial changes in the relative abundance of these constituents create local variations in the ion or electron density.

At low and medium latitudes photoionization [Eq. (2)] is mainly responsible for the creation of charged-particle distributions. At higher latitudes precipitating energetic electrons and ions from the magnetosphere and from the solar wind (a stream of charged particles with an average speed of 400 km s^{-1} and a density of $\sim 10^7\ m^{-3}$ constantly blowing towards the Earth's magnetosphere) significantly contribute to the production of ionospheric electrons via the following processes:

$$X + e \rightarrow X^+ + e_n + e', \tag{4a}$$

$$X + i \rightarrow X^+ + e_n + i' \tag{4b}$$

$$(e' = e - 36\ \text{eV},\quad i' = i - 36\ \text{eV}),$$

where e and i are energetic ($\geqslant$ 100 eV) electrons and ions, respectively. [One electron volt (1 eV) is the energy an electron gets when passing through a voltage drop of 1 V.] Each collision process of the type shown in Eq. (4) decreases the energy of an incoming particle by an average 36 eV. A 10-keV particle bombarding the atmosphere will on the average participate in 300 collisions and thus produce 300 ion pairs before it comes to a complete stop at or above ~90-km altitude.

Notice that in the processes listed in Eqs. (2) and (4) the molecules and/or atoms will have lost an electron and thereby become positively charged. A gas that contains free electrons and positive ions is called a plasma. Because an ionospheric plasma contains roughly the same number density of electrons and ions, it is for all practical purposes electrically neutral.

In the polar regions (i.e., poleward of ~60° magnetic latitude), the energy source from the solar wind and its interaction with the magnetosphere is of particular importance. The solar wind is indirectly the main generator of auroras, electric fields, and currents in the upper atmosphere (i.e., ⩾100 km) (cf. Secs. 6 and 7).

4. THE IONOSPHERIC LAYERS

On the basis of the results of ionospheric studies by radio technique, it has been agreed to divide the ionosphere into different regions as illustrated in Table 1. The first to be identified was a layer of ionization near 100 km, the E layer, so named because of the electric field (i.e., the E field) of the reflected radio waves with which it was measured. Above the E region lies the F region, while the region underlying was named D.

A typical ionospheric electron density profile for mid-latitude, daytime conditions is shown in Fig. 5. The different regions reflect radio waves with different wavelengths. While short waves (i.e., ≃100-m wavelengths equivalent to a frequency ⩾3 MHz) are reflected from the F region, the longer radio waves (i.e., ~1000 m) require less density for reflection and are reflected from the E region. These reflection differences allow the ionosondes to measure the ionization profile with height by

Table 1. Characteristics of the ionospheric regions.

		Electron density		
Region	Height (km)	Day (m^{-3})	Night (m^{-3})	Production sources
D	50–90	10^9	10^8	xuv+cosmic rays
E	90–140	10^{11}	$<10^{10}$	xuv+auroral particles
F_1	140–200	3×10^{11}	10^{10}	uv+auroral particles
F_2	200–400	10^{12}	10^{11}	uv+transport from below

measuring the variation of travel-time delay of the reflected radio signal with frequency.

At higher frequencies or shorter wavelengths signals pass through and are not reflected. Thus the variable ionosphere has a pronounced influence on long-distance radio communication and navigation. By comparing the electron density given in Table 1 for the D and E regions with Fig. 1, it is clearly seen that only a tiny fraction of the atmospheric gases are ionized. The majority of the molecules remain neutral in the lower ionosphere.

4.1 The Topside Ionosphere (> 400 km)

The region above the peak density of the F layer is called the topside ionosphere. The density decreases slowly with increasing altitude, with the rate of decrease being a function of temperature. This region was called the topside because its density profile could not be determined by radio-wave sounding techniques from the ground. Its characteristics were first determined by *in situ* sounding from above with transmitters on satellites and by sounding rocket measurements. In the lower part O^+ and O are the major ion and neutral species, respectively. Above approximately 600 km the lighter atomic ions He^+ and H^+ can dominate. In the upper part of the topside ionosphere, the plasma is effectively fully ionized.

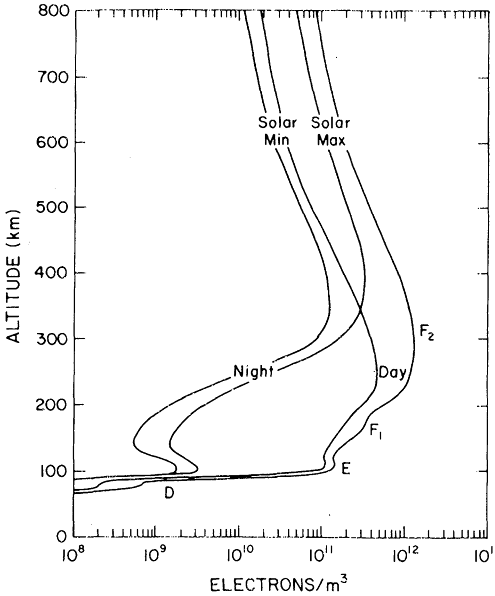

FIG. 5. Typical mid-latitude electron density profiles for solar maximum and minimum for both daytime and nighttime conditions. The different ionospheric layers are marked off in this figure (from Rees, 1989).

4.2 The F Region (> 140 km)

Above the E layer (i.e., > 140 km up to a height arguable in the scientific community) lies the F region. In the following we will define the upper height as that where the light ions (helium and hydrogen) begin to dominate over the heavier ions, in particular oxygen (between 500 and 1000 km depending on conditions). This height will vary with temperature. Note that the F region overlaps the lower part of the topside ionosphere. Even if production of ionization peaks below 200 km, the maximum electron density is found at considerably greater (up to 350 km) heights. In 1933 it was found that the F region during daytime often has two maxima, thus splitting into F_1 and F_2 layers. Typical peak electron densities are 3×10^{11} and 10^{12} m^{-3} in the F_1 and F_2 layers, respectively, while the neutral density is approximately 10^{15} m^{-3}. The most important ions in the F region are O^+, NO^+, O_2^+, and N_2^+. The important F-layer ionization source is found in the xuv band between 10 and 90 nm. It should be pointed out that N_2^+ reacts quickly with O via the process

$$N_2^+ + O \rightarrow NO^+ + N. \quad (5)$$

In the F_1 region (normally only a ledge in the lower F region with peak density near 180 km) the following reaction is also important:

$$O^+ + O_2 \rightarrow O_2^+ + O. \tag{6}$$

The conclusion is that NO^+ and O_2^+ together with O^+ are the most numerous ions below 200 km, while O^+ and the light ions dominate in the upper part of the F region (i.e., F_2 layer). Thus most of the ions in the F_2 layer are atomic.

The continuity equation for the F_2 layer can be written

$$\frac{dn_e}{dt} = q - \beta n_e + \mathbf{v} \cdot \nabla n_e, \tag{7}$$

where q is the production rate of electrons, n_e is the electron density, and β is the recombination (attachment) coefficient. Note that the loss of electrons depends linearly on electron density. In addition, the last term in Eq. (7) shows that there are pronounced drift effects. Electrons and ions are also able to escape from the ionosphere along open magnetic fields at polar latitudes. This loss of plasma—called the polar wind—can have a significant effect in the polar ionosphere. Plasma flow from one hemisphere to the magnetic conjugate ionosphere is important at midlatitudes. The inner magnetosphere or plasmasphere is populated by outflow of plasma along magnetic field lines from the ionosphere at mid latitudes.

4.3 The E Layer (90–140 km)

The E layer was the first ionospheric layer to be recognized. Since the typical daytime electron density is 10^{11} m^{-3}, and the neutral density at 120 km is 10^{17} m^{-3}, the E region is weakly ionized, and collisions between charged particles and neutral species are important in determining the conductivity and ion motion. The chief ions are O_2^+ and NO^+. The dominant neutral species in this region are N_2 and O_2. In the upper part of the layer O^+ occurs in significant quantities. N_2^+ is also produced but rapidly lost through charge exchange via the reaction

$$N_2^+ + O_2 \rightarrow N_2 + O_2^+. \tag{8}$$

In the lower part of the layer, NO^+ dominates.

Because NO has such a low ionization potential, Lyman-α radiation ($\lambda = 121.6$ nm) is the main ionization source. The predominant loss term is dissociative recombination, which takes the form [cf. also Eq. 3(b)]

$$O_2^+ + e_n \rightarrow O_2 \rightarrow O + O. \tag{9}$$

[In process (9) both momentum and energy are conserved, which makes this process very fast.] The continuity equation for this layer can be written

$$\frac{dn_e}{dt} = q - \alpha\, n_e^2, \tag{10}$$

where α is the recombination coefficient for all reactions of the type described by Eq. (9). Because of the high neutral density, drift effects of type shown by the gradient term in Eq. (7) can be neglected. More recent results based upon equilibrium between production and loss (i.e., no time variations) have given α values in good agreement with laboratory measurements. Also, rocket measurements have been very useful in testing Eq. (10).

Near 100 km a thin layer of enhanced ionization, known as sporadic E, sometimes exists. This layer can contain enough electrons to reflect high-frequency (HF) radio signals that would normally propagate through to the F region.

4.4 The D Region (50–90 km)

Because of the relatively high neutral density in this region, the low ion densities, and the dominance of collisions, the classical radio techniques used to study the E and F regions of the ionosphere are not applicable. Rocket techniques provide the only *in situ* measurements since this region is not accessable to satellites and balloons. Electron density does not show a marked peak, but rather a gradual increase with height (cf. Fig. 5).

The important ionization sources are listed in Table 1. X rays between 0.1- and 1-nm wavelengths are a principal source below 90 km. Solar protons from flares on the Sun also create D-region ionization. The bottom of the D region, where the electron density is very low (i.e., 10^8 to 10^9 m^{-3}), is produced by galactic cosmic rays. Thus there are hardly any diurnal variations in the lower D region during quiet conditions.

The primary ions are NO^+ and O_2^+. In addition, negative molecular ions and hydrated ions (water-vapor complexes) have been observed. One reaction producing negative ions may be

$$2O_2+e_n \rightarrow O_2^- + O_2. \qquad (11)$$

Production (of particularly complicated positive and negative ions), recombination, and other loss processes in the D region are complicated and not fully understood.

Because the D region is important for the energy balance as well as a principal region for absorption of radio waves propagating over long distances, further studies by extending modern incoherent-scatter radar and lidar techniques to this region have just begun.

5. GLOBAL DISTRIBUTION OF IONIZATION

Detailed studies of the ionosphere by simultaneous, coordinated satellite, rocket, and ground observations have clearly demonstrated large temporal and spatial ionospheric variations. Before the space age, studies were limited mainly to the regular ionospheric variations; i.e., seasonal, diurnal, and solar-cycle responses. These variations are at least partially due to the rotation of the Earth with its geographic axis tilted relative to the Sun and the geomagnetic axis tilted relative to the geographic axis, and long-term activity variations on the Sun. Both the photoionization, the main source for maintaining the medium- and low-latitude ionosphere, and magnetospheric and solar-wind ionization contributions will also vary considerably and thereby add to the complexity of the global distribution.

As seen from Eq. (10), the electron density in the E region during stationary conditions is

$$n_e=(q/\alpha)^{1/2}=c_1(\cos\chi)^{1/2}, \qquad (12)$$

because the ion production rate q is proportional to the cosine of the zenith angle (χ) of the Sun. Because of the regular diurnal variation alone, the electron density will thus vary as $\cos\chi$. During winter in the northern hemisphere, when the polar region is completely in darkness for a few months, photoionization is practically absent, and precipitating particles become the principal ionization source for the E region.

Because the lifetime of ions is much longer in the F regions than below, they can be transported considerable distances from their origin. The polar F-region densities vary greatly depending on the proximity to auroral particle and dayside uv sources. Just equatorward of the nocturnal auroral oval a minimum in electron density, called the electron trough, is very pronounced during the winter months. This trough has a limited latitudinal extent and it is very deep from 16, to 0600 MLT (magnetic local time). During this time, the F-region density can be as low as 10^9 m^{-3} (cf. Table 1).

To illustrate the global distribution of ionization and its seasonal variation, Plate 1 presents the local time-averaged global distribution of plasma density versus month of the year. These measurements are from the Defense Meteorological Satellite Program (DMSP) satellite orbiting at 830 km and are averaged over a 2-y period. The distribution at the topside ionosphere is representative of other F-region altitudes, although variation with altitude will occur. All p.m. local times are averaged together. The dayside low-latitude maximum, which stretches to higher latitudes in the summer hemisphere, is clearly evident, as is the depletion in the winter polar cap. The trough at subauroral latitudes does not appear because this latitude variation is lost by averaging. A polar view of a typical ionization distribution in the southern high-latitude regions at the altitude of F-region maximum is shown in Plate 2(a) along with a similar plot in Plate 2(b) for 12 h later. This is a simulation using the Utah State University ionospheric model (Schunk, 1988) that has been run over a 24-h period with constant inputs. The polar hole, ionization from auroral oval precipitation, and the mid-latitude trough are clearly seen.

An additional diurnal variation occurs at high latitudes because of the offset of the geomagnetic pole from the geographic pole. Electrodynamically driven effects are controlled by the geomagnetic field, while neutral atmospheric and solar ionization effects are dominated by the geographic axis. As a result the ionosphere is stirred daily with the rotation of the geomagnetic axis about the geographic axis in universal time (UT). Comparing Plate 2(a) with 2(b) illustrates the maximum differences from this effect as these times were chosen when the magnetic pole was toward and away from the Sun relative to the geographic pole. These variations from stirring are added to those from solar and magnetic activity to produce very dynamic behavior of the ionosphere in the auroral and polar cap regions.

6. ELECTRIC FIELDS, CONDUCTIVITY, AND CURRENTS

There are three principal sources of electric fields in the global electrical circuit: the thunderstorm-generated atmospheric electric field, the tidal-wind–generated S_q ionospheric electric field, and the magnetospheric convection electric field driven by the interaction of the solar wind with the magnetosphere. The last two are important to the upper ionosphere, while all three interact at the lower boundary. The coupling of these generators is dependent on the ionospheric conductivity.

The motion of charged particles in the ionosphere depends on electric and magnetic fields, on the ionization density, and on collisions. Thus conductivity is directionally dependent. It may be divided into three terms: σ_0 is the specific conductivity along the magnetic field **B**, σ_P is the Pedersen conductivity in the direction perpendicular to the magnetic field and along the perpendicular component of the electric field **E**, and σ_H is the Hall conductivity in the direction perpendicular to both the magnetic and electric fields. The profiles of the conductivities with altitude are shown in Fig. 6. Note that the specific conductivity scale is six orders of magnitude greater than the other two. For this reason the electric field parallel to the magnetic field is, to first approximation, zero, and the perpendicular electric field maps along magnetic field lines. The Hall conductivity typically peaks near 110 km while the Pedersen conductivity peaks near 130 km. Above 200 km the collision frequencies are so small that the charged-particle motion is controlled strictly by the electric and magnetic fields. The ion velocity at these altitudes can be expressed by

$$\mathbf{v}_i = (\mathbf{E} \times \mathbf{B})/B^2. \qquad (13)$$

At high latitudes the magnetic field lines project out into the magnetosphere. The magnetospheric electric fields project along the magnetic field into the ionosphere and impose a potential pattern on the high-latitude regions. Electric fields at high latitudes are typically 20 to 60 mV m^{-1} and can exceed 200 mV m^{-1} during disturbed conditions. The ion flow is along the equipotentials, and this flow is also the principal driving force for neutral winds at F-region altitudes. When the interplanetary magnetic field has a southward component, the flow patterns form two convection cells with a negative potential minimum near 16 h and a positive potential maximum near 04 h. The shape of the patterns is dependent on the dawn–dusk component of the interplanetary magnetic field. Representative patterns are shown in Fig. 7. For positive (negative) B_y the BC pattern is applicable to the northern (southern) hemisphere while the DE pattern is applicable to the southern (northern) hemisphere. Typical values of the difference in potential between the maximum and minimum range from 30 to 150 kV depending on magnetic activity. In extreme cases

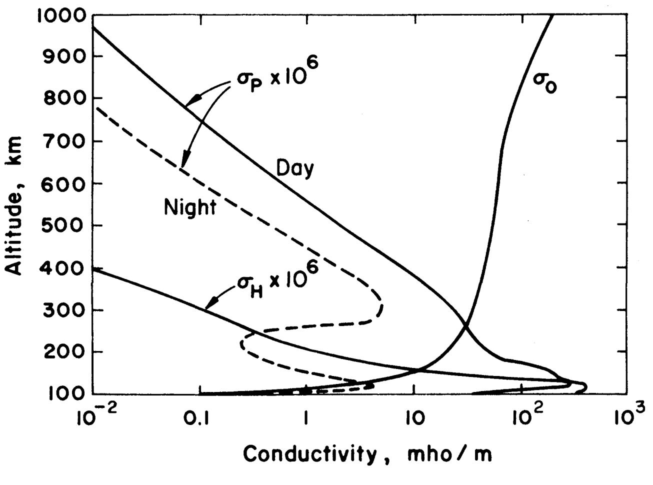

FIG. 6. Typical conductivity values for the mid-latitude daytime ionosphere. Notice the change of scale for the Hall and Pedersen conductivities. The dashed curve is a typical nighttime profile of the Pedersen conductivity also with the scale change (from Kelley, 1989; adapted from Johnson, 1961).

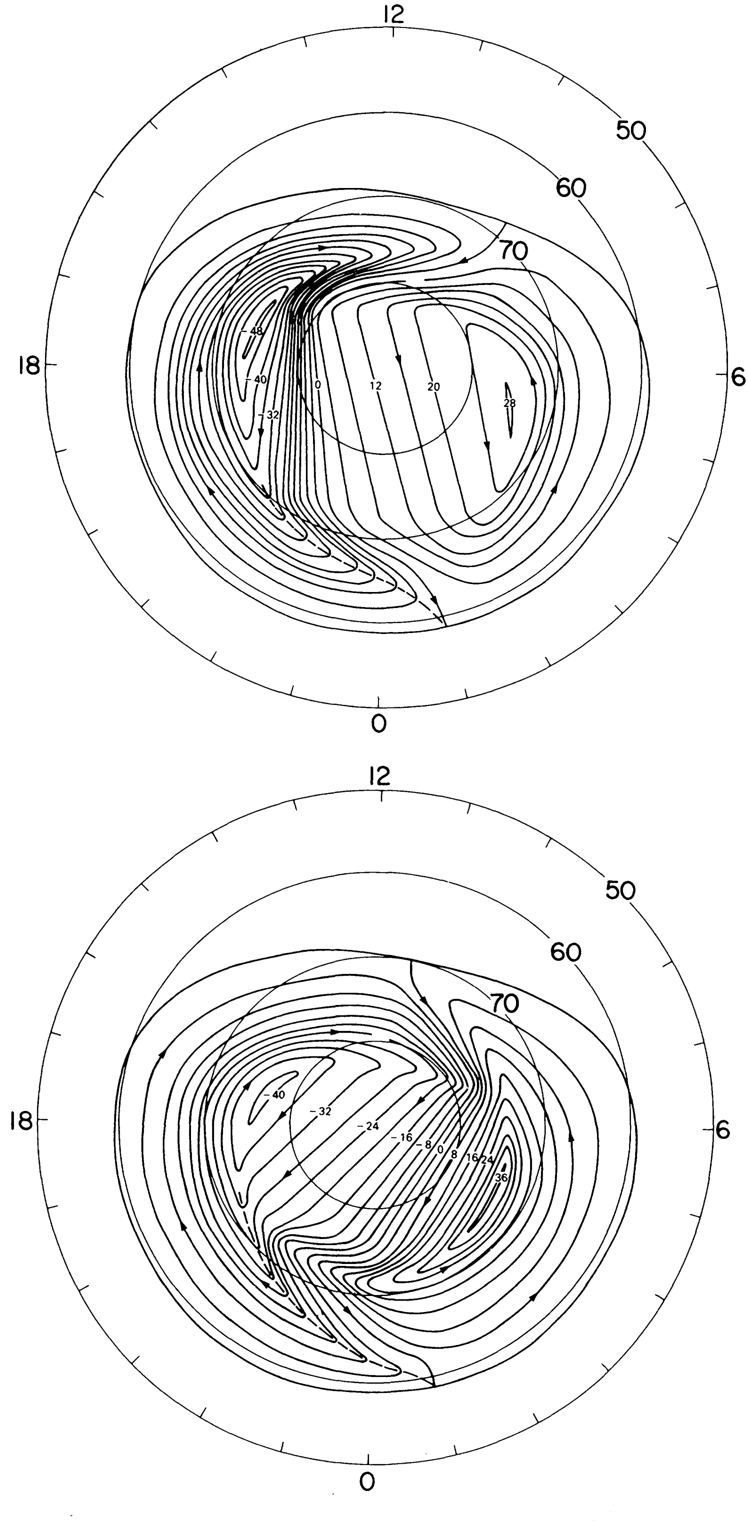

FIG. 7. Two convection patterns of Heppner and Maynard (1987) for a southward interplanetary magnetic field to illustrate the variation in the pattern with the east–west component (B_y) of the interplanetary magnetic field (IMF). The BC pattern (bottom) is for the northern hemisphere for positive B_y. The DE pattern (top) is for the northern hemisphere during negative B_y. For the southern hemisphere the same patterns apply with the opposite sign of the IMF B_y component. The contours represent equipotentials spaced at 4 kV and are representative of average activity conditions. The magnitude of the potential difference between the potential minimum on the evening side and the potential maximum on the morning side (76 kV in the above patterns) varies from ~20 to over 200 kV with varying magnetic activity.

it may exceed 200 kV. When the interplanetary magnetic field component B_z is northward, the two-cell patterns become distorted and can evolve into more than two cells. The potential differences are generally very small and the electric fields are extremely variable, in some cases making it difficult to recognize a pattern (Heppner and Maynard, 1987).

Under steady-state conditions the electric fields from the magnetospheric generator are poleward of about 60° magnetic latitude. A shielding layer in the inner magnetosphere prevents penetration of the magnetospheric electric fields inside of about 4 Earth radii, which projects along the Earth's magnetic field to 60° latitude. As magnetic activity changes, the shielding must be reestablished. Magnetospheric electric fields temporarily penetrate closer to the Earth and project along the Earth's nearly dipolar magnetic field lines, which are equipotentials, to lower latitudes in the ionosphere. At middle latitudes the ionospheric electric field is a combination of these penetration electric fields and S_q dynamo electric fields generated by neutral wind and tidal motions of the neutral atmosphere, which through collisions drive ions across magnetic field lines. This ionospheric E-region tidal generator is driven by a complex combination of solar-heating–induced neutral winds and gravitational effects from the Sun and Moon. Electric fields are small, of the order of a few mV m^{-1}, with a total potential drop of about 10 kV.

At the lower edge of the D region the gas is only weakly ionized and the conductivity becomes isotropic. The atmospheric electric field is vertical and couples to **E** fields from the other two sources. The atmospheric vertical electric field in the lower D region is small since 90% of the 300-kV potential drop between the Earth and the ionosphere exists below 10 km and the electric field is inversely proportional to the conductivity. Under conditions where all electrons are tied to heavy negative ions, gravitationally driven and/or differential neutral-wind–driven ion motion can generate anomalously large (V m^{-1}) local electric fields.

The ionospheric electric fields drive horizontal currents in the ionosphere, which are observed in the ground magnetometer recordings. These are principally Hall currents in a layer around 110 km (Fig. 6). At midlatitudes these are strongest during the day when the conductivity peaks. At the magnetic equator the Hall current would be principally downward and is impeded from flowing because of the decreasing conductivity. A polarization electric field results, causing an apparent enhancement of conductivity (Cowling conductivity) and an enhanced east–west current called the equatorial electrojet. The magnitude of the electrojet current peaks with the conductivity near 1100 LT (see Chapman and Bartels, 1940).

In high-latitude regions ionization from solar xuv radiation is supplemented by ionization from the energetic particles producing the aurora (see Sec. 8). Within the auroral oval the conductivity due to auroral particle precipitation dominates, and the conductivity varies with magnetic activity. The Hall currents driven by the magnetospheric convection electric fields are large. They are referred to as auroral electrojets because of the primary currents being confined in altitude to the peak of the Hall conductivity profile. On the evening side the currents are eastward, while after midnight they are westward. The two electrojets overlap in the midnight region at the Harang discontinuity. The conductivity, electric fields, and currents are extremely variable. Current continuity under these spatially and temporally variable conditions requires field-aligned currents, or Birkeland currents, to flow.

Birkeland currents couple the ionosphere with the magnetosphere. The upward currents carried by the precipitating auroral electrons are balanced by downward currents, primarily carried by upward-flowing, low-energy electrons. The large-scale pattern of field-aligned currents (shown in Figure 8) can be divided at most local times into two principal regions. Region-2 currents couple to the inner magnetosphere, and currents flow into the ionosphere on the evening side and out of the ionosphere on the morning side. Region-1 currents couple to the magnetospheric boundary layers and flow out of the ionosphere on the evening side and into the ionosphere on the morning side. Near noon and midnight these patterns overlap, and three current layers are common (Iijima and Potemra, 1978; Potemra, 1990). Additional weaker current systems are observed poleward of the oval especially during periods when the interplanetary magnetic field has a northward component. Field-aligned currents are closed in the

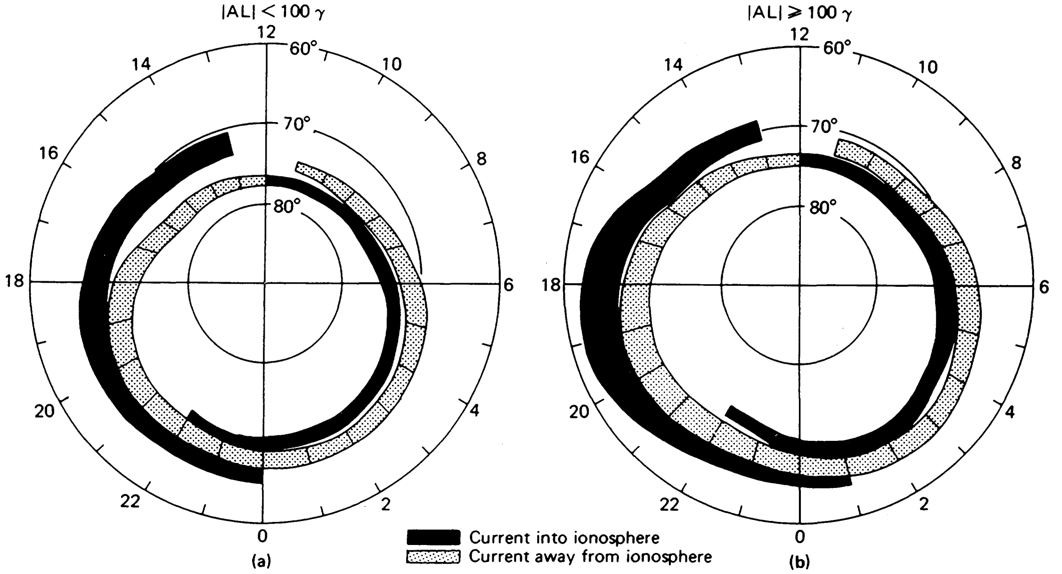

FIG. 8. A summary of the distributions and flow directions of large-scale field-aligned currents based on Triad data for weakly disturbed and active conditions (from Iijima and Potemra, 1978). AL is related to the maximum current intensity in the westward auroral electrojet and is the larger of the two components of the auroral activity index AE. The units are in nT (1 $\gamma = 1$ nT). Thus the left plot is for magnetically quiet conditions and the right plot is for active conditions.

ionosphere principally by Pedersen currents. In all these current regions the direction of the current is the average direction. Structured field-aligned currents in both directions exist side by side in all regions, a necessary consequence of the variability of the conductivity and the electric fields.

7. AURORA—THE POLAR LIGHT

The aurora, as illustrated in Plate 3, is certainly one of the most spectacular of nature's phenomena. In earlier times, inhabitants of northern Canada, Greenland, and the Nordic countries saw the northern lights as omens from the gods portending disaster, signs from deceased relatives, a battle of the gods, or a weather sign. For those interested in the history of the aurora, monographs by, e.g., Brekke and Egeland (1983) and Eather (1980) are available.

Those who admire the beauty of wonders in the dark sky may find nothing comparable to a night with magnificent auroral displays. Unfortunately, this impressive and imagination-inspiring display can only be seen regularly by people living near the polar region. At these latitudes, Aurora Borealis (i.e., in the north) and Aurora Australis (in the southern hemisphere) routinely appear in the so-called auroral zones. Consequently, auroras are far from most population centers. Even today, the area of the southern auroral zone (roughly around Antarctica) is inhabited only intermittently. In the northern auroral zone, which crosses Alaska, central Canada, northern Scandinavia, and northern Siberia, these majestic lights are a routine part of the daily life of these northern people.

The instantaneous distribution of aurora versus time and latitude is given by an oval-shaped belt of maximum activity called the auroral oval (cf. Fig. 9). These zones represent the average statistical occurrence of aurora and are approximately centered about the geomagnetic poles. Notice that both the location and width vary significantly from midnight to midday. They also vary with solar and magnetic disturbances as shown in Fig. 9. The oval expands equatorward during disturbed periods and contracts during quiet periods. Auroral emissions called polar cap arcs also appear poleward of the oval, but with markedly less frequency and intensity. The frequency of auroral occurrence, as well

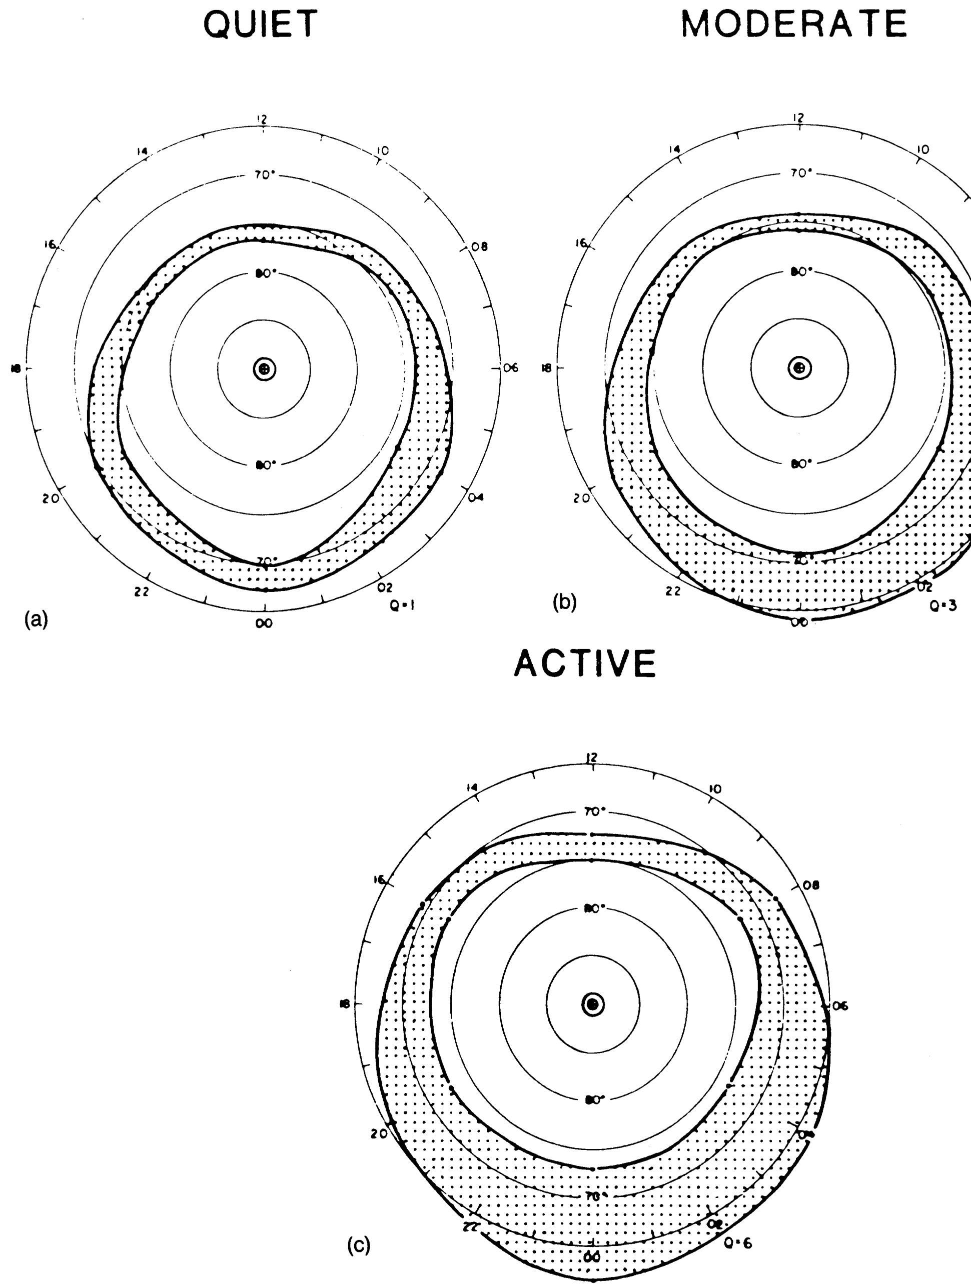

FIG. 9. Variation in the size of the auroral oval for different solar or magnetic activity; quiet, moderate, and disturbed conditions.

as its intensity and location, is clearly correlated with the degree of activity on the Sun. This is also borne out by the 27-d recurrence tendency (i.e., the rotation period of the Sun) as well as the 11-y sunspot cycle. However, auroral activity peaks one to two years after sunspot maximum. The oval width and location for quiet, moderate, and active conditions are illustrated in Fig. 9.

Auroral intensity can vary from being barely detectable among the stars to a luminance bright enough to veil the stars completely.

Thus the intensity of this polar light can vary over more than four orders of magnitude. At maximum intensity the illumination on the ground is comparable to moonlight, and ~100 times stronger than starlight. With a modern 35-mm camera, an f/1.4 lens, and a fast color film (e.g., 400 ASA), an exposure time of ~1 s is needed to photograph a bright aurora.

By watching the aurora, one may get the impression that a confusingly large number of different auroral forms and structures occur. However, by categorizing them into four primary forms—i.e., arcs and bands, auroral rays, spiral structures, and diffuse surfaces—the customary occurrence forms can be explained.

Of all characteristic properties of the northern light, none have been discussed and studied more than its height. On the basis of about 20 000 parallactic measurements between 1910 and 1940 (Störmer, 1955), it was proved that auroral arcs and bands, auroral glow, and surfaces lie predominantly within the height interval 95–150 km, whereas isolated rays or bundles of rays may have an altitude considerably higher (i.e., >200 km). The average height of dayside aurora is typically 150 km higher than nighttime aurora. A few auroral forms—called sunlit aurora—are found up to 1000 km. Today, the luminosity height profile may be measured *in situ* by instrumented rockets. A few tens of such flights have been carried out, showing that the height profile is directly related to the energy of the precipitating particles from the magnetosphere. The lower border near 100 km is excited by electrons of 5 to 15 keV. The peak emissions on the dayside, which typically are near 300 km, are from particles precipitating with energies of ten to a few hundred eV.

Although a weak aurora appears to the eye as white, increased intensity reveals the predominant green color together with red and blue. As illustrated in Plate 4, the optical spectrum of an aurora consists of a great number of spectral lines and bands—from ultraviolet to infrared wavelengths. These emissions are primarily due to a two-step process; i.e., precipitating energetic particles collide with the Earth's upper atmosphere, converting their kinetic energy into chemically excited states of atoms and molecules that in turn generate photons of wavelengths determined by the specific gas (i.e., oxygen, nitrogen, helium, etc.) and the relaxation processes. The auroral emissions of atomic lines and molecular bands can therefore be considered as the "fingerprints" of atmospheric constituents.

Symbolically, this can be written

$$N_2+(e \text{ and/or } i)\rightarrow(N_2^+)^*+(e' \text{ or } i')+e_n, \tag{14}$$

where e' $(i')=e$ $(i)-36$ eV and the asterisk denotes an excited state. Equation (14) is followed by radiation of the first negative bands:

$$(N_2^+)^*\rightarrow N_2^+ + h\nu \quad \text{(aurora at 391.4 and 427.8 nm).} \tag{15}$$

Because the probability of process (14) followed by (15) (spontaneous emission as excited species relax to a lower energy level) is nearly independent of energy of the primary particles, these blue auroral bands at 391.4 and/or 427.8 nm can be used to determine the net downward particle energy. Quantitative considerations show that one photon is emitted at $\lambda=391.4$ nm per 25 ion pairs produced.

The brightest auroral emission is the "green line" at 557.7 nm, which is due to atomic oxygen. But, as these emission photons are not emitted spontaneously as in process (15), it is a forbidden transition. Another commonly observed line—particularly in the polar cusp—is the red line at 630 nm, which is also emitted from excited oxygen. This is also a forbidden transition. Allowed or permitted transitions occur very rapidly (i.e., 10^{-7} s). Forbidden transitions, which violate the quantum-mechanical selection rules, still do occur, but only after a much longer time, i.e., ≈ 0.7 and 110 s for the green and the red lines, respectively. For the nearly 2-min lifetime of the red-line transition, collision deactivation (without light emission) is very likely for altitudes below about 200 km. Thus, the red 630-nm [OI] emission will always peak at altitudes above 200 km.

The intensity, height, and spectral content of the aurora are projections of magnetospheric processes onto the high-latitude ionosphere, much like the cathode-ray tube in a television set. The magnetic field lines to which the particles are tied trace out to the plasma sheet in the nightside and magnetospheric boundary layers and the cusp on the dayside. The aurora provides a continuous monitor of these activities. The advantage of using the aurora in the ionosphere as a monitor of these near-Earth processes over any conceivable system of *in situ* measurements is that the size over which the phenomena are occurring in the ionosphere differs in scale from that in the magnetosphere by a factor of perhaps as much as 10^6. Continuous high spatial and temporal resolution observations provide another advantage of studying ground measurements of aurora.

8. DYNAMICS OF THE IONOSPHERE

During recent years ionospheric variations, both small-scale irregularities and large-scale variations connected with specific solar events, such as solar flares—and more recently coronal mass ejections—have received special attention (cf. SOLAR RADIATION). Flares are the most dramatic of the solar events. Here we will briefly list in chronological order the most dramatic ionospheric effects of a large solar event.

Approximately 8 min after a flare occurs, the first effect in the Earth's ionosphere—the so-called sudden ionospheric disturbance (SID)—is observed on the sunlit portion of the Earth. The existing source is enhanced x rays from the Sun with a factor of 100 and even more increase in solar radiation between 0.1 and 1 nm. As a result, the electron density in the D region is significantly enhanced. Long-distance radio-wave propagation is seriously disturbed, while the propagation conditions for frequencies with longer wavelengths may be improved. The SID events normally last less than 1 h.

Major flares are normally connected with large fluxes of relativistic protons (typically 100 MeV, i.e., comparable to the energies of cosmic rays). Within one to a few hours these energetic solar particles reach the Earth's ionosphere poleward of typically 50° magnetic latitude. The result is a complete "blackout" of all long-distance radio communications at high latitudes, which often lasts for many days. These are called polar cap absorption (PCA) events, named for their effect upon radio-wave transmissions. The physical explanation is that these high energy particles cause a new ionospheric layer in or below the regular D region. Even with an electron density of only 10^8 to 10^9 m^{-3}, the absorption effects are so large because of the high collision frequency at these low altitudes. Again, the enhanced D region will improve long-wavelength transmissions that are reflected from the D layer.

The third class of ionospheric disturbance is called auroral absorption (AA) in radio terminology, or, more generally, magnetic substorm events. A major solar event will produce both a magnetic storm and substorm events (while a magnetic storm is a global phenomenon lasting days, substorms are episodic releases of magnetospheric energy into the ionosphere primarily to the auroral oval, lasting on the order of one hour). AA events occur not only from flares, but can also depend on other solar and solar-wind irregularities (not always well defined). As both x rays and the solar xuv radiation vary in phase with the solar activity, marked changes in electron densities and irregularities are also caused by these radiations. About 30 to 60 h after this solar activity, AA effects are observed particularly in the oval within ±5–6 h around magnetic midnight. The ionospheric disturbances from magnetic storms and substorms are primarily caused by auroral electrons; i.e., electrons between 0.1 and 100 keV. The occurrence of individual substorm events is normally irregular, and there may be several events in one disturbed night. Particle bombardment introduces local changes in E- and F-region ionization. The electric fields are generally enhanced and variable, and activity expands equatorward. Since auroral particles are the principal source of nighttime E- region ionization, changes in this region are large and rapid during the substorm. Transport increases in importance for determining F-region densities. As the substorm activity passes its peak, large electric fields, called subauroral ion drift (SAID) events, develop on the equatorward edge of the auroral region in the trough. In this region, also, the subauroral red arc or SAR arc is sometimes seen as a result of heating of the upper F region by energy coupled along magnetic field lines from the inner edge of the plasma sheet in the inner magnetosphere.

Solar abnormalities may exist for several solar rotation periods, and ionospheric disturbances may peak at 27-d intervals, i.e., when the same place on the Sun faces the Earth again. Not all magnetic storms are caused by solar flares. Recent research points to coronal mass ejections, which may come from flares or may be from other active regions on the Sun, as the carriers of the enhanced plasma in the solar wind that causes magnetic storms. The magnetic storm typically lasts a few days with enhanced substorm activity during the period.

9. RADIO PROPAGATION EFFECTS

For the same reasons that radio waves were important in the discovery of the ionosphere, the ionosphere greatly influences radiowave propagation. For the longer wavelengths that cannot penetrate the ionosphere, the reflection of these waves to a first approximation obeys Snell's law. Signals can propagate within the Earth–ionosphere cavity to great distances. Amateur radio operators quickly learn that different frequency bands propagate better depending on daytime or nighttime conditions. The E layer is normally greatly reduced at night because of higher neutral densities, shortening the recombination time, and signals that would be reflected by the E layer in the daytime pass through to the F region at night. This allows communication to greater distances while bypassing nearer regions, a process often referred to as "skip."

Reflection from a smooth layer is well behaved, while reflection from an irregular region can greatly distort the signal. During magnetic storms the high-latitude regions are disturbed, which in turn disrupts or greatly changes communication characteristics. Skip becomes irregular. In the case of a PCA event (cf. Sec. 8), the energetic solar protons create extra ionization in the D region. This results in communication blackouts for high frequencies.

The ionosphere also influences the propagation of VHF and UHF radio waves to and from satellites at frequencies that normally are not reflected. Irregularities in the ionization density create both phase and amplitude distortions in radio waves as they propagate through the ionosphere. Increasing the bit error rate can make communications marginal. These distortions are referred to as scintillations. Scintillations vary widely in space and time; however, two regions of high scintillation activity deserve specific mention. At low latitudes scintillations are especially prevalent in the evening hours. After sunset the E region disappears because of recombination, leaving a sharp gradient in the plasma density. This results in a more dense fluid over a less dense fluid, which is subject to a Rayleigh-Taylor instability. Bubbles of low-density plasma form and rise through the F region creating irregularities referred to as equatorial spread F. This causes major communications problems because of the resulting scintillations. Auroral precipitation, especially in the auroral oval, is also a major source of irregularities and therefore scintillations. In addition, the polar cap can also have significant amounts of irregularities. Patches of ionization are created in the auroral-zone F region near noon and are convected across the polar cap to the nightside by the electric fields. These patches are scources of scintillations.

10. PLANETARY IONOSPHERES

Since the flyby of the planet Venus in the 1960s by the Mariner probes, a wealth of information on planetary ionospheres has been gathered from other spacecraft by *in situ* and remote sounding techniques. The outer planets have been explored by Voyagers 1 and 2. Pioneer Venus orbited Venus for nearly a decade, providing extensive information about ionospheric structure and dynamics. During the coming decade planetary ionospheres will receive more and more attention. In this section we will only list a few important ionospheric facts about the planets.

Even though several of the basic physical and chemical processes (i.e., production, loss, and transport) that control planetary ionospheres may be similar to those on Earth, major differences occur in the composition and height distribution of the neutral atmospheres as compared to the Earth. One other important factor is the difference in the magnetic fields of the planets. The magnetic moments on the other inner planets, particularly Venus, are low, while the outer planets have large magnetic fields when compared to the Earth.

The ionospheres of the inner planets have several similarities to the Earth's E layer. The most abundant ion is O_2^+ even if there is practically no neutral O_2 in their upper atmospheres. This is due to photodissociation of CO_2, which is a major gas in the planets' atmospheres. Even the maximum plasma densities are found between 100 and 200 km. In a similar way to the terrestrial ionosphere, transport processes are important for determining electron and ion densities at greater altitudes. However, because their magnetic fields are so weak, magnetic conjugate effects are generally nonexistent. The solar wind interacts directly with the ionosphere on Venus, with the plasmapause and bow shock standoff distance being determined by the balance of the plasma pressure with the solar-wind pressure.

Both the densities and, especially, the vertical height distributions of the ionospheres are significantly different at the major outer planets. Taking Jupiter as a typical example, the major ion is H^+ with its peak density above 500 km. Also H_3^+ (H_2^+ reacts with H_2 to form H_3^+) is of special importance in Jupiter's ionosphere. The upper atmosphere of Jupiter consists mainly of molecular hydrogen, while H, He, and CH_4 are also important constituents. Again, both photoionization and solar-wind–ionospheric interactions are principal ionization sources. Because of Jupiter's large magnetic field, a significant ionospheric difference is expected from mid- and low-latitude to polar regions where energetic particles also become important. Particularly for the outer planets, information about background atmospheres is insufficient, and their chemical reactions are poorly understood. Furthermore, there is no direct information on electron and ion temperatures in the ionosphere.

11. QUESTIONS FOR THE FUTURE

Although the fundamental processes related to the large-scale formation and nature of the ionosphere are fairly well understood, many problems concerning structure and dynamics, energy balance, physical and chemical couplings, etc., still remain. Here we will only briefly mention some items that will have a high priority during the coming decade.

Coupling and transport of ionization between the auroral zones and regions further poleward and equatorward are not well mapped and explained. Both horizontal and particularly vertical transport (the so-called polar wind) from high latitudes need further experimental and theoretical attention. New incoherent-scatter radars for the central polar regions, where even the electron density profiles are poorly known, closely coordinated with simultaneous rocket and satellite measurements, should have priority.

It may surprise readers that the ionospheric layer closest to the Earth—i.e., the D region between 50 and 90 km—is least known and understood. Here the atmospheric pressure is large and collisions totally dominate so that the usual ground techniques for studying the ionosphere are not applicable. Because collision frequencies exceed the critical frequencies for the region, absorption dominates.

Progress in the next decade will be toward exploration of the lower ionosphere and understanding the complexities of this intricate coupling between regions. Global scale models like the Utah State University ionospheric model (Schunk, 1988; Schunk and Szuszczewicz, 1988) along with *in situ* satellite measurements and ground-based radar sounding of the ionosphere should greatly increase our understanding of processes in the upper ionosphere. However, data at lower altitudes are limited in scope and coverage by the inaccessibility of the D and E regions to satellite measurements. Sounding rockets have provided limited coverage, but cannot provide a large-scale picture of the dynamics of these regions necessary to address the complicated feedback mechanisms associated with geomagnetic storms and substorms. Models can simulate most instantaneous conditions, but have too many unconstrained variables to specify the time dependence accurately. NASA is planning a mission in the latter part of the decade called TIMED (thermosphere–ionosphere–mesosphere energetics and dynamics) to address some of these problems. TIMED will perform an exploratory study of the physical and chemical processes acting within and upon the coupled mesospheric, thermospheric, and ionospheric system between 50 and 180 km. The energetics of these regions, the global circulation and dynamics, the chemistry and composition, and the ionospheric structure and electrodynamics will be primary objectives of this mission. It will also begin to address possible anthropogenic changes in this region, questions raised because of global change that appears to be taking place in the atmosphere below.

GLOSSARY

Aurora: Optical emissions in the upper atmosphere (> 90 km) due to excitation of molecules and atoms by precipitating energetic particles from the magnetosphere and solar wind.

Auroral Oval: An oval-shaped belt around the geomagnetic pole in each hemisphere between about 60° and 80° geomagnetic latitude that is the location of the majority of the auroral emissions. The oval expands and contracts with changes in magnetic activity.

Conjugate Auroras/Disturbances: Simultaneous phenomena in both hemispheres at locations connected by the same geomagnetic field lines.

Convection: The global scale motion of plasma in the ionosphere driven by electric fields. The motion is generally sunward in the auroral zone and antisunward over the polar cap following lines of equipotentials in the electric-field pattern.

Ionosonde: A transmit and receive system for determining the structure of the ionosphere by measuring the reflection height of radio waves at various frequencies.

Ionosphere: A region of partially ionized gas between 50 and 1000 km where free electrons and ions coexist in an electrically neutral plasma. Subdivided into **D region:** ionospheric region between 50 and 90 km above the Earth; **E region:** ionospheric region between 90 and 140 km; **F region:** ionospheric region above 140 km; **topside ionosphere:** ionospheric region above the peak of the F region.

Magnetic Local Time: Local time defined in a magnetic latitude and longitude system centered on the Earth's geomagnetic axis.

Magnetic Storm: Large-scale disturbance of the magnetosphere and ionosphere caused by the arrival of an enhanced region of solar-wind density and velocity caused by a solar disturbance. The magnetic storm typically lasts 1–3 d from onset to recovery.

Magnetic Substorm: An episodic release of energy into the auroral region from the magnetosphere causing enhanced auroral activity and magnetic disturbances in the polar ionosphere lasting approximately 1 h.

Magnetosphere: The region between the ionosphere and the magnetopause, a boundary determined by the balance of the plasma pressure of the solar wind and the magnetic pressure of the Earth's magnetic field. The Earth's dipole magnetic field is pushed in on the dayside and stretched out into a tail on the nightside. The typical standoff distance of the magnetopause on the dayside is 10 Earth radii.

Plasma: An electrically neutral, partially or fully ionized gas containing free electrons and ions.

Polar Cap: The region poleward of the auroral oval.

Polar Ionosphere: The ionosphere poleward of about 60° magnetic latitude (encompassing the auroral oval and polar cap).

Polar Wind: The outflow of ionized particles from the polar ionosphere.

Solar Wind: Low-density supersonic plasma flowing out from the Sun which interacts with the Earth's magnetosphere.

Trough: A region of low electron density equatorward of the nighttime auroral oval.

Universal Time (UT): Time referenced to 0° longitude or the Greenwich meridian.

INTRODUCTION

The main mission of every laboratory is to conduct scientific investigations to develop an aspect of a new technology or product or to improve an existing technology or product. The success of the experiments, which are an important part of the scientific investigative efforts, depends to a large extent on the availability of the appropriate test and measurement tools to quantify physical phenomena in complex measurements. Consequently, instrumentation users are faced with the ultimate responsibility of selecting the appropriate instrument for the scientific task in view of the diversified and rapidly changing technologies associated with the instrumentation field. The instrumentation industry, particularly, has undergone major changes that are directly related to the technlogical advances in electronics that evolved over the past five decades.

One major change was marked by the invention of the transistor in the 1940s. That was the beginning of semiconductor electronics. By replacing the vacuum tube, the transistor (solid state device) sent the instrument designer back to the drawing board, so to speak, and a new generation of instruments emerged. The newly developed instruments afforded better accuracy and improved stability, were more efficient and more compact, and offered faster response than their predecessors that were based on vacuum-tube technology. In the 1960s and the 1970s, electronics research developed solid-state devices capable of performing complex functions that included many discrete components such as chips, transistors, resistors, diodes, and capacitors integrated in a single silicon substrate. Today, these devices are known as integrated circuits (ICs). Further research and development in the IC field led to the microprocessor, which can be considered as a second turning point—if we consider the transistor as being the first—in the electronics and the instrumentation industries. Most modern test and measuring devices use one to three microproces-

sors to add "intelligence" (i.e., capabilities that allow these devices to perform complex functions that previously required several instruments and off-line calculations). In addition, with microprocessors, test and measurement instruments combined the best of two worlds—the digital and the analog.

This article, in its scope and content, is intended for readers in a wide range of technical disciplines. The topics covered and their treatment, therefore, were chosen with that in mind. The article introduces a class of instrumentation that is most commonly used in the laboratory for conducting a variety of tests and performing a wide range of measurements as well as measurement systems for large-scale data monitoring and processing. The discussion includes principles of operation, and the underlying technologies associated with the latest development and functionality of these instruments. Also discussed are issues that confront instrument users when interfacing analog and digital devices for measurement applications necessitated by modern technologies.

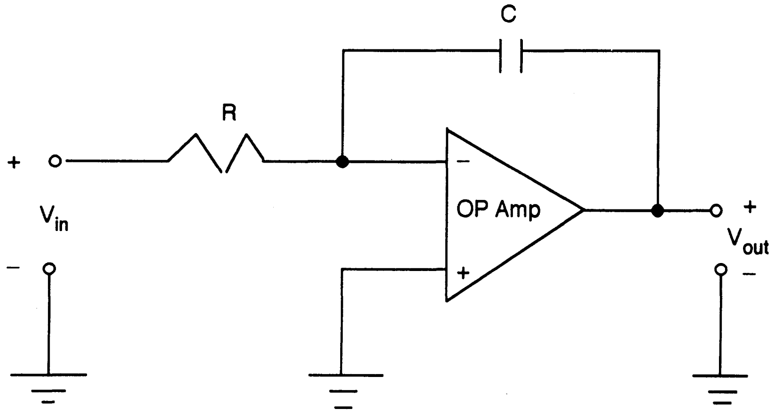
It should be noted that all standards, communication protocols, and conventions cited in this article are based on those adopted in the United States—which may or may not be the same as those adopted by other countries.

1. TEST AND MEASUREMENT INSTRUMENTATION

1.1 Digital Voltmeters

The digital voltmeter (DVM), also known as the digital multimeter (DMM), is one of the most versatile instruments used in the laboratory. It is a multifunction instrument capable of measuring ac and dc electrical quantities such as volt, current, and resistance. The analog signal to be measured is introduced to the instrument, and it produces nearly instantaneously a direct visual digital display of the measured quantity. This type of instrument is available in analog form, but DVMs are now more commonly used than the analog counterpart. The DVM displays the readings on a liquid crystal display (LCD) or on a light-emitting diode (LED) device, which is an integral part of the meter. (See DISPLAY DEVICES for more details on digital display.)

In dc measurement, the dc quantity is an average value taken over some time interval *T* to smooth any fluctuations. The average value is computed by a simple averaging circuit in one of two ways. The first approach is to apply the signal to a true integrating circuit (true averaging) by using an operational amplifier with a capacitor in its feedback path (Fig. 1). In the second approach, the average value is obtained by using a low-pass filter circuit,



$$V_{out} = -\frac{1}{RC}\int V_{in}dt = -\frac{t}{RC}V_{in}$$

time constant (τ) in seconds = RC ; R in ohms, C in farads

FIG. 1. Active integrator using operational amplifier (op-amp). It is used in some voltmeters as true averaging circuits in root-mean-square measurements.

which is simply a resistance–capacitor (*RC*) network (Fig. 2). The *RC* network continuously smooths the signal fluctuations to produce, after approximately three to five time constants, an average value of the signal (*RC* averaging). Some other digital voltmeters consist simply of an analog-to-digital converter (ADC) (discussed in Sec. 3.1) and an integrated display device such as a LED or LCD. Some DVM designs employ other techniques to compute the average value for a dc signal, but they will not be discussed here; the reader can consult ELECTRICAL INSTRUMENTATION or Helfrick and Cooper (1990).

Ordinarily, ac measurement is given in terms of a root mean square (rms) value, also known as the effective value. Mathematically, the rms value of a voltage signal $v(t)$ is given by

$$V_{\mathrm{rms}}=\left(\frac{1}{T}\int_0^T v^2(t)dt\right)^{1/2}. \qquad (1)$$

If $v(t)$ in Eq. (1) is a sine wave, that is, given by

$$v(t)=V_m\sin\omega t, \quad \omega=2\pi f, \qquad (2)$$

where V_m is the sine-wave amplitude, ω is the radian frequency in radians per second, and f is the frequency in cycles per second (cps) or hertz (Hz), then the rms value (V_{rms}) can be computed from Eq. (1) to be $V_m/\sqrt{2}$.

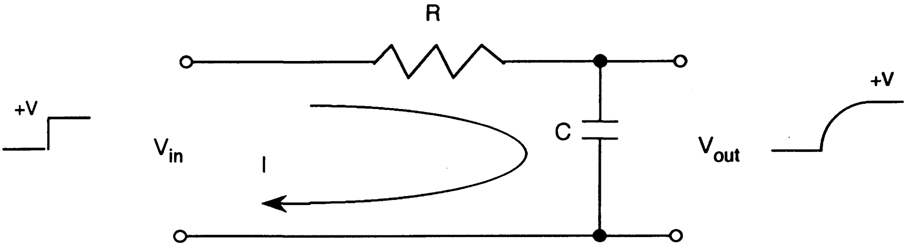
DVMs, which provide rms measurements based on the concept expressed by Eq. (1), are known as ***true mean square*** (TMS) instruments. The underlying TMS concept can be simply outlined by

1. squaring the instantaneous value of the signal,
2. averaging the squared instantaneous value over the sampling time, and
3. taking the square root of the measured mean square value.

One type of TMS DVM squares the voltage of the applied signal by using a detector circuit with a square-law characteristic. The squared voltage signal is time averaged by using either a true averaging circuit or an *RC* averaging circuit. The square-root function can be accomplished by a proper readout scale calibration. Other types of TMS-type DVMs use detectors that compute rms value directly. When highly accurate rms measurements of nonsinusoidal signals are required (e.g., random signals), methods based on the heating power of the wave forms are used since heating power is directly proportional to the mean squared voltage.

Some voltmeters are calibrated to read the rms value of a sinusoidal signal, but they do not actually measure the rms value of the applied signal. These instruments usually consist of a simple rectifier followed by an equivalent low-pass smoothing filter such that a quantity proportional to either the mean absolute value (average rectified value) or peak value of the applied signal is measured. The mean absolute value for a sinusoidal voltage signal $v(t)$ is defined as

$$\overline{|v(t)|}=\frac{1}{T}\int_0^T |v(t)|dt, \qquad (3)$$



$$V_{out}(t) = V_{in}\,(1 - e^{-t/RC})$$

time constant (τ) in seconds = RC; R in ohms, C in farads

FIG. 2. Low-pass resistance–capacitor (RC) filter used in some voltmeters as RC averaging circuits in root-mean-square measurements.

where $v(t)$ is the absolute value and $\overline{|v(t)|}$ is the mean of the absolute value. For either a peak or mean absolute-value measurement, a readout in terms of the rms value of a sine wave can be obtained by a proper readout scale calibration. This calibration is easy to accomplish since the peak, mean absolute, and rms values of a sine wave have fixed relationships. For the sine wave in Eq. (2), the peak value is V_m, the mean absolute value is $\overline{|v(t)|}=(2/\pi)V_m$ and the rms value is $V_m/\sqrt{2}$. Some instrument designs take advantage of these relationships because peak- or mean absolute-value detection circuits are rather cheaper to build than true rms detection circuits. These simple instruments will produce inaccurate readings if they are used to measure complex periodic signals that are not sinusoidal.

DVMs are available in a wide range of capabilities to measure dc and ac voltages from <1 mV to >1000 V, currents from less than a milliampere to several amperes, and dc resistances from less than an ohm to up to several gigohms. Inaccuracy of the meters is generally determined by the degree of stability of the reference voltage used in the circuit and the inherent error of ±1 unit in the least significant digit (LSD). Better accuracy can be realized with an increased number of display digits because of the higher resolution that can be attained. Digital voltmeters are available with up to $8\frac{1}{2}$ digits for bench-type versions and up to $4\frac{1}{2}$ digits for the portable-type (hand-held) versions. A meter with $4\frac{1}{2}$ digits can display four full digits ranging from 0 to 9, and one digit (leftmost) that displays only a 1 or 0. Therefore, this meter can display up to 19 999 counts of resolution, whereas a meter with $5\frac{1}{2}$ digits can display 199 999 counts of resolution, as shown in Table 1. Most recently, frequency measurement has been added to the DVM's measurement capability. Hand-held DVMs with built-in frequency counters that can measure from 1 Hz to >20 kHz are now commercially available.

1.2 Oscilloscopes

The oscilloscope, also commonly known as a scope, has been and is still considered to be one of the most versatile general-purpose electronic measuring instruments available for industrial applications as well as scientific experimentation. The scope is capable of capturing, displaying, and analyzing analog signals of various wave forms. The applied signal is displayed on a phosphorescent screen as an illuminated two-dimensional x-y trace. The signal magnitude is always displayed on the vertical y axis (vertical deflection), while the x axis (horizontal deflection) is used either as the time base or to display a second input signal to produce an X-Y plot of the two signals.

The most common use of an oscilloscope is to produce a plot of the input signal against time. The input signal is sensed and applied to the scope through a probe designed for that purpose. Most laboratory oscilloscopes have a 12.7-cm-diam (5-in.-diam) screen, but larger screens up to 53.3 cm (21 in.) are also available. Large-screen oscilloscopes usually cannot attain the high-frequency capability of the 12.7-cm (5-in.) types.

The modern oscilloscope, regardless of its sophistication, consists basically of the same building blocks, or components used in earlier models, as illustrated in Fig. 3. The cathode-ray tube (CRT) is the main output device that displays a trace of the signal wave form. The signal trace is produced by a focused narrow beam of electrons projected from an electron gun through a set of vertical and horizontal deflection plates. Application of voltages to these plates creates an electric field that deflects the electron beam, causing vertical and horizontal displacement of its focused beam

Table 1. Relationship between the number of display digits and the resolution.

point on the phosphorescent screen. With the proper design, the displacement can be made closely linear with the applied voltages. In standard CRTs, the phosphor is electrically refreshed before the phosphorescence decays to avoid blinking or flickering of the displayed trace. Some CRTs, storage CRTs, do not require continual refreshing to maintain the displayed trace. This type of CRT is discussed in Sec. 1.2.2.

The horizontal amplifier drives the horizontal plates with a ramp voltage, causing the focused spot to sweep from left to right at a constant speed. The trigger or synchronizing circuit provides the mechanism that defines the starting point of every successive sweep of the displayed trace. For proper synchronization of the sweep and the input signal applied to the vertical deflection plates, triggering of the sweep is initiated by energizing the trigger circuit from the leading edge of the input signal itself. External sources also can be used for sweep triggering.

Laboratory oscilloscopes may be classified in many ways. Usually, the distinctions are based either on frequency-response capability or on CRT characteristics.

1.2.1 Analog Oscilloscopes. An analog oscilloscope usually deploys an electrostatically deflected CRT with a standard refresh phosphor and real-time display circuitry. With this circuitry, the CRT beam deflection traces exactly the signal across the screen as the event occurs. For repetitive signals, the beam traces the signal pattern over and over, resulting in a bright wave form displayed on the screen.

Analog oscilloscopes can be classified into low- and high-frequency categories. The low-frequency oscilloscope typically has video-frequency capability ranges from dc to about 10 MHz (10-MHz bandwidth), and the high-frequency oscilloscope is capable of displaying single-shot signals with rise times as fast as 0.7 ns ($\sim$500 MHz).

Two of the most important considerations when evaluating a scope are the bandwidth and the rise time. The bandwidth is defined as the frequency range between dc and the maximum frequency at which the scope could display a signal with an attenuation of no more than 3 dB, and it determines the signal capturing performance that could be expected from the scope. The rise time is defined as the time it takes the signal to change from 10% to 90% of its final value, as shown in Fig. 4. The rise time determines the ability of the scope to deal with short events such as fast transients with short durations. The bandwidth and the rise time t_r are related by the approximation

$$\text{bandwidth} = 0.35/t_r. \tag{4}$$

It should also be realized that the rise time of a signal as observed on the screen is not just the rise time of the signal but also includes the rise time contributed by the scope and according to the approximate relationship

$$t_r(\text{observed}) = [t_r^2(\text{signal}) + t_r^2(\text{oscilloscope})]^{1/2}. \tag{5}$$

1.2.2 Analog Storage Oscilloscopes. Analog storage oscilloscopes can display signals of very low frequencies or low repetition rates, or even single fast events. They can temporarily store (for several minutes) wave forms in their display CRTs for extended visual analysis. The storage CRT, unlike the standard type, does not require continual refreshing to maintain a displayed trace. The storage capabilities of this type of CRT are attributed to the type of phosphor used with the screen. Phosphor types with different characteristics are classified according to their storage capabilities as short, medium, or long persistence, as indicated by Table 2.

Storage oscilloscopes are useful in applications where display measurements are difficult to observe on a standard oscilloscope CRT. Single-shot events, such as the wave

P2	Blue-green	Green	Medium	Scopes
P7	Blue-white	Yellow-green	Variable[b]	Radar, medical
P11	Blue-violet	Blue	Medium to short (<1 s)	Photographic recording
P19	Orange	Orange	Long (few min)	Radar

[a] Fluorescence is the light emitted as a beam strikes the phosphor, whereas phosphorescence is the light after an excitation beam is removed.

[b] Persistence can vary from short to long depending on filter color.

form resulting from some destructive testing or fast-occurring phenomena, are transient in nature and are quickly lost unless the wave form can be either photographed or stored on the CRT itself. Signals with very slow repetition rates are also difficult to view on standard oscilloscopes because of the phosphorescence decay. Comparison of two wave forms is often difficult when a standard oscilloscope is used since CRT refresh characteristics do require simultaneous testing of the two circuits. In storage oscilloscopes, one signal trace is stored for comparison with a second signal obtained later. Analog storage oscilloscopes have their own limitations because of the high cost of storage CRTs and the limited storage time depending on the type of phosphor used.

1.2.3 Digital Oscilloscopes. The digital oscilloscope is capable of measuring and displaying a repetitive wave form by sampling the input signal with an ADC at regular intervals and internally storing the values in solid-state memory. Nonvolatile memory can provide data storage without degradation or loss of data for up to five years with the power removed from the instrument. The stored data can be retrieved later to reconstruct the signal by a digital-to-analog converter (DAC) (discussed in Sec. 3.2) long after the signal is removed from the input. The reconstructed signal can be displayed on the screen as a series of dots, representing signal values, located closely enough to appear as a continuous trace. The number of these values on the screen determines the vertical resolution as dictated by the input ADC. A 10-bit ADC provides a full scale of 1024 discrete values that, when used to represent a single-shot signal, results in a resolution comparable to that of an analog storage oscilloscope.

The sampling rate for sampling a real-time signal needs to be carefully considered to reconstruct the signal accurately. As shown in Fig. 5, sampling at a rate less than the signal's own frequency gives false indication of a much slower signal. This phenomenon is known in sampling theory as *aliasing*. Theoretically, the sampling frequency f_s, also known as the Nyquist frequency, should be at least twice that of the input signal's highest-frequency component to ensure accurate results.

The number of ADCs used in the sampling process is an important consideration. When one ADC is shared by two or more input channels and one channel is in use, it can sample the input signal at full speed. When two channels are in use, the effective sample rate for each channel is reduced by 50%. The result is that a single-shot frequency performance can be reduced in half. Some manufacturers recently introduced a digital storage oscilloscope and DVM integrated into one compact hand-held meter. The scope is dual trace with 50-MHz bandwidth and sampling rate of 25 megasamples per second. The DVM can measure the true rms of ac or ac-plus-dc signals with 8-bit resolution.

1.3 Function Generators

The function generator instrument is commonly used in testing, calibration, and signal simulation applications. The generator can deliver a variety of wave forms whose frequencies are adjustable over a wide range with high accuracy. The only input to the instrument is the ac power required for the electronic circuitry. The output can be selected from a set of commonly used standard wave-

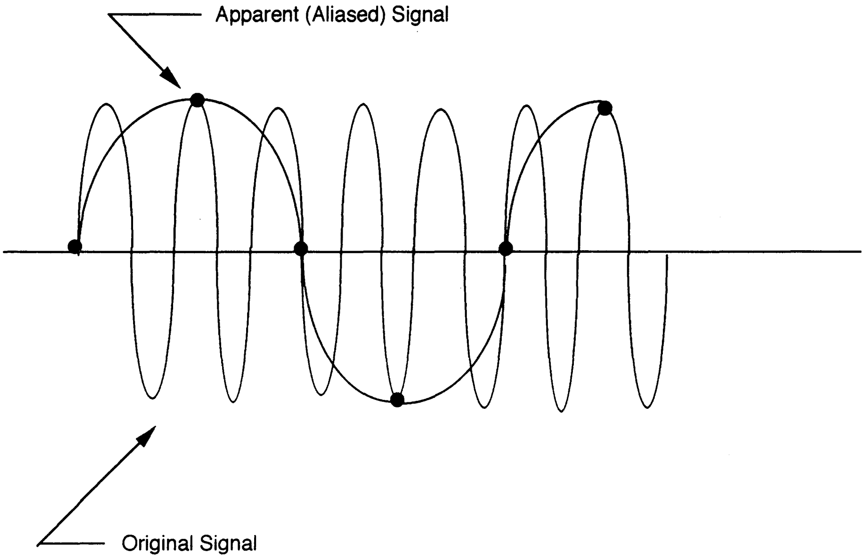

FIG. 5. Aliasing. A 16-kHz sine wave sampled at 20 kHz appears to be a 4-kHz sine wave.

forms such as the sine wave, haversine, triangular, square, and sawtooth (Fig. 6). Modern function generators can offer waveforms with frequencies adjustable from 1 μHz to 80 MHz. In addition to standard wave forms, arbitrary or user-defined waveforms (for special applications) can be created on a personal computer (PC) by using a specific software developed for this purpose and then downloaded to the generator by a standard instrument interface (IEEE-488/GPIB interface discussed in Sec. 2.3). Arbitrary signals such as video test signals and mechanical vibration can be used in simulating responses of some physical systems. When equipped with the IEEE-488 interface, the function generator can also provide remote control of various functions and allows the generator to be integrated with automatic testing systems.

Some function generators have a very useful feature for phase locking the generator with external signal sources. With phase lock, one function generator can be phase locked to a harmonic of the sine wave of a second function generator. By adjusting the phase and amplitude of the harmonics, many other wave forms can be generated as the result of summing the fundamental frequency from one generator with the harmonics of the other. The function generator can also be phase locked to a frequency standard. With such arrangements, the generated outputs have the standard source frequency accuracy and stability.

It is very difficult to give a unified description of the internal structure of all available generators since the structure varies from one

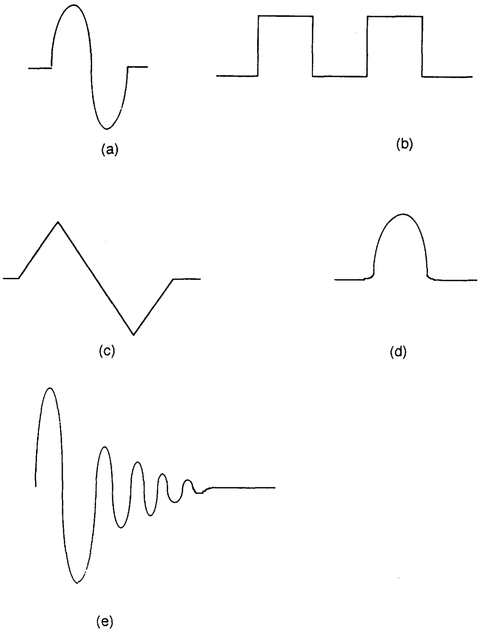

FIG. 6. Typical output wave forms produced by function generators: (a) sine wave; (b) square wave; (c) triangular wave; (d) haversine; (e) example of an arbitrary (user-defined) wave form.

instrument designer to another. However, the underlying concept can be illustrated by the structure of the function generator in Fig. 7 (Helfrick and Cooper, 1990).

This structure represents a function generator with three outputs (sine, triangular, and square waves) with a frequency range of 0.01 Hz to 100 kHz. The frequency can be adjusted either manually from the instrument front panel or from an external source. The frequency control circuit has the function of regulating two current sources.

The upper current source supplies a constant current i to the integrator A whose output voltage V_{out} increases linearly with time according to the relationship

$$V_{\text{out}} = -\frac{1}{C}\int i\,dt, \qquad (6)$$

where C is the capacitance of the condenser in the feedback path of the operational amplifier K. The slope of V_{out} varies proportionally with the upper current. The integrator output is connected to a comparator whose state changes at a predetermined level on the positive slope of the integrator's output. This change of state results in cutting off the upper current supply to the integrator, and the lower current source is switched in.

The lower current source supplies a reverse current to the integrator, resulting in a linear decrease of its output with time. At a predetermined level on the negative slope of the output, the comparator switches to cut off the lower current source while simultaneously switching in the upper source once again. The switching action between the two current sources results in a triangular wave form at the output of the integrator. The switching action of the comparator causes its output to toggle between two fixed voltage levels, resulting in a square wave. The sine wave can be generated from the triangular signal by a diode-resistance network. Such a network can be designed to alter the slope of the triangular wave in a piecewise linear approximation fashion as its amplitude changes, with < 1% distortion. Figure 8 illustrates the basic idea of piecewise-linear approximation of nonlinear functions by using the diode-resistance circuit. The accuracy of such an approximation is determined by the number of line segments used. The approximate curve is obtained by the summation of the individual line segments, whose "breakpoint" voltages and slopes are determined separately for each segment. The operational amplifier function is to sum up the segments by summing up the currents from the individual diode-resistance circuits at the summing junction. The feedback resistor R_f provides the scaling function.

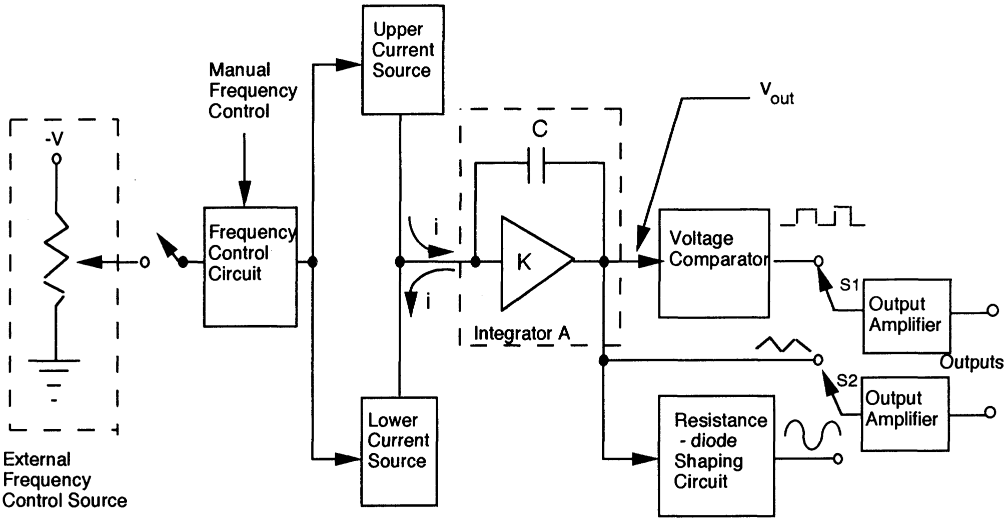

FIG. 7. Basic elements of a function generator providing three standard wave forms through two separate outputs. Some generators have only one output.

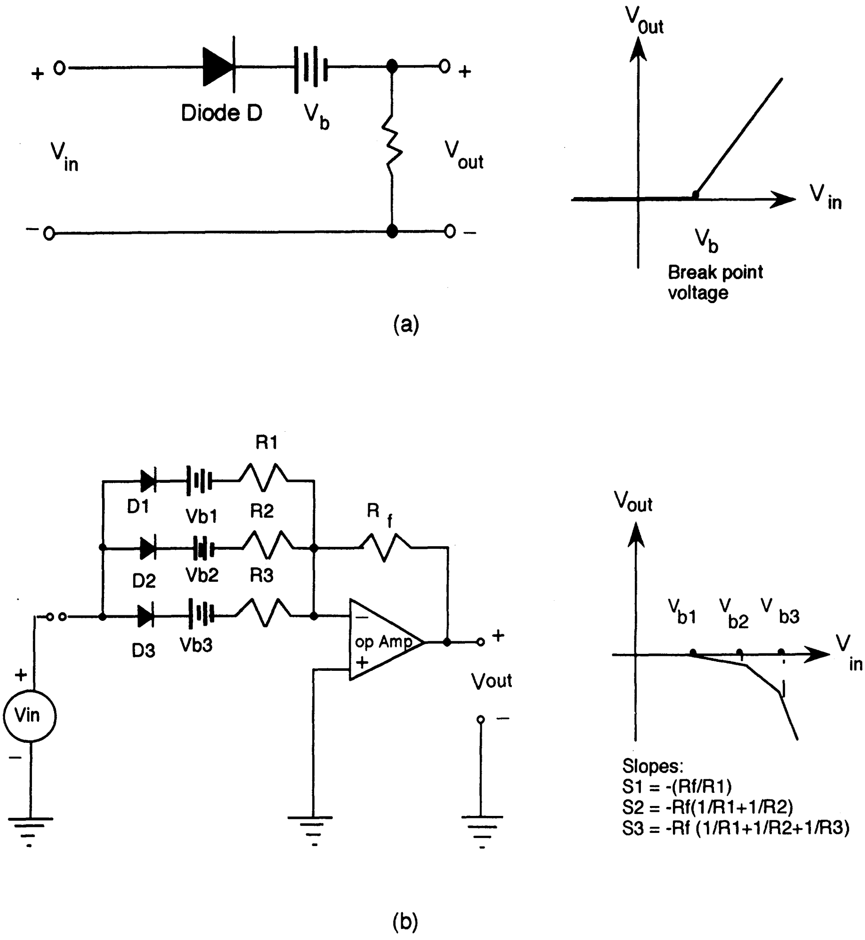

FIG. 8. Piecewise approximation: (a) simple line segment; (b) multiline segment approximation with summing amplifier.

1.4 Recorders

Recorders, in general, represent a fairly inexpensive class of recording devices primarily used for capturing and preserving data long after the signal has ceased. These recorders can be classified on the basis of their principle of operation and function. In this section, three conventional types of recorders that can be described as stand-alone instruments are discussed. The other forms of recorders require interfacing with some peripheral devices to provide the user with the level of man–machine interaction necessary for recalling and displaying the data. These types of recorders are discussed in the ELECTRICAL INSTRUMENTATION and RECORDING DEVICES and, therefore, will not be covered here.

1.4.1 Analog Recorders. The analog recorder receives analog (real-time) signals and produces a continuous time record or trace on a strip of calibrated paper (chart) traveling at a constant velocity under a motor-driven writing pen (Fig. 9). The widely known strip-chart recorder, commonly used in laboratory applications, has chart motion perpendicular to the pen deflection. The basic recorder has a single writing pen dedicated for a single input. The multipen version, usually up to six pens, produces traces of several signals simultaneously with different colors. Also available are multi-input recorders, each accommodating as many as 30 input signals and using a dot printing head instead of the writing pen. Circular-chart recorders are also available and are used primarily in industrial applications.

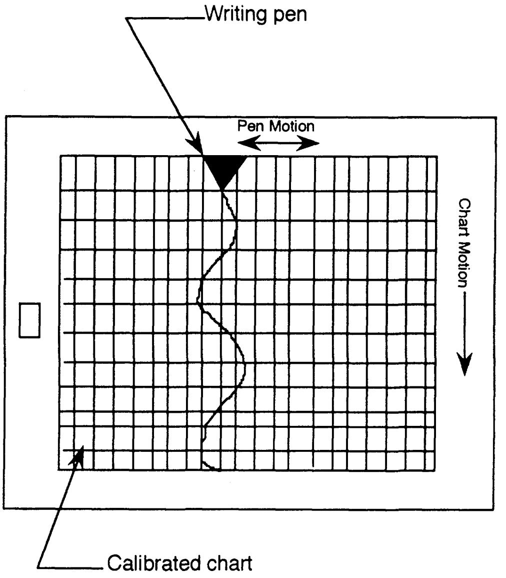

FIG. 9. Strip-chart recorder.

Some modern recorders use a pen-deflection mechanism based on improved versions of the moving-coil galvanometer type widely recognized as the D'Arsonval movement. More modern designs employ a digital servomechanism to drive the writing pen. Although servo systems vary in their design and hardware implementation, their principle of operation is very much the same. Figure 10 is a block diagram illustrating the principle of a closed-loop null-balance servo system used for driving the writing pen in recorders. The modern servomechanism consists basically of a dc motor and associated components (gears or linkages) to drive the pen and an encoder (position transducer) to detect and feed back the pen position. As a null-balance positioning system, the balance position is always being sought by the servo system as the input signal changes. The error produced is proportional to the signal change, causing the servo to drive the pen in the appropriate direction to offset the error. Scaling circuits are used to scale the input and the position signals appropriately before they are summed to produce the positional error.

With the advances in microprocessor technology, analog recorders are provided with advanced features unsurpassed by the earlier generation. Such features provide the analog recorder with improved flexibility useful for laboratory experimentation. One of the new powerful features is the programmability of input types, full-scale ranges, and chart speed without the need for operator programming skills. With this feature, the recorder can be programmed to record temperature by using a thermocouple or resistance-thermometer detector (RTD) in one application and can be easily reprogrammed to use the same recorder hardware with different input signals such as voltage or current in another application. Some computational capabilities are also now possible, such as computing the mean, minimum, and maximum values as well as having an integral digital readout and printout of the programmed setup. Although modern analog recorders are reliable, economical, and accurate (better than ±1%), their response is limited by the inherently slow pen mechanism. Typical frequency response is on the order of a few hundred hertz. Analog

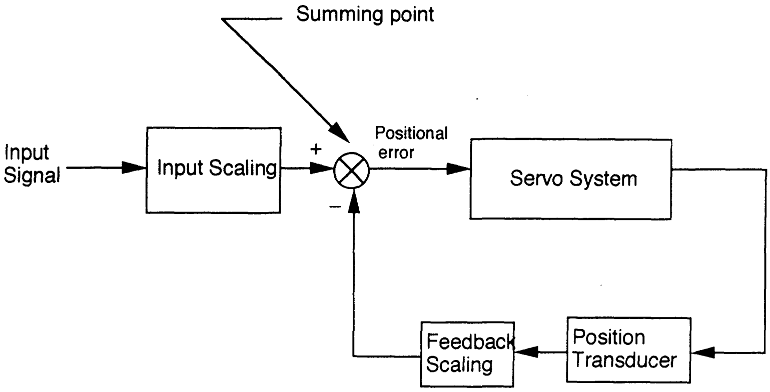

FIG. 10. Functional block diagram of a null-balance servo.

oscilloscopes (discussed in Sec. 1.2.1) also fall into the class of analog recording instruments.

1.4.2 Digital Recorders

1.4.2.1 Digital Wave Recorders. The development of high-speed ADCs (discussed in Sec. 3.1) together with the ready availability, small size, and reasonable cost of digital memories and associated digital-processing hardware has resulted in the development of the digital wave recorder.

The incoming analog voltage signal is digitized by an ADC with a resolution dependent on the digital output capability of the converter. An 8-bit ADC has a resolution of 1 part in 256 (0.4% accuracy), and a 10-bit ADC has a resolution of 1 part in 1024 (0.1% accuracy). The analog input can be sampled at adjustable rates (100 000 samples/s or more is possible). The sampled values are stored in a nonvolatile solid state memory for later processing of the data. The sampling rate and memory size must be selected to suit the duration and wave form of the physical event being recorded.

To view the wave form, stored data are read from memory through a DAC (discussed in Sec. 3.2), and the resultant signal is displayed on an integral CRT screen (discussed in Sec. 1.2). The data can be read from memory at a slow rate to allow the original event (which may have been rapidly changing, such as a one-shot transient) to be reproduced at a rate that is easy to view or even to record on one of the slower recording devices (such as a strip-chart or *X-Y* recorder). Data can also be read out from memory at a faster rate repetitively where, in such a case, a one-shot transient can appear as a continuous wave form that can be easily observed and analyzed. Digital memory can also be accessed directly (by bypassing the DAC) by a PC-based data acquisition system (DAS) (discussed in Sec. 2.3) for manipulation and processing of the recorded data.

Other developments in digital recording devices include visual trend display, where several channels of information are continuously and simultaneously updated, stored, and displayed on the CRT as bar charts or in pen-recorder-type traces.

1.4.2.2 Programmable Recorders. Combining digital technology, microcomputing, and analog recording capabilities has allowed a programmable class of recorders to become available. The result is a digital potentiometric recorder that is superior to the analog recorder. The programmability of the device provides the kind of flexibility and diversity required by the experimental nature of laboratory investigations. The sampled and stored data can be plotted against time or one channel against another with 0.1% full-scale accuracy. Additional capabilities attributed to the intelligence provided by on-board microprocessors are computing functions such as addition, subtraction, multiplication, division, averaging any two curves point by point, differentiation, integration, and normalization. In addition to these functions, the data for plotting can be offset, scaled, or expanded. Another form of digital recording device is the digital oscilloscope discussed in Sec. 1.2.2.

1.4.3 *X-Y* Recorders. The *X-Y* recorder, also known as the *X-Y* plotter, is another type of analog recorder, in which one variable can be plotted against a second variable in two-dimensional Cartesian coordinates (Fig. 11). The function plot is produced by simultaneously introducing two signals to the instrument, where each signal serves as an input to independent pen-driving mechanisms. The writing pen is driven in a two-dimensional plane by the two systems (*X* axis and *Y* axis) to produce the plot on chart paper. The most common chart paper sizes for this type of recorder are the standard 21.6×27.9 cm ($8\frac{1}{2}\times11$ in.) or 27.9×43.2 cm (11×17 in.). The chart paper in this case is held in place on a flat surface by an electrostatic field. Other instruments are available with roll chart paper with a variable speed selectable over a wide range to a maximum of 80 cm/s (31.5 in./s) (for example), with accuracy > 1% of full scale.

Two common mechanisms are available for driving the writing pen: (1) the servo system, described earlier, mostly employed in modern *X-Y* recorder designs, and (2) the optical galvanometer. The optical galvanometer offers significant improvements by eliminating the friction and inertia problems associated with the conventional galvanometer. As illustrated by Fig. 12, a small fixed mirror fastened to a moving coil is positioned to reflect a beam of light (from a light source) on light-sensitive, moving chart paper. When the coil turns, the light beam deflects over the paper, causing a trace on the chart. The re-

cording speed varies somewhat between self-balancing potentiometer types (earliest form of recording mechanism) and oscilloscopes (analog form). The frequency response of the structure shown is flat from dc to 100 Hz at full-scale deflections and nonlinearity of 1% of full scale (Doebelin, 1983).

Many *X-Y* recorders also can perform as strip-chart recorders by allowing for one of the axes to serve as a time base if so desired. The strip-chart recording function can be accomplished by introducing a voltage ramp to one of the axes and the signal to the other. The ramp can be generated by charging a capacitor with a constant current, thus causing the voltage to change linearly with time. The corresponding servo system will then cause its axis to translate at a constant speed. Most modern *X-Y* recorders offer the choice of a wide range of dc input voltages for each axis. As many as 19 different ranges and a sensitivity from as low as 0.1 mV/cm to 50 V/cm is not uncommon.

1.5 Spectrum Analysis

In many measurement applications, the analysis of signals in the frequency domain in terms of amplitude versus frequency is quite important and desirable; vibration analysis is a good example. The distribution of signal amplitude against frequency is known as the spectrum. Spectrum analysis and computation depend on signal behavior whether periodic or nonperiodic. Almost all physical measurements that we deal with can be classified as *periodic* or *nonperiodic.*

Fourier (the mathematician) showed that periodic signals (e.g., sine, square, triangular wave) expressed in the continuous-time domain can be represented by a sum of components at harmonic frequencies. If $x(t)$ is a periodic function [i.e., $x(t+T)=x(t)$, where T is the time period], then it can be approximated by Fourier transform by the summation

$$x(t)=\sum_{n=0}^{\infty} a_n \cos\omega_n t+b_n \sin\omega_n t, \tag{7}$$

where

$$a_n=\frac{1}{T}\int_0^T x(t)\cos\omega_n t\, dt,$$

$$b_n=\frac{1}{T}\int_0^T x(t)\sin\omega_n t\, dt,$$

$$\omega_n=n\omega_0,$$

ω_0=fundamental radian frequency,

which results in a discrete amplitude–frequency spectrum where frequency contents exist at discrete values only, as shown in Fig. 13(a).

With the advent of computer technology and its growth in the 1960s, a fast-Fourier-transform (FFT) algorithm [based on the discrete Fourier form (DFT)] was developed by Tuckey and Colley to compute the FFT by using digital computers [see FOURIER AND OTHER MATHEMATICAL TRANSFORMS or one of the textbooks on the subject (e.g., Brigham, 1974)]. The FFT algorithm is simply an efficient means of calculating the DFT $X(n)$ of a discrete signal $x(kT)$ (signal expressed in discrete-time domain) by

$$X(nf_s/N) = \sum_{k=0}^{N-1} x(kT_s)\,W^{nk}, \tag{8}$$

where $W = e^{-j(2\pi/N)}$ is a complex exponential weighting term, and the sampling frequency $f_s = 1/T_s$, which for sampling interval $T_s = 1$ can be written in the simpler form

$$X(n/N) = \sum_{k=0}^{N-1} x(k)\,W^{nk}. \tag{9}$$

For nonperiodic signals, typical of most physical measurements, the amplitude–frequency spectrum is continuous where frequency contents are distributed over some range depending on the signal, as shown in Fig. 13(b). To calculate the frequency spectrum of nonperiodic signals, another technique based on the concept of power spectrum density function is used, as will be discussed in Sec. 1.5.2.

1.5.1 Fourier Analyzers. The development of the computationally efficient FFT technique led to the development of the Fourier analyzer. FFT-based analyzers provide fast, high-resolution spectrum and network analysis with the information presented on a CRT. Unlike the spectrum analyzer discussed below (swept tune), the Fourier analyzer can measure dynamic signals (in real time) because they measure all frequencies simulta-
